Lateral Malleolus Fractures. Isolated fractures of the lateral malleolus with less than 3 mm displacement and no talar shift may be stable. An external rotation stress radiograph or a gravity test is used to assess the competency of the deltoid ligament, with the goal of the test to exclude deltoid injury. If the patient has a deltoid injury, in addition to the fibular fracture, then the patient will need surgery. The fracture will require anatomic reduction in order to restore normal ankle joint congruity. The talus can sublux laterally following lateral malleolus fractures, and even 1 millimeter of talar shift decreases the surface contact between the talus and the tibia by 40%, increasing the risk of developing arthritis. Open reduction and internal fixation of the fibula is usually done with plate and screws.

Medial Malleolar Fractures. An isolated fracture of the medial malleolus is usually an avulsion-type injury. Minimally displaced fractures can be treated with a cast or walking boot, while displaced fractures are usually fixed with screws.

Bimalleolar Fractures. Fractures to both the medial and lateral malleoli usually require surgery. These injuries are more unstable, and the talus will often sublux or completely dislocate laterally. They are treated by reducing and fixing both malleoli during surgery. Occasionally, the posterior articular surface of the distal tibia, or posterior malleolus, can be fractured as well, resulting in a trimalleolar ankle fracture. Often it is a small fragment and does not need to be fixed; however, if it involves a significant amount of the articular surface, the posterior malleolus should be fixed with screws placed either anteriorly, posteriorly, or with an antiglide plate. In all ankle fractures, especially in ones associated with deltoid rupture, a syndesmotic injury should be considered. After the fixation of

Figure 43-20. Ankle fracture with syndesmotic injury (*white arrow*).

the fractures, an intraoperative external rotation stress test will diagnose syndesmotic injury.

Syndesmosis Injuries. The syndesmosis is comprised of several ligaments between the distal tibia and fibula that provide stability to the ankle joint by resisting axial, rotational, and translational forces. The syndesmosis can be disrupted at the time of ankle fractures and requires special attention (Fig. 43-20). Widening of the space between the distal tibia and fibula after fixing the fractures is indicative of a syndesmosis injury, and an intraoperative external rotation stress radiograph can be helpful for evaluation. Such injuries are treated with one or two screws placed laterally from the fibula into the tibia, parallel to the ankle joint. Patients are kept non-weight-bearing for several weeks. The screws are often removed after 3 to 6 months, though they can be left in place and are typically asymptomatic.

Maisonneuve Fractures

A Maisonneuve fracture is a fracture of the proximal fibula associated with fracture of the medial malleolus or rupture of the deltoid ligament. There is always an associated syndesmotic injury (Fig. 43-21). Diagnosis may be difficult, and the injury may be missed. These injuries require surgical treatment with fixation of the syndesmosis by screws from the fibula to the tibia.

Calcaneal Fractures

Calcaneal fractures usually occur following a fall from a height and are often associated with other injuries, including lumbar spine fractures. There is a high incidence of compartment

Figure 43-21. Maisonneuve fracture showing proximal fibular fracture and associated ankle injury with disruption of syndesmosis.

syndrome of the foot associated with calcaneal fractures. These injuries are often intra-articular and can result in collapse of the weight-bearing posterior facet of the calcaneus. The Bohler angle, which is normally between 20° and 40°, would be reduced or even flattened. CT scans are useful to better visualize the fracture pattern. Some fractures can be treated nonoperatively in a well-padded splint with patients being kept non-weight-bearing for up to 12 weeks. Displaced intraarticular fractures can be treated surgically once the swelling subsides and the wrinkle test is positive. Surgery can be done with lag screws or with plate and screw fixation. Despite adequate treatment, calcaneal fractures can be debilitating injuries, leading to significant heel pain and arthritis. The outcome of surgery depends on the comminution of the fracture and degree of articular involvement. The more fragments seen on a CT scan, the worse the outcome for the patient. Wound complications are a problem for calcaneal fractures with the risk being even higher in diabetics, smokers, and in open fractures. Open calcaneal fractures have a high rate of amputation.

Talus Fractures

Fractures of the talus commonly result from forced dorsiflexion of the ankle, causing the talar neck to impact on the anterior distal tibia. The dominant blood supply is the artery of the tarsal canal. The blood supply to the talus can be jeopardized after a displaced fracture and may lead to osteonecrosis (Fig. 43-22), which is an unfortunately common complication following talus fractures. The incidence of osteonecrosis depends on the degree

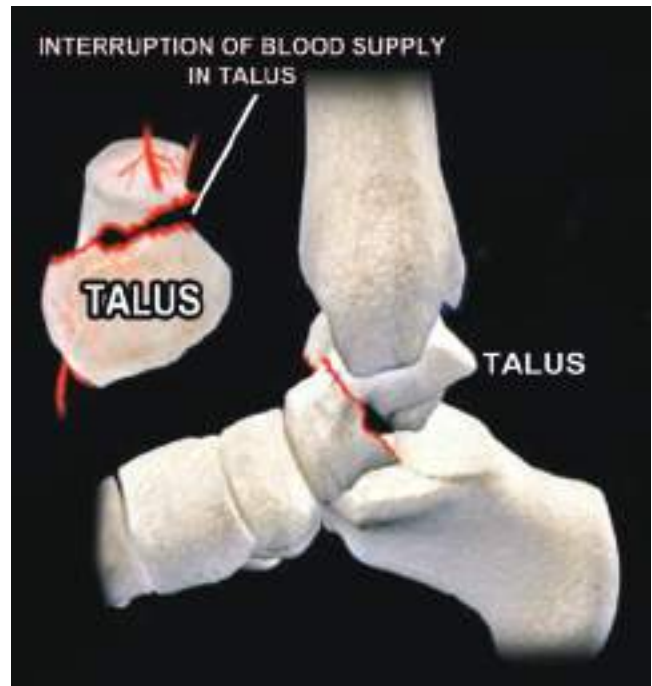

Figure 43-22. Displaced talar neck fracture. Notice the interruption of the blood supply in the talus.

of displacement of the fracture. The Hawkins' sign is a subchondral lucency that is seen on the mortise X-ray at 6 weeks and indicates that there is vascularity of the talus. This indicates that there is no avascular necrosis. Nondisplaced fractures are treated with a cast and have a 15% risk of osteonecrosis, while displaced fractures are often treated surgically with screw fixation. There is a high risk of osteonecrosis, ranging from 30% to 100%. Subtalar arthritis is the most common complication from this injury. Varus malunion that results from inadequate reduction is the most preventable complication. This complication leads to a decreased subtalar range of motion and eversion. With varus malunion, the patient will walk with the foot internally rotated.

Foot Fractures

The tarsal bones, including the navicular, the cuboid, and the three cuneiform bones, link the hind foot to the metatarsals and provide mechanical stability to the arch of the foot. Isolated fractures to these bones are rare and are often treated nonoperatively with a cast or boot. Cuboid fractures are also known as “nutcracker fractures” and may indicate a Lisfranc injury. Stress fractures of the navicular can be occult, and a diagnosis may be challenging to make in a patient that complains of foot pain. An MRI may be needed for diagnosis. Treatment is often a short leg non-weight-bearing cast. The Lisfranc ligament, which connects the second metatarsal base to the medial cuneiform, is an important stabilizer of the midfoot. Lisfranc injuries can be seen following torsional forces to the foot or from crush injuries. These injuries can be missed and often require surgery because anatomic reduction is extremely important for a successful outcome. Open reduction and internal fixation is the technique used for Lisfranc fractures. Primary arthrodesis is often used for purely ligamentous injuries. The main complication of Lisfranc injuries is posttraumatic arthritis. Metatarsal fractures similarly result from twisting or crush injuries and most can be treated

nonoperatively with a hard-soled shoe and weight-bearing as tolerated. The base of the fifth metatarsal, however, warrants close attention. Fifth metatarsal fractures at the metaphyseal-diaphyseal junction (fourth and fifth metatarsal articulation) are called *Jones fractures*. These fractures can jeopardize blood flow, are at risk for nonunion, and may be associated with cavovarus hindfoot. Jones fractures need close follow-up to assess for healing if treated by short-leg cast and non-weight-bearing. In athletes and active young patients, screw fixation is usually used to stabilize the fracture. Injuries to the metatarsal-phalangeal joints and phalangeal fractures can be treated symptomatically or with buddy taping with weight-bearing as tolerated in a hard-soled shoe.

SPORTS MEDICINE

Introduction

Sports medicine deals with the prevention and treatment of injuries related to sports and exercise. These injuries encompass various areas in the musculoskeletal system. In recent years, sports-related injuries have increased, and the sports medicine field has been expanding. There are multiple factors leading to this increase in sports-related injuries. They include athletes participating in one sport year-round, more “weekend warriors” participating in sporting activity, and increased expectations for higher performance.

The orthopedic subspecialty of sports medicine treats a broad spectrum of patients, ranging from children who have just started participating in their first sports to the specialized care of professional athletes. Medical treatment of athletes, recreational or professional, can be complex as short- and

long-term outcomes are influenced by the higher demand that athletes put on their bodies. Additionally, the orthopedic sports medicine specialist does not only treat the patient’s injuries but also has to consider the patient’s attempted return to his or her previous level of activity. “Getting back in the game” is sometimes subject to pressure and competing interests from third parties (e.g., team members, coaches, parents, fans). This can make the athlete’s treatment and the rehabilitation a challenging process.

Surgical intervention for ligament and cartilage injuries in sports medicine patients is usually done using arthroscopic techniques. The most frequently injured joints are the shoulder, knee, and hip. Therefore, treatment of common injuries in these joints will be the scope of this section.

SHOULDER

Rotator Cuff

Rotator cuff injuries are among the most common reasons to visit an orthopedic sports specialist. Often, these injuries are associated with forceful or repeated overhead and pulling movements. The rotator cuff provides shoulder movement and glenohumeral joint stability, and injuries can typically lead to pain, weakness, and restricted movement of the arm. Over recent years, improvement of surgical indications, operative techniques, and rehabilitation protocols has led to better outcomes. Studies suggest that arthroscopic techniques are equal or superior to open techniques for most indications. Controversies surrounding rotator cuff repair remain and include use of acromioplasty, enhancement of healing with orthobiologics (Fig. 43-23), single- vs. double-row fixation, and the treatment

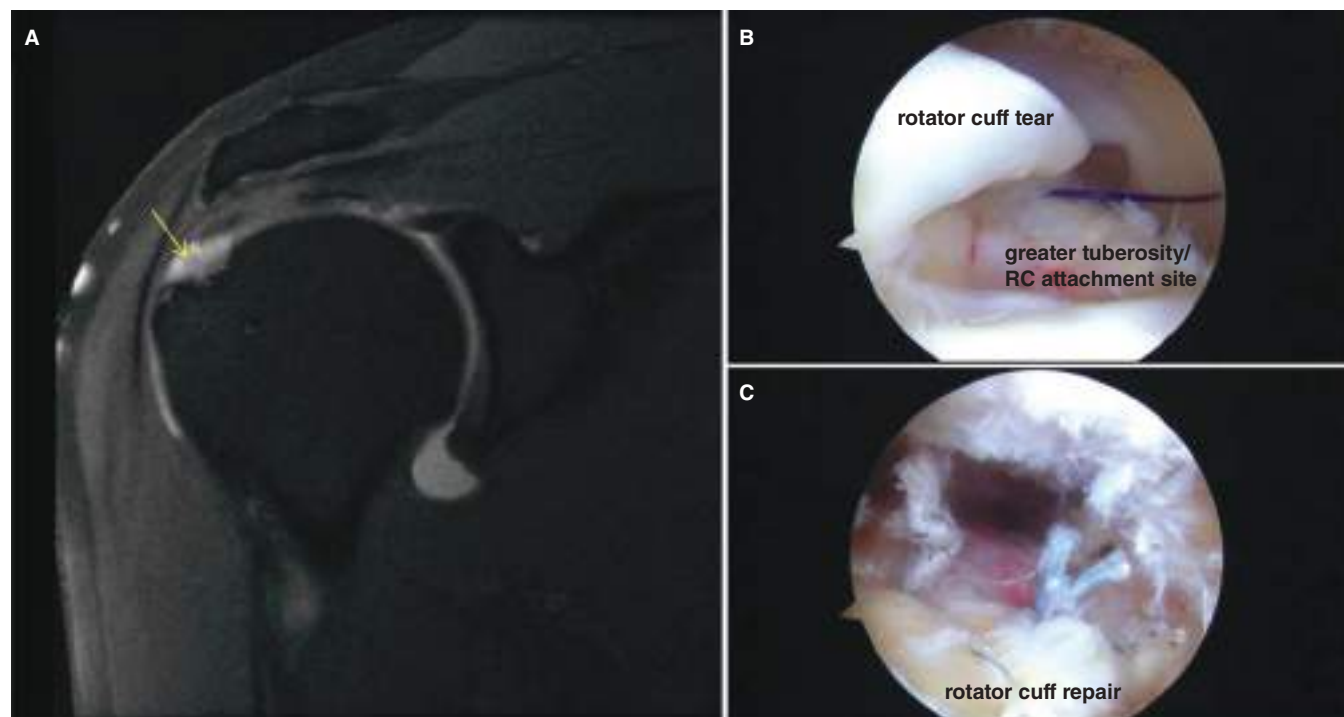

Figure 43-23. Imaging and treatment of rotator cuff tears. **A.** Magnetic resonance imaging coronal T2 image showing a full-thickness and moderately retracted tear (*arrow*) of the supraspinatus tendon. **B.** Arthroscopic image showing the supraspinatus tendon as viewed from a posterior portal during the surgery. **C.** Arthroscopic image showing completion of repair of the supraspinatus tendon tear using suture anchors imbedded in the greater tuberosity of the humerus and attached sutures that capture and reduce the torn tendon to its native insertion site.

of massive or large tears. Rehabilitation after surgery plays an important role to restore strength, motion, and function and, ultimately, to return the patient to his or her previous level of activity. The standard rehabilitation protocol is made up of three consecutive stages: immobilization, passive exercise, and active exercise. Immobilization can be established by using a sling, and passive exercises should be initiated by the therapist in the first 4 to 6 weeks after surgery. The therapist moves the arm in different positions to improve range of motion (ROM) while providing support. After 4 to 6 weeks, active exercises can be gradually introduced. At 8 to 12 weeks, muscle strength and improvement of arm control are increased by starting a strengthening exercise program.

Shoulder Instability

The most common etiology for shoulder instability is related to trauma, especially shoulder dislocation. After a shoulder has dislocated, it becomes vulnerable to repeat episodes of instability and may develop into a chronic problem. Most of the shoulder's stability is provided dynamically by the rotator cuff and statically by the shoulder capsule and ligaments. The most common dislocation is in the anterior-inferior direction. Typically, patients with an anterior dislocation present with pain and an externally rotated shoulder. Younger patients are more susceptible to suffer from repeat dislocations than older patients. The position of the humeral head with respect to the glenoid and other bony pathology can be identified with radiographs. Views from different angles should be obtained to thoroughly evaluate the patient; an anterior-posterior (AP) view, a glenoid (axillary) view, and a "Y" view of the shoulder are recommended in assessing this injury. Immediate reduction of the glenohumeral joint is paramount to the initial treatment of this injury. Repeat radiographs should be attained to ensure that the humeral head is appropriately positioned. As soft tissue structures are typically damaged in these injuries, an MRI can be obtained to evaluate these structures.

Relocation of the shoulder is generally accomplished with the patient in supine position and the arm under gentle traction and slight abduction. Some sedation is helpful as it relaxes the patient's musculature. Whether or not to immobilize a first-time-dislocated shoulder remains controversial, as does the position of immobilization. Additionally, some surgeons argue that early surgical repair of capsulolabral structures is appropriate as the recurrence rate in the young population is high and may lead to more extensive bony involvement and ultimately more invasive open procedures.

Prolonged immobilization is not recommended because this will often lead to substantial stiffness in the shoulder and does not appreciably decrease the redislocation rate. Unfortunately, many patients experience recurrent dislocations, in which case surgical stabilization of the shoulder should be considered. Arthroscopic stabilization procedures have been the gold standard treatment for the majority of injuries related to shoulder dislocations, typically a tear of the anteroinferior capsulolabral complex (Bankart lesion). There are a subset of injuries, typically involving large glenoid bony lesions, that require more extensive intervention with a Latarjet procedure or bone grafting. After surgery, the shoulder is temporarily immobilized with a sling. When the sling is removed, exercises will be started to rehabilitate the shoulder, improve ROM, and prevent scarring. Strengthening exercises will gradually be added to the rehabilitation plan.

Posterior Dislocation of the Shoulder

Posterior dislocations of the shoulder are rare and could be missed. This dislocation can occur due to electric shock or seizures. Examination of the patient will show limitation in external rotation of the shoulder. The shoulder will be locked in an internally rotated position. The posterior dislocation could be missed on the AP view of the shoulder, and an axillary view should be obtained to avoid missing the injury.

Superior Labrum and Biceps Tendon

The labrum is a structure that helps to deepen the shoulder socket and stabilize the glenohumeral joint. Additionally, it serves as an attachment point for many of the shoulder ligaments, as well as the long head of the biceps tendon. A superior labrum anterior and posterior (SLAP) lesion may occur in the superior part of the labrum, usually anterior and posterior to the attachment of the biceps tendon, with occasional involvement of the biceps tendon in certain cases. Injuries to the superior labrum can be caused by trauma or by repetitive shoulder motion, such as in throwing athletes. Radiographs are generally obtained to evaluate for concomitant bony injuries or osteoarthritic changes. The labrum itself, and other soft tissue, is better visualized with MRI with addition of a gadolinium arthrogram adding sensitivity for labral injury detection (Fig. 43-24). A coronal view MRI will clearly show the condition of the superior labrum.

Conservative and operative treatments have had mixed results depending on the patient's age, activity level, type of tear, and presence of concomitant injuries. If symptoms do not improve with adequate physical therapy and/or nonsteroidal anti-inflammatory drugs (NSAIDs), surgical intervention is usually indicated. Some SLAP injuries involve the biceps tendon, which may require either tenotomy or tenodesis.

After surgical repair, the shoulder needs to be immobilized to protect the repair and allow for healing. Usually a sling is used for 4 weeks after surgery. Then a physical therapy program will gradually start improving range of motion and prevent scar formation and stiffness from developing. As healing progresses, exercises to strengthen the shoulder muscles and the rotator cuff will gradually be added to the program typically around 4 to 6 weeks after surgery. Return to early interval throwing can generally be allowed around 3 to 4 months after surgery.

Impingement Syndromes

After minor trauma or repetitive injury, patients may experience pain and discomfort which can be due to irritation of the tissues in the subacromial space. In many cases these shoulder impingement syndromes are caused by simple bursitis or tendonitis of the long head of the biceps or supraspinatus tendon. Occasionally, impingement syndromes can progress to tears of the supraspinatus tendon, which can be confirmed by MRI or ultrasound.

The goal of treatment is to reduce pain and restore function. Initial treatment is generally nonsurgical and involves rest, NSAIDs, and physical therapy. If pain is not adequately relieved, an injection of a local anesthetic and corticosteroid may be helpful, for both therapeutic and diagnostic purposes.

If conservative treatment does not relieve pain, surgery is recommended, with the goal to excise the bursa and create more subacromial space. Generally, surgery is performed arthroscopically and encompasses bursectomy and subacromial decompression via acromioplasty. If the rotator cuff (supraspinatus tendon) is also injured, arthroscopic repair is usually indicated to restore

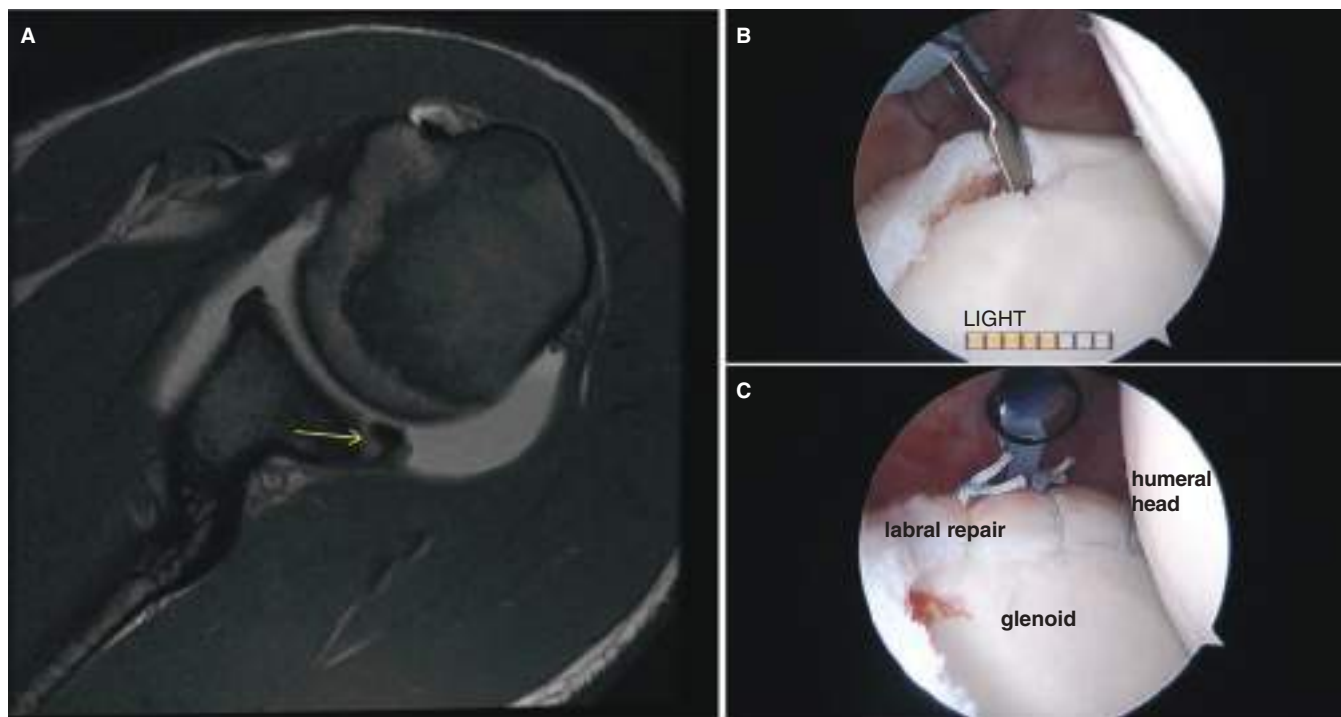

Figure 43-24. Imaging and treatment of a shoulder glenoid labrum tear. **A.** Magnetic resonance imaging axial T1 image showing a tear of the posterior superior labrum (*arrow*). **B.** Arthroscopic image with the patient in the lateral decubitus position showing detachment of the torn labrum away from the glenoid. **C.** Arthroscopic image demonstrating repair of the labrum to its attachment site using anchors in the glenoid and sutures that fixes the labrum to the glenoid.

function and can be accompanied by a bony resection of the inferior portion of the acromion.

The Acromioclavicular Joint

The acromioclavicular joint is a gliding synovial joint comprised of the lateral end of the clavicle and medial facet of the acromion, and it has limited mobility. The joint is stabilized by three ligaments: the superior acromioclavicular ligament, the inferior acromioclavicular ligament, and the coracoclavicular ligament. Injuries to these ligaments are commonly sustained by a lateral blow to the shoulder while playing contact sports such as football and ice hockey and may cause displacement of the joint. An acromioclavicular sprain is also referred to as a shoulder separation. The least severe, types I and II, are typically treated conservatively. Treatment of type III injuries, where the clavicle is displaced up to 100%, is controversial. Some advocate for early surgical intervention, while others recommend symptomatic treatment followed by ligament reconstruction if symptoms persist. Types IV to VI, where the coracoclavicular ligaments are completely torn and the clavicle is significantly displaced, are often treated surgically.

KNEE

The knee is the largest joint in the human body and is a pivotal hinge joint, which allows flexion and extension as well as some medial and lateral rotation. The knee bears tremendous axial loads as well as torsional and shear forces, making it vulnerable to both acute injury and the development of osteoarthritis. In sports, the major stabilizing structures such as the ACL and the medial collateral ligament (MCL) are frequently injured. Other common knee injuries involve the menisci, posterolateral corner (PLC), posterior cruciate ligament (PCL), and patellofemoral joint.

Menisci

The menisci are crescent-shaped pieces of fibrocartilage that provide joint stability, shock absorption, load distribution, and proprioception to the knee. Sudden meniscal tears often happen during sports, usually during contact or twisting injuries to the knee. Symptoms associated with a meniscus tear include pain, swelling, stiffness, catching, and locking of the knee. Radiographs are typically obtained to assess for a concomitant bony injury, the presence of (early) osteoarthritis, and leg alignment abnormalities. However, since menisci are radiolucent and are not seen on radiographs, an MRI is obtained to assess the status of the menisci and the soft tissue surrounding the knee joint (Fig. 43-25). Small tears on the outer edge of the meniscus may not cause symptoms, and provided the knee is stable, nonsurgical treatment may be sufficient.

The most commonly performed surgical procedure for meniscus tears is partial (subtotal) meniscectomy. However, it has become increasingly clear over recent years that preservation of the load-distributing function of the meniscus is important in preventing the development of early osteoarthritis. Research into the use of orthobiologics (e.g., microfracture of the notch, fibrin clot) for meniscal repairs has expanded the indications for repair rather than excising the torn fragment, especially if the fragment is large. Tears have been reported in virtually all portions of the meniscus, with radial and longitudinal tears being the most common. Meniscal root tears are less common, but they are increasingly being recognized as devastating injuries that cause serious alterations of knee contact forces. Surgical techniques are developing to repair the root to restore its function. Meniscus transplantation may be an option for young patients with a largely deficient meniscus.

Figure 43-25. Imaging and treatment of a knee lateral and meniscus tear. **A.** Magnetic resonance imaging sagittal T2 image of the knee showing a displaced bucket-handle lateral meniscus tear (*arrow*). **B.** Arthroscopic image showing the remnant rim of the lateral meniscus prior to reduction and fixation of the torn bucket-handle fragment. **C.** Arthroscopic image after the torn segment is reduced and fixed to the remaining meniscus and the lateral capsule using suture.

The paradigm of treatment of torn menisci is shifting thanks to the development of superior surgical techniques, use of orthobiologics, and promising first results with root repair and meniscus transplantations. Nowadays, physicians are well informed on the significance of meniscal preservation when there is potential for healing.

Directly after surgery, the knee is immobilized with a brace and weight-bearing is protected to allow the meniscus to heal. When healing is complete, range of motion and strength will need to be regained. Physical therapy is an integral component of healing and return to play, which usually is allowed between 4 and 6 months after surgery.

Collateral Ligaments

The MCL is the most frequently injured knee ligament, which usually occurs after excessive valgus stress of the knee. In more severe injuries, tearing of the meniscus and ACL can also occur, which is known as the “unhappy triad.” This is most often seen in contact sports with a lateral blow to a planted leg, causing a significant valgus force.

The MCL has good healing potential, and grade I and II injuries usually improve with bracing and activity modification. Grade III injuries may also improve with conservative treatment, and often these injuries are initially treated non-operatively. The majority of MCL injuries occur in the mid-substance or at the femoral insertion side. There is a small subset of tibial-sided grade III tears that are associated with

worse clinical outcome following conservative treatment, and therefore surgical repair is often recommended. Reconstruction is rare because surgical repair is usually effective in restoring the MCL. LCL injuries are much less common than MCL ligament injuries, but, similarly, most are managed conservatively.

With return of range of motion and normal gait pattern, patients are functionally progressed towards return to sports. A functional brace during sports is often advised.

Cruciate Ligaments

The cruciate ligaments are situated centrally within the intercondylar notch of the knee. The biomechanical function of both the ACL and the PCL is complex and three-dimensional, but both play an important role in providing anteroposterior and rotational stability of the knee.

ACL tears are a common sports injury, especially in sports involving sudden stopping and cutting (e.g., soccer, basketball) or contact (e.g., football). A torn ACL will result in altered knee biomechanics and kinematics and thus can potentially lead to the early development of degenerative changes. Since a torn ACL will not heal on its own, surgical ACL reconstruction is generally the treatment of choice in patients who are young and active. Patients with a more sedentary lifestyle and who experience no persisting or disabling instability in daily life may be effectively treated with conservative management (i.e., bracing and physical therapy).

Figure 43-26. Magnetic resonance imaging of a torn anterior cruciate ligament (ACL). A–C. Proton density sagittal cuts, showing antero-posterior tibial insertion site length measurement “x,” intra-articular ligament length measurement “y,” and ACL inclination angle measurement “z.” Oblique (in the same plane as the ACL runs) coronal cuts showing a complete ACL tear with separate images of a PL bundle tear (D) and an anteromedial bundle tear (E).

A patient with an ACL tear typically presents with pain and swelling, instability, loss of ROM, joint line tenderness (if there is an associated meniscus injury), and discomfort while walking. The Lachman’s exam is the best clinical test for an ACL tear. Radiographs are obtained to evaluate joint condition and possible associated osseous injuries. To visualize the ACL and other soft tissue in the knee, an MRI should be obtained. Although an MRI is not required to make the diagnosis, the information it provides is invaluable with regard to objectifying anatomic characteristics by taking measurements, assessing concomitant injuries, and presurgical planning in general (Fig. 43-26).

Reconstruction is performed with use of a tendon-graft that will replace the native ACL. Commonly used graft sources include the patellar, hamstrings, and quadriceps tendons. These tendons can be harvested from the same knee (i.e., autografts) during the same procedure. Alternatively, a cadaver graft (i.e., allograft) can be used. Both have their associated benefits, including the absence of donor site morbidity with an allograft and better healing potential with an autograft. As such, it is important to have a discussion with the patient and provide the necessary information for them to make an informed decision regarding graft type.

Injuries of the PCL are less common than other knee ligaments. Frequently seen causes are a bent knee hitting a dashboard in a car accident or falling on a knee that is bent during running. A rupture of the PCL is usually better tolerated than ACL rupture, since many tears (i.e., grades I and II) have the potential to heal on their own and do not result in much knee instability. Most grade I and II injuries are treated non-operatively. Combined PCL/PLC, PCL/MCL, and grade III PCL injuries do present a challenge with regard to appropriate management. Chronic PCL-deficient (grade III) knees have an increased incidence of osteoarthritis, particularly in the patellofemoral and medial knee compartments. Indication for surgery is influenced by age, activity level, and the presence of concomitant injuries. Different surgical techniques have been proposed; the most common are the “inlay” technique and the transtibial technique.

The goal of cruciate ligament (both ACL and PCL) reconstruction is to restore native knee kinematics, provide the patient with the best potential for a successful outcome, and to prevent the development of long-term complications, such as osteoarthritis.

Posterolateral Corner

Critical structures of the posterolateral corner are the LCL, popliteus tendon, and popliteofibular ligament. These structures each contribute to the static and dynamic stability of the knee and are commonly seen in combination with other ligamentous injuries, most notably the ACL. It is important to evaluate the PLC after any knee injury as a deficient PLC causes altered knee biomechanics and subsequently increases the stress on surrounding stabilizing structures. As such, it has been shown that a deficient PLC is a primary cause of graft failure in cruciate ligament reconstruction.

Acute high-grade injuries of the PLC with obvious deficient structures require surgical intervention. Since primary repair becomes increasingly difficult as time between injury and surgery increases, a cut-off of 2 to 3 weeks is usually the limit to repair the deficient structures. With more chronic PLC injuries or midsubstance tears, reconstruction is recommended to restore knee stability.

HIP

Femoroacetabular Impingement

Femoroacetabular impingement (FAI) is a pathologic condition that refers to impingement of the anterior femoral head-neck junction against the anterosuperior acetabular labrum. This is frequently caused by abnormal bony offset at the femoral head-neck junction and is called CAM impingement, which usually affects young males. On the other hand, a Pincer lesion usually occurs due to abnormal acetabular version and excessive anterolateral acetabular bony rim coverage, or a combination of these, which usually occurs in females. Recognition of FAI can be clinically and radiologically difficult. However, familiarity with this disorder is essential

because FAI can lead to labral tears, cartilage delamination, and, if untreated, osteoarthritis.

Commonly, patients present with anterior groin pain exacerbated by activities involving hip flexion or pain over the greater trochanter, as well as grinding or popping. Patients report pain with flexion and internal rotation, and after prolonged sitting. On examination, there is a decrease in internal rotation that appears out of proportion to the loss of the other ranges of motion, and flexion can also be limited. The impingement test, elicited by 90° of flexion and adduction and internal rotation of the hip, is almost always positive, signified by pain in the groin region.

The imaging findings of FAI can be seen on plain radiographs, CT scan, MRI, and magnetic resonance angiography. Some of the abnormalities seen include abnormal lateral femoral head/neck offset seen as a lateral femoral neck bump, os acetabuli, synovial herniation pits, acetabular over-coverage, hyaline cartilage abnormalities, and labral tears.

Treatment of FAI has traditionally been surgical and has evolved from open surgical treatment with acetabuloplasty, to combined open-arthroscopic-assisted techniques, to all arthroscopic techniques. Hip arthroscopy is becoming increasingly popular and is being more frequently applied for this indication. This popularity is largely the result of studies reporting on improvement of functional outcome measures with follow-up of 10 years in some studies and with relatively low complication rates.

SPINE

Spinal Trauma

In spinal injury, spinal stability must be assessed and the patient immobilized until the spine is cleared. CT scan is more reliable in assessing spine injury than plain radiographs. In patients with ankylosing spondylitis, an MRI is the best study to rule out occult fracture and epidural bleeding. When neurologic deficits are present a decompressive procedure may be indicated. In spinal cord compression, prompt decompression should be performed. Spinal cord injuries should be triaged to trauma centers since trauma center care is associated with reduced paralysis.

Occipital Cervical Dislocation

Motor vehicle accidents can cause dislocation of the occiput on the condyles of the atlas (C1). Most patients with this injury

suffer cervical cord injury and do not survive. Traction on the spine is contraindicated. Treatment consists of stabilization and fusion in situ using a screw plate from the mid cervical spine to the occiput.

Fractures of C1 (Jefferson Fracture)

Fracture of the C1 ring was described by Jefferson in 1920. The thin anterior and posterior rings of the C1 vertebra fracture with axial loads. C1 fracture causes the lateral masses of C1 to spread, which can be visible on an open-mouth view. A lateral view of the C-spine may show the fracture; however, this injury could be missed due to inadequate visualization of the occipitocervical junction. CT scan is the ideal study for a Jefferson Fracture. The transverse ligament may be ruptured with a Jefferson fracture, and this will render the fracture unstable, which can cause injury to the spinal cord (Fig. 43-27). Jefferson fractures may be associated with other spine fractures. This injury is rarely associated with neurologic injury. The treatment of a Jefferson fracture is based on the integrity of the transverse ligament. The integrity of the transverse ligament is assessed by the amount of C1 lateral mass displacement determined by open-mouth radiograph and CT scan. Significantly displaced fractures (less than 7 mm) indicate disruption of the transverse ligament. An increase in the atlanto-dense interval (ADI) may indicate a transverse ligament injury. Normally, the ADI is less than 3 mm, as seen on the lateral view. An unstable injury with a rupture of the transverse ligament may need a posterior C1-C2 fusion.

Bracing with a cervicothoracic orthosis or a halo ring and vest is the recommended treatment for nondisplaced and minimally displaced fractures; significantly displaced unstable fractures require more definitive surgical treatment.

Fractures of C2 (Odontoid Fracture)

Half of normal cervical rotation occurs at the atlantoaxial joint. The odontoid (Dens) is a small bony process which arises from the body of C2, and articulates with the body of C1 (the Atlas). There are three types of odontoid fractures (Fig. 43-28). Type I fractures are the most common and are avulsion fractures off the tip of the dens. Type I fractures occur when there is tension applied to the alar ligaments (which span from the tip of the odontoid to the skull bypassing the C1 vertebra). Type I fractures are stable and managed nonoperatively.

Type II fractures, at the base of the odontoid, results from lateral loading forces. Operative stabilization in patients with a high risk of fracture nonunion is the preferred treatment since immobilization in a halo vest results in nonunion rates ranging

Figure 43-27. Jefferson fracture with and without ligamentous injury. Note the increased ADI and the potential compression of the spinal cord (orange color).

Figure 43-28. The three types of Odontoid fractures.

from 20% to 80%. The risk of nonunion includes displacement greater than 5 mm, angulation greater than 10 degrees, age over 50 years, smoking, and delayed diagnosis more than 4 weeks. Nonunion occurs due to interruption of the blood supply. Transfixing the odontoid fracture with a screw maintains rotational movement. Posterior fusion of C1 on C2 is another option, but this results in decreased cervical spine rotation; 50% of rotation of the cervical spine comes from C1 and C2 joint.

Type III fractures extend into the body of C2, below the origin of the odontoid process. The cancellous bone is rich in blood supply and usually heals well. Type III fractures are generally treated with a halo brace.

Hangman's Fractures of C2

Hangman's Fractures are a bilateral fracture of the pars interarticularis (Fig. 43-29). The spinal canal is usually widened, and neurological deficits rarely occur (Fig. 43-30). It results from sudden extension forces on the neck. Treatment is simple immobilization in a halo vest. Higher energy injuries causing severe extension forces can dislocate the C2-3 facet complex and damage the C2-3 disc. Significantly displaced Hangman's fractures are managed by internal fixation and bone grafting between C2 and C3. When the fracture is severely angulated, it may indicate a flexion distraction injury, and traction on the C-spine may exacerbate the injury.

Compression Fracture of the Cervical Spine

In C3 to C7 an axial load can cause fracture of the endplate while preserving the posterior cortex of the vertebral body. These fractures generally heal well and are treated nonoperatively with analgesics and a cervical brace.

Figure 43-29. Lateral view shows displaced hangman's fracture.

Burst Fractures of the Cervical Spine

Burst Fractures of the cervical spine usually result from axial loads such as in diving and motor vehicle accidents. The injury results in displacement of bony fragments into the canal, injuring the spinal cord. Burst fractures are treated surgically by anterior decompression (corpectomy) and reconstruction using a bone graft strut stabilized with a plate and screws.

Unilateral and Bilateral Facet Dislocation

This injury is usually associated with motor vehicle accidents. A restrained passenger can suffer forced flexion with distraction resulting in dislocation of the facets. The diagnosis can be made on lateral radiographs. Unilateral facet dislocation can be missed on an X-ray. It usually shows less than 25% subluxation on an X-ray, and it affects the nerve roots. Bilateral facet dislocation will have more than 50% subluxation on an X-ray and may cause severe spinal cord injury. Treatment consists of closed reduction with axial traction utilizing cranial tongs, graduated application of weight, and periodic X-rays. The patient is kept awake for safety concerns. A closed reduction should not be done if the patient is not awake. Facet dislocations could be associated with disc herniation. An MRI is the study of choice to rule out disc herniations and should be done prior to reduction in an unconscious patient or prior to open reduction and/or surgical fixation. When a reduction is obtained, the patient is taken to surgery for fusion, which may be performed anteriorly

Figure 43-30. Hangman's fracture cross-section view shows widening of the canal, and therefore the spinal cord is not affected.

Figure 43-31. Fracture of the transverse process of C6 or C7.

or posteriorly. Anterior surgery is necessary if the patient has an associated herniated disc.

Clay-Shoveler's Injury

Clay-shoveler's injury can result from a motor vehicle accident or from shoveling soil or clay. The injury (of C6, C7, T1, and T2) is the result of avulsion fracture of the spinous process by the paraspinal muscle forces (Fig. 43-31). The fracture is treated nonoperatively with analgesics and a soft collar.

FRACTURES OF THE THORACIC AND LUMBAR SPINE

Thoracic Lumbar Spine Injury

The ribs stabilize fractures of the thoracic spine, making these fractures more stable than similar fractures of the lumbar spine. Neurologic injuries are more common in the thoracic and proximal lumbar spine because of the presence of the spinal cord, which ends at the L2 level, as well as the small spinal canal diameter of the thoracic spine.

Compression Fracture

Compression fractures result from osteoporosis as well as trauma. Compression fractures involve a fracture of the anterior part of the vertebral body without associated posterior cortex fracture. Thoracolumbar compression fractures are treated nonoperatively with braces and analgesics.

Burst Fracture

Burst fractures are caused by falls and high-energy automobile accidents. The posterior cortex fracture (middle column involvement) differentiates the burst fracture from a compression fracture. The injury may be associated with neurological deficits due to retropulsion of bone into the canal. A vertical lamina fracture may contain an invaginated segment of the dura mater with accompanying nerve root injury and dural tear. Widening of the pedicle in an AP view of the spine will indicate a burst fracture. CT scan will define the bony injury, and an MRI will show compression of the neural elements and any injury to the posterior ligaments.

Treatment is nonoperative with an orthoses and mobilization of the patient if the fracture is stable. Surgery is done for decompression and destabilization of the spine if the patient has neurologic deficits or if the fracture is unstable.

Seatbelt Injuries (Flexion Distraction Injuries)

A seatbelt injury occurs when there is acute forward flexion of the trunk and anterior (i.e., seatbelt) restraint. The pelvis and upper torso move forward, and failure of the spine under tension begins with the posterior elements. Tearing of the dorsal fascia, the interspinous ligament, dislocation of the facets, and tearing of the discs occurs. Seatbelt injury may be bony or ligamentous (Fig. 43-32). The bone of the spinous process, the lamina, the pedicles, and the vertebral body fail in tension ("chance

Figure 43-32. Seatbelt injuries (flexion-distraction injuries) can be bony or ligamentous.

fracture”). The bony injury could be stable. Flexion distraction injuries involving the soft tissue, with injury to the posterior spine elements, are usually unstable. This unstable injury will require internal fixation and fusion with bone grafting. This spine injury may be associated with a colon injury, especially in children.

Fracture Dislocations of the Spine

Fracture dislocations of the spine displace the bony elements by translation or rotation, resulting in canal narrowing and nerve injury.

Reduction of the displaced bones is the best way to improve the canal dimensions.

Patients with fracture dislocations of the spine and partial nerve function can recover. Fracture dislocations are treated operatively with surgical stabilization.

Disc Herniation

Disc herniation, most common between ages of 20 and 50, can occur in the cervical, thoracic, or the lumbar spine, and consists of a tear of the annulus allowing the nucleus pulposus material to extrude through the annulus and enter the canal, pressing on the exiting nerve or the “traversing” nerve roots. In the cervical spine, spinal cord compression can occur.

Symptoms of most disc herniations resolve within 8 weeks as the nerve root accommodates and inflammation recedes. The bulk of the extruded nucleus pulposus resorbs over time. When symptoms persist beyond 6 to 8 weeks, surgery with excision of the involved disc and decompression of the nerve roots may be indicated.

In cervical disc herniation, an anterior approach to the spine is performed with dissection through a transverse incision on the neck. Dissection is carried between the trachea, esophagus medially, and the carotid sheath laterally. The disc is then removed. The disc space is usually filled with bone graft to fuse the vertebrae. A locking screw low profile titanium plate is then attached to the vertebrae.

Posterior decompression and laminotomy exposes the posterior elements of the spine. A portion of the lamina is removed to allow access to the canal to correct foraminal impingement or to remove lateral disc herniations. While the posterior approach does not require fusion with plates and screws, central disc herniation cannot be managed through a posterior approach since the spinal cord cannot be safely retracted.

In thoracic spine disc herniation, the posterior approach is contraindicated because it may lead to paralysis.

For lumbar disc herniation, a midline incision is used, and laminotomy allows visualization of the lateral recess. Retraction of the dura allows visualization of the traversing nerve roots as well as of the disc fragment.

Cauda Equina Syndrome

Cauda equina syndrome is uncommon and occurs from a central disc herniation (Fig. 43-33). This can be a difficult diagnosis to make; however, it is a true emergency, and a delay in diagnosis can lead to permanent impairment. The patient will complain of back pain with bilateral leg pain. Bladder and bowel difficulty such as incontinence and frequency, saddle anesthesia, decreased perianal sensation, impotence, diminished rectal tone, and motor deficits. MRI will show a central disc herniation. Treatment is with urgent diagnosis and urgent surgical decompression. The results are better if the decompression is done within 48 hours of onset of symptoms. A central disc herniation

Figure 43-33. Image showing central disc herniation affecting the cauda equina and the classic posterolateral disc herniation affecting a nerve root.

causing cauda equina should be differentiated from a posterolateral disc herniation. The posterolateral disc herniation usually affects a nerve root and can be treated conservatively, at least initially. In the case of central disc herniation, it affects the cauda equina (the lumbosacral nerve roots), and this is a surgical emergency. Spontaneous recovery does not occur, and the outcome is catastrophic, including permanent loss of bowel and bladder control as well as the ability to have an erection if treatment is delayed.

Spinal Stenosis

A loss of hydration of the discs causes loss of disc height and bulging of annular tissue and the ligamentum flavum, which effectively narrows the canal (spinal stenosis). Osteophyte formation on the facet joints can also cause nerve impingement. Cervical stenosis can cause myelopathic symptoms (hyperreflexia, problems with fine hand dexterity, balance problems resulting in gait disturbance, weakness, and pain). In patients with low back pain and gait disturbance, obtain an MRI of the cervical spine to rule out cervical myelopathy. Pathology of the lumbo-sacral spine does not cause gait disturbances.

Lumbar stenosis causes neurogenic claudication (progressive pain, weakness, and numbness in the legs). The claudication symptoms result from standing and walking, which increases lumbar lordosis. Extension of the spine decreases the spinal canal diameter as well as the foramen size and worsens the condition. The symptoms resolve with sitting and bending forward (i.e., over a shopping cart) (Fig. 43-34). Flexion of the spine increases the spinal canal diameter as well as the foramen size and decrease the symptoms. The patient may have a normal neurologic exam, and it is important to study the vascular status of the patient and differentiate between neurologic and vascular claudication. Examine the pulses, prescribe a noninvasive vascular study if necessary. In general, walking causes the symptoms for both conditions, and standing relieves the vascular claudication symptoms. Spinal stenosis is treated with NSAIDs, epidural steroid injections, and physical therapy. Resistant cases may require surgical decompression.

Spinal stenosis usually occurs in patients over 50 years of age. With degenerative spondylolisthesis or scoliosis, fusion with instrumentation is usually required to prevent progression of the deformity.

Figure 43-34. Person is seen bending over shopping cart to improve symptoms.

Back Pain and Degenerative Disc Disease

Back pain occurs in the majority of adults but is usually self-limited, resolving in 1 to 2 weeks. Chronic unremitting back pain may suggest the possibility of infection, malignancy, or metastatic disease.

While radiographs are one option in the management of disabling low back pain, they are ineffective at ruling out malignancy, and radiographic findings correlate poorly with symptoms. Patients with severe degenerative symptoms may have no pain, while others with mild degenerative findings complain of severe pain. The potential for secondary gain and psychiatric problems and the unpredictable results of spine fusion add to the difficulty of diagnosis and choosing a treatment plan.

Intervertebral disc replacement prostheses are experimental in the treatment of degenerative disc disease. The potential for loosening, creation of wear debris, and bone loss complicating revision surgery are concerns, as are the proximity of the device to the spinal canal and the great vessels.

Scoliosis

Scoliosis is a lateral curvature of the spine. Lateral bending of the spine is always accompanied by rotational deformity (coupling).

In order to measure the severity of scoliosis, lines are drawn along the endplates of the vertebral bodies at either end of the curve, and the angle formed when these lines intersect determines the magnitude of the curve.

Scoliotic curves are classified as congenital, degenerative, metabolic (mucopolysaccharidoses), neurogenic (cerebral palsy), and myogenic curves (muscular dystrophy). Idiopathic scoliosis is the most common form and represents a spectrum of genetic disease.

Adults with scoliosis may present with axial pain and imbalance in posture. Treatment for scoliosis may include anti-inflammatory medications, therapy, and activity modification. In severe cases with objective deformity, surgical correction of the deformity may be indicated.

Idiopathic Scoliosis

The majority of idiopathic scoliosis curves become apparent during adolescence and progress during skeletal growth. Initial management consists of observation. Rapidly progressing curves are treated with braces. Brace treatment is recommended for curves between 20 and 40 degrees. For patients with large

curves, surgical intervention may be needed using rods with grafting and fusion.

Neuromuscular Scoliosis

Neurologic conditions such as polio and cerebral palsy can lead to “uncompensated” scoliosis curves where the patient is unable to lean with his upper body to restore balance. Scoliosis correction surgery may be needed to facilitate sitting balance and to avoid skin breakdown caused by pelvic obliquity.

JOINT RECONSTRUCTION

Introduction to Arthritis

Arthritis refers to a large number of medical conditions, including osteoarthritis, rheumatoid arthritis, septic arthritis, and post-traumatic arthritis. Each has the potential to lead to loss of articular cartilage lining the joints. According to the CDC and the National Health Interview Survey, approximately 55 million **10** adults (22% of the U.S. population) have been diagnosed with some form of arthritis. This number is projected to grow to an astounding 67 million adults by 2030 (or 25% of the U.S. population).

Arthritis causes pain, loss of range of motion, decreased ability to perform work duties or participate in social functions, and decreased quality of life. The number of individuals suffering from arthritic conditions will continue to rise as the “baby boomer” generation enters old age and the prevalence of obesity rises in the U.S. population, as age and obesity are two major factors in the onset of arthritis.

Examination of the Patient

A thorough history and physical examination is indicated for all orthopedic patients. Patient history should include location, quality, severity, timing, and radiation of pain along with any referred pain, associated signs and symptoms, modifying factors, or prior treatments, including both conservative and surgical measures. Other details within the history and physical examination are equally important in establishing a diagnosis and successfully developing a treatment plan. If you listen carefully to your patients, they will often tell you their diagnosis.

For example, location of “hip pain” can narrow a differential diagnosis. Patients with activity-related groin pain often are found to have hip arthritis, whereas patients with

Figure 43-35. Trendelenburg Gait resulting from weakness of abductor muscles.

peritrochanteric pain (lateral hip pain) may be suffering from trochanteric bursitis. The importance of listening and focusing on the patient's description of location and type of pain cannot be overemphasized.

Physical examination should begin by observing the patient's gait, both with and without assistive devices if possible. This demonstrates the extent of the patient's functional deficit and the effect of the patient's pain. Typical gait patterns include antalgic gait due to pain, or a "Trendelenburg gait" (Fig. 43-35) where abductor weakness may lead to a poor outcome following total hip arthroplasty. Other aspects of the exam include assessment of leg length discrepancy, joint contractures, skin changes, assessment for prior surgical incisions to identify prior treatments or plan future surgical approaches, neurovascular status, and strength, as well as range of motion. These details document functional status and help to formulate a differential diagnosis. Patients with "hip pain" may have lumbar spinal stenosis, radiculopathy, or vascular disease that may play a large role in their presentation. Once an appropriate physical examination is performed, weight-bearing radiographs are needed. Advanced imaging, including CT and MRI, are rarely indicated in the initial workup. Once a diagnosis is made, specific treatment directed towards the patient's condition can be initiated. The goals of treatment are to improve pain, preserve motion, and maximize patient function, independence, and quality of life.

Nonoperative Management and Prevention of Arthritis

Nonoperative measures to treat arthritis include weight loss, activity modification, rest, physical therapy, NSAIDs, bracing, and assistive devices such as a cane or walker. These treatments have the potential to decrease symptoms and improve function and quality of life. For example, holding a cane on the opposite side of the symptomatic extremity reduces the forces across the

Figure 43-36. Holding the cane on the opposite side of the pathology is beneficial in decreasing arthritis pain in the hip.

hip joint and subsequently decreases hip pain (Fig. 43-36). In nearly all cases, it is best to treat patients nonoperatively prior to recommending surgery.

Health and exercise can also play a role in the prevention of arthritis. Weight loss of as little as 11 lbs (5 kg) has been shown to decrease the risk of developing knee osteoarthritis in **11** women by 50%. Similarly, patients who engage in regular physical activity have a lower incidence of arthritis. However, despite nonoperative treatment, surgical intervention may be required to effectively manage patient symptoms.

Injections

Joint injections are commonly performed into the knee and shoulder. Common injections into the knee include corticosteroids and hyaluronic-acid gels. Corticosteroid injections can decrease inflammation within the joint. These injections are usually administered in combination with a local anesthetic, such as lidocaine, in order to provide more immediate relief for both diagnostic and therapeutic purposes. If the patient has immediate relief of pain with injection of the joint, this localizes the source of the patient's pain to the joint and may assist with diagnosis. Diagnostic hip injections are particularly helpful in distinguishing pain resulting from hip versus lumbar spine pathology. Any benefit received is therapeutic for the patient. Hyaluronic acid injections in the knee are frequently used and are commonly referred to as "viscosupplementation." The viscosity of the synovial fluid is increased by hyaluronic acid, but its role and mechanism are not well defined yet. There is a risk of joint infection, cartilage injury from the needle, hemarthrosis, and failure to receive benefit. Short-term altered glucose metabolism in diabetic patients is common with corticosteroid injections. The efficacy of hyaluronic acid injections has been questioned by recent evidence summarized in the American Academy of Orthopaedic Surgeons' Clinical Practice Guidelines.

Surgical Management of Arthritis

The most commonly performed procedure for arthritis of a major joint is arthroplasty, or joint replacement. Joint replacements, including hip and knee arthroplasty, are considered two of the most successful procedures performed in all of surgery. However, nonarthroplasty options exist and are typically performed for certain indications and goals.

Osteotomy. Osteotomy is cutting of the bone to change the position of the fragments, thereby improving rotation, alignment, or angulation. Osteotomy can be performed for both congenital and acquired deformities that contribute to the patient's pain or development or progression of disease. Pelvic and femoral osteotomy can be utilized in the treatment of developmental dysplasia of the hip. The position of the acetabulum can be altered with pelvic osteotomies in order to provide more appropriate coverage of the femoral head, which is typically deficient anteriorly and laterally. Femoral osteotomies can be performed to correct version and varus/valgus deformity of the femoral neck. Osteotomies are performed to obtain more normal alignment and coverage of the femoral head within the acetabulum to prevent or delay future disease.

An osteotomy commonly used in the knee is a proximal tibia osteotomy. An adult patient who presents with isolated medial compartment knee arthritis and associated varus deformity would be a candidate for a valgus-producing (high tibial) osteotomy. An osteotomy that realigns the knee into slight valgus has the potential to off-load the medial compartment, slow disease progression, and prevent or delay the need for further procedures (unicompartmental or total knee arthroplasties).

Arthrodesis. Arthrodesis is a treatment option for severe arthritis where the overlying articular cartilage is removed and two opposing bones heal together with the use of hardware (internal or temporary external fixation) often supplemented by bone graft. After successful arthrodesis, no motion is possible through the joint and the source of pain is removed. Arthrodesis of large joints, such as the knee, shoulder, or hip, are typically explored as an option in the face of infection, in older adult, low-demand patients or in young, active patients who are considered too young for a joint replacement (out of concern for component wear and the need for early revision). Arthrodesis can also serve as a "last resort" procedure in orthopedics when joint preserving treatments fail due to fracture or infection. Ankle arthrodesis is the primary procedure performed in adult patients with traumatic arthritis of the ankle.

Joint Arthroplasty/Joint Replacement. Joint arthroplasty is the most common option for patients suffering from pain associated with arthritis in a joint. The surfaces of the bones are replaced after removing the damaged articular cartilage. The amount of bone and the determination of how to make the bone cuts is made based on preoperative radiographs and templating, cutting guides, anatomic measurements, and soft tissue/ligament balancing. The cut bony surfaces are covered with new components, usually made of metal, ceramic, or polyethylene. These new components are sized to appropriately match the patient, based on templated preoperative radiographs, intraoperative measurements, and examination for stability, leg length, alignment, and range of motion.

If all compartments or surfaces of the joint are replaced, the arthroplasty is referred to as a total joint arthroplasty. In

Figure 43-37. Osteoarthritis femoral head. Note erosion of weight-bearing cartilage and peripheral osteophytes.

comparison, if only one surface or compartment of the joint is replaced, it is referred to as hemiarthroplasty (hip, shoulder) or unicompartmental arthroplasty (knee). Total hip and knee arthroplasties are considered among the most successful of all surgical procedures performed in terms of patient outcome and improvement in pain.

Hip Arthroplasty

Background Hip arthroplasty is utilized for end stage arthritis in the hip that has failed a reasonable trial of nonoperative measures (Fig. 43-37). Conventional hip arthroplasty commonly refers to *total hip arthroplasty* where both the femoral head and acetabulum are replaced or resurfaced, respectively. Finally, hemiarthroplasty describes the replacement of the femoral head and neck with a stemmed femoral component in isolation. The acetabulum is not addressed surgically.

History of Hip Arthroplasty The history of hip arthroplasty (hip replacement) may be broken down into "Pre-Charnley" and "Post-Charnley" eras, referring to the significant contributions of Sir John Charnley to the evolution of hip arthroplasty. Prior to Charnley's contributions, hip arthroplasty consisted of a variety of procedures with highly variable results. Early attempts at relieving hip pain were made with interpositional arthroplasty, where tissue layers, plastic, or metal were placed between the worn articular surfaces. Fracture of the interposed material or loosening of components often led to failure.

Later attempts introduced stemmed components to improve fixation. One of the earliest femoral components was designed by Austin-Moore. This prosthesis replaced the femoral head and neck with a metal component secured into the femoral shaft with a stem extending down the diaphysis. This prosthesis was utilized in hemiarthroplasty for many years and served as

a step in the development of total hip arthroplasty with the later addition of the acetabular component.

Surgical Approaches to the Hip A variety of approaches to the hip joint have been utilized in joint arthroplasty, including anterior approach (Smith Petersen), anterolateral approach (Watson-Jones), lateral approach (Hardinge), and posterior approach (Kocher Langenbach). Each approach contains a unique set of advantages and disadvantages. The following is a brief summary of the most common approaches that are utilized in total hip arthroplasty.

Anterior approach (Smith Petersen): This approach is an internervous and intermuscular approach. It utilizes the internervous plane between the femoral nerve and superior gluteal nerve. Superficially, the plane between the sartorius (femoral nerve) and tensor fasciae lata (superior gluteal nerve) is dissected in the deep layer and the plane between the rectus femoris (femoral nerve) and gluteus medius (superior gluteal nerve) is dissected. Advantages to this approach include supine positioning, use of intraoperative fluoroscopy for acetabular component positioning, and discontinuation of all ambulatory assistive devices 1 week earlier than other approaches. Downsides include difficult preparation and placement of the femoral component with higher rate of femoral fracture/femoral component revision, higher rate of wound complications, and lack of a true extensile approach.

Posterior approach (Kocher–Langenbach): The posterior approach is a muscle-splitting approach without an internervous plane. After incising the skin and subcutaneous fat, the fascia lata is incised along with the gluteus maximus. The short external rotators are exposed and dissected, including the piriformis, superior and inferior gemelli, obturator internus and externus, and quadratus femoris. This allows internal rotation of the hip along with flexion and adduction to dislocate the hip. The posterior approach with posterior soft tissue repair has no increased rate of dislocation compared to the anterior approach. The posterior approach is extensile and provides excellent exposure of both the femur and acetabulum for complex and revision cases.

Lateral approach (Hardinge): While there have been many modifications to the original Hardinge approach, first

described in 1982, most involve releasing the anterior one-third of the gluteus medius, underlying minimus, abductor tendon, and vastus lateralis distally in one sleeve off of the greater trochanter. The capsule is then incised to expose the hip joint. Care must be taken to protect the superior gluteal nerve during this exposure, which lies 5 cm proximal to the tip of the greater trochanter.

Exposure of the acetabulum is excellent with the modified Hardinge approach, which is extensile. However, access to the posterior column is limited compared to the posterior approach. The increased risk of postoperative Trendelenburg gait, other pathologic gait, and heterotopic ossification compared to all other approaches to the hip have made it far less commonly performed than the posterior approach. Minimally invasive total

12▶ hip arthroplasty is associated with decreased visualization intraoperatively and associated risks of component malposition, intraoperative fracture, and nerve or vascular injury. In fact, the only documented benefit of minimally invasive techniques appears to be a smaller incision, but with increased soft tissue tension intraoperatively comes the risk of compromised wound healing and periprosthetic joint infection.

Bearing Surfaces in Hip Arthroplasty The most common combination of bearing surfaces used in total hip arthroplasty is a metal (generally cobalt chrome) or ceramic prosthetic head, articulating with a polyethylene liner. Metal on metal (MOM) articulations have largely been abandoned in total hip arthroplasty as they are associated with production of metal ions that deposit in solid organs, pseudotumors that are locally destructive to soft tissue/bone, and risk of early failure (Fig. 43-38). Ceramic on ceramic articulations have the lowest friction of all current bearing combinations. However, ceramic may fracture or squeak in ceramic on ceramic total hip arthroplasties.

Alignment of Hip Arthroplasty Components Proper alignment of hip arthroplasty components is vital to a successful procedure and patient outcome. Surgeons aim for appropriate alignment of components to restore a functional and stable range of motion. This is accomplished with combined version of the femoral and acetabular components, appropriate abduction of the acetabular components, and staying true to Sir John Charnley's principles: establishing a low friction articulation,

Figure 43-38. Failed ceramic on metal hip arthroplasty components. Note the metallic staining on the ceramic femoral head.

medializing the acetabular component and center of rotation and restoring abductor length and tension with restoration of appropriate length and femoral offset. Inappropriate placement of components can lead to early failure, accelerated component wear, dislocation, need for revision surgery, as well as poor patient outcomes and satisfaction.

Knee Arthroplasty

Background Knee arthroplasty is indicated for end-stage arthritis that has failed a reasonable trial of nonoperative measures (Figs. 43-39 and 43-40). Knee arthroplasty commonly refers to total knee arthroplasty where the distal femur, tibia, and patella are resurfaced after any remaining articular cartilage and a layer of subchondral bone are resected. A unicompartmental knee arthroplasty consists of replacing one compartment of the knee, most commonly the medial compartment.

Surgical Approach to the Knee Total knee arthroplasty is generally accomplished through a medial parapatellar approach. This approach utilizes a longitudinal skin incision extending, on average, 5 cm proximal to the patella to the medial aspect of the tibial tubercle distally. Dissection is carried down to the capsule. To gain access to the joint, an arthrotomy is performed medial to the patella extending proximally along the most medial aspect of the quadriceps tendon and distally just medial to the patellar tendon. This approach provides excellent exposure to all three compartments of the knee after patellar dislocation.

Figure 43-39. Valgus deformity. Osteoarthritis of lateral compartment right knee.

Figure 43-40. Osteoarthritis of both knees. Note varus alignment of right knee and valgus alignment of left knee (windswept deformity).

Once the joint surfaces are adequately exposed, remaining articular cartilage and a thin layer of underlying bone are removed prior to placement of prosthetic components. Bone cuts are made based on preoperative templating, cutting guides, ligament balancing, and anatomic measurements (Figs. 43-41 and 43-42).

Bearing Surfaces in Knee Arthroplasty The femoral component consists of a metal prosthetic cap sized to fit the normal shape of the distal femur. The tibia is cut perpendicular to the anatomic and mechanical axis, and a flat, stemmed, metal tray is placed that serves as a base plate for a polyethylene bearing surface. The patella is usually resurfaced with a polyethylene component.

Two types of primary total knee arthroplasty systems exist, including cruciate retaining and posterior stabilized systems. As the name implies, with cruciate retaining systems, the PCL is retained in hopes of preserving more normal knee structures and minimizing bone loss, while in posterior stabilized systems the ligament is sacrificed and the components are designed to accommodate for the loss. These two systems have equivalent results in knee arthroplasty.

Alignment and Balancing in Knee Arthroplasty Appropriate sizing and positioning of the components and balancing of the size and geometry of bony gaps in flexion and extension are essential for a successful knee arthroplasty. Inappropriate component position can lead to early wear and failure, instability, pain, and stiffness.

Computer Navigation, Robotics, and Joint Arthroplasty

Computer-navigated joint arthroplasty has the theoretical benefit of more accurate and consistent placement of arthroplasty components through intraoperative feedback to the surgeon regarding component position, planned bone cuts, and alignment. Disadvantages include increased costs of the technology, prolonged operative times, and risk of infection/fracture at the sites of intraoperative sensor placement within bone. Use of

Figure 43-41. A. Varus knee with osteoarthritis. B. Right total knee replacement.

Figure 43-42. Computer-assisted robotic targeting arm for total knee replacement.

computer navigation in total joint arthroplasty has been shown to minimize outliers in alignment, but there has been no proven benefit in survival or function secondary to computer-navigated or robotic-assisted joint replacement.

Fixation Options in Joint Arthroplasty

Components in hip and knee arthroplasty can be secured with cement or biologic fixation. The cement most commonly used is polymethylmethacrylate (PMMA). PMMA serves as a grout between the component and the bone surface. Components secured without cement are grit blasted or porous coated to allow bony on growth or ingrowth, respectively. Hydroxyapatite can also be utilized on implant surfaces to promote bone ingrowth or ongrowth through osteoconductive properties. A majority of hip joint arthroplasty components are now secured without cement, where initial fixation of components is accomplished through press fit techniques. In knee arthroplasty, cement utilization is generally preferred. In hip replacement patients where biologic fixation is unreliable, such as older adults, osteoporotic or previously irradiated cement may be a better option. With revision total hip arthroplasty, cement fixation of components has been shown to lead to earlier mechanical failure.

Osteolysis and Aseptic Loosening. Osteolysis is a term used to describe abnormal resorption of bone. Osteolysis can be caused by underlying infection, metastatic disease, or in case of joint replacement, the production of wear debris. Even with appropriately positioned components, some wear of the bearing surfaces is expected over time. However, wear rates as well as the size and amount of wear debris differs with the bearing surface. Friction in ceramic on ceramic articulations is the lowest of all bearing surfaces; however, there is increased risk of component fracture and postoperative “squeaking.” In metal or ceramic on polyethylene articulations, wear debris is produced, and polyethylene particles are phagocytized by local macrophages. Activated macrophages lead to an osteolytic process and bone resorption. Particulate methylmethacrylate cement debris can also play a role in osteolysis by damaging the polyethylene bearing surface. Osteolysis has been shown to be significantly decreased with the advent and use of highly cross-linked polyethylene. Improperly positioned components or patient-related factors such as high impact activities can lead to increased wear. A substantial osteolytic response may occur and lead to component micromotion and aseptic loosening. Patients who present to clinic with pain following joint arthroplasty and an increasing zone of osteolysis in the periprosthetic region frequently need revision surgery (Fig. 43-43). Alternative bearing surfaces continue to be explored in hopes of decreasing component wear, associated osteolysis, and aseptic loosening.

Complications in Joint Arthroplasty

The risk of any complication following joint arthroplasty procedures falls in the range of 5% to 10%. Risks shared by hip and knee arthroplasties include infection, intraoperative or postoperative fracture, vascular injury, need for intraoperative or postoperative blood transfusion, nerve injury or nerve palsy (most commonly involving the deep peroneal nerve and loss of ankle dorsiflexion), stress shielding, component fracture or wear, and medical complications, including venous thromboembolic disease (DVT and PE), myocardial infarction, or cerebrovascular accident. Complications unique to total hip arthroplasty include dislocation, leg length discrepancy, and iliopsoas impingement or tendonitis.

Figure 43-43. Failed total knee replacement. Note subsided, loose, tibial component.

Dislocation Following Hip Arthroplasty. Dislocation can result from malpositioned components (inadequate combined version of the femoral stem and acetabular component; extremes of inclination of the acetabular component), noncompliance, cognitive or neuromuscular disorders, compromised soft tissue envelope from revision surgery, fracture, or insufficient restoration of length and/or offset. Comparable dislocation rates have been found with anterolateral, lateral, anterior, and posterior with soft tissue repair (approximately 0.5%) approaches. History, physical examination, and radiographs are vital to proper treatment of dislocation. Closed reduction can usually be performed with conscious sedation and gentle traction or manipulation. Rarely, open reduction may be necessary. Component position should be assessed in patients with multiple dislocations. Patients with recurrent dislocations and suboptimally positioned components may require component revision. Patients with recurrent dislocations and properly positioned components should be considered for conversion to a device with a larger prosthetic head (dual mobility construct) or a constrained total hip arthroplasty implant that provides improved stability.

ORTHOPEDIC PATHOLOGY AND ONCOLOGY

Diagnosis of Malignant Bone Tumors

History. Diagnosis of musculoskeletal tumors begins with a thorough patient history. A history of unremitting pain unrelated to activity or pain that interferes with sleep suggests malignancy. Patient age can help in establishing a differential. Round

blue cell lesions are most likely neuroblastoma in a 5-year-old, Ewing's sarcoma in a 10-year-old, lymphoma in a 20-year-old, and myeloma in a 60-year-old. Gender also aids in the differential. For instance, giant cell tumor is more common in females, while osteosarcoma is more common in males. Multiple bone involvement may suggest enchondromas (Ollier disease, Maffucci's syndrome) or osteochondromas (multiple hereditary exostoses).

Laboratory Tests. Laboratory tests determine the level of cellular turnover (lactate dehydrogenase [LDH]) or of bone destruction (calcium, alkaline phosphatase). Elevated prostate-specific antigen (PSA) suggests prostate cancer.

Imaging. Radiographic studies are critical in the diagnosis of bony tumors. Radiographs can help assess the aggressiveness of the tumor. Four questions should be addressed when assessing radiographs: (a) Where is the tumor—in which bone (Table 43-1) and in which part of the bone is the lesion? (Table 43-2) (b) What is the tumor doing to the bone (clinical behavior)? (c) What is the bone doing to the tumor (biologic response)? and (d) What is the matrix pattern? Matrix is the acellular interstitial substance produced by tumor cells. Particular attention should be paid to the junction between the tumor and the host bone since this margin can also indicate the aggressiveness of the tumor. Ewing's sarcoma has a characteristic

“onion skin” periosteal reaction pattern. This reaction pattern also occurs in other tumors and infections.

OSTEOSARCOMA

The most common primary malignant bone tumor is osteosarcoma (Fig. 43-44). Osteosarcomas are classified as osteoblastic, chondroblastic, fibroblastic, telangiectatic, round cell, or MFH-like, according to the predominant cell type. Most osteosarcomas present in patients between 10 and 20 years of age. Secondary osteosarcomas occur in older patients in abnormal bone affected by Paget's disease, radiation, or bone infarct.

Intramedullary Osteosarcoma

This is the most common primary sarcoma of the bone. It usually occurs in the distal femur or the proximal tibia in young people. This condition may also occur at the proximal humerus, proximal femur, or pelvis. It usually presents itself as a high-grade extracompartmental disease. It can metastasize to the lung, which is called a “skip lesion,” but the lung is the primary site of metastases. Long term survival is 75% with adequate treatment. The response to chemotherapy (98% necrosis of the

Figure 43-44. Osteosarcoma.

tumor after chemotherapy is a good sign) and the stage of the disease determines the prognosis. Young patients may present with pain and swelling, with X-rays showing plastic lesions in some areas of destruction with periosteal reaction called “Codman’s Triangle.” X-rays may show bone formation with a sunburst appearance. MRI should involve the entire bone to diagnose the skip metastasis. CT scans of the chest are usually done to find primary metastases. Alkaline phosphatase is usually high. Diagnosis is typically confirmed with a biopsy, which is done after staging the tumor. Proper biopsy technique should be employed, which includes longitudinal incisions. As a general rule, the biopsy should be done by the same surgeon who will provide the definitive treatment for the patient. Treatment of osteosarcoma will be preoperative chemotherapy and wide resection, followed by postoperative chemotherapy.

Parosteal Osteosarcoma

Parosteal osteosarcoma is a low-grade surface osteosarcoma that appears as if it were stuck on the bone, especially in the posterior distal femoral metaphysis (80%). The differential diagnosis includes osteochondroma and myositis ossificans. Treatment consists of wide excision. The prognosis is 95% 5-year survival as it is a low-grade tumor.

Periosteal Osteosarcoma

Periosteal osteosarcoma is a high-grade tumor. It occurs on the anterior surface of the distal femur or proximal tibia. The lesion appears chondroblastic on histology. Radiographs show scalloping of the underlying cortex with a “sunburst” periosteal reaction. Treatment is chemotherapy and wide surgical excision. The 5-year survival rate is 80%.

Paget’s Sarcoma

Paget’s sarcoma is a rare complication of Paget’s disease. In Paget’s disease with multiple bone involvement, osteogenic sarcoma, fibrosarcoma, chondrosarcoma, and MFH have occurred, most often in the pelvis, but also in the femur, humerus, spine, and skull. This malignant transformation occurs in less than 1% of patients. The patient will complain of new onset pain and swelling. The physician must have a high index of suspicion in patients with Paget’s who previously had no pain. Imaging may demonstrate osteolytic areas and loss of normal fatty marrow and multifocal lesions. Treatment of Paget’s sarcoma is chemotherapy and wide surgical excision. The prognosis is poor, and the 5-year survival rate is less than 10%.

Radiation-Induced Sarcoma

The three criteria for diagnosis of radiation-induced sarcoma are (a) histology different from the original lesion, (b) sarcoma develops in the irradiated field, and (c) a 3- to 5-year latent period between radiation and sarcoma development. Radiation for carcinoma of the breast and cervix can result in osteosarcoma, chondrosarcoma, fibrosarcoma, or MFH. Treatment is a combination of chemotherapy and surgery.

EWING’S SARCOMA

Ewing’s sarcoma is the second most common primary bone tumor in patients under 25 years of age. The typical presentation is a tumor in the diaphysis of long bones, especially the femur. It can also be seen in the pelvis, the proximal tibia, and proximal humerus, and it is usually seen in young white males. It has a t(11:22) translocation and positive CD99. The patient

Figure 43-45. Ewing’s sarcoma.

may have pain and fever with an elevated sedimentation rate and WBC count; the condition may be confused with an infection. An “onion skin” periosteal reaction may be seen on radiographs. A large soft-tissue extension from the primary bone tumor may be seen, and histology reveals a small, round, blue cell tumor (Fig. 43-45). Diagnosis is confirmed with bone marrow biopsy specimen. Bone scan can identify multiple lesions. Treatment is chemotherapy and surgery or radiation therapy for spine or pelvic lesions.

CARTILAGE-FORMING TUMORS

Chondrosarcomas

Chondrosarcomas typically occur in male patients over 40 years of age, and they are the third most common primary bone malignancies. Primary chondrosarcomas can form clear cell, mesenchymal, or dedifferentiated neoplastic cartilage. Secondary chondrosarcomas may also develop in preexisting lesions such as exostoses or enchondromas. Pelvis, shoulder, and ribs are common locations. Chondroid or “popcorn” calcifications are typical on radiographs. Clear cell chondrosarcoma and mesenchymal chondrosarcoma occur in younger patients (second to fifth decades of life). Clear cell chondrosarcomas are low-grade lesions that often affect the epiphyses. The dedifferentiated chondrosarcoma is a high-grade chondrosarcoma with a less than 10% survival rate. It has a biomorphic histology, with a chondroid component and a high-grade spindle cell component.

The treatment of chondrosarcoma is surgical excision, since cells are not chemosensitive or radiosensitive. For high-grade lesions, wide or radical resection is recommended. Pelvic and scapular chondrosarcomas have a high recurrence rate, and adjuvant chemotherapy does not improve survival rates.

FIBROUS LESIONS OF BONE

Desmoplastic Fibroma

Desmoplastic fibroma is a rare tumor occurring in the mandible, femur, pelvis, radius, or tibia in young adults. It presents as a painful lesion. Radiographs show a metadiaphyseal “soap bubble” appearance and endosteal scalloping. Histology resembles

desmoid tumors or fibromatosis. Recommended treatment is wide excision to avoid recurrence.

Malignant Fibrous Histiocytoma of Bone

MFH occurs in the metadiaphysis of long bones after conditions like nonossifying fibromas and bone infarcts. It may present with pain or by a pathologic fracture. Radiographs typically show destructive lesions with soft-tissue extension. Histology resembles osteosarcoma with pleomorphic spindle cells, histiocytes, and giant cells, but no neoplastic osteoid formation. Treatment is chemotherapy and wide surgical excision.

Malignant Vascular Tumors

Hemangioendothelioma. Hemangioendothelioma is a malignant neoplasm arising from vascular endothelium in long bones and most often occurs in the lower extremity. Radiographs show a metadiaphyseal lytic lesion with a “soap bubble” appearance. Histology reveals eosinophilic cells in a basophilic stroma. Lesions may be multifocal. Treatment consists of curettage for low-grade lesions and wide excision +/- radiation therapy for high-grade lesions.

Hemangiopericytoma. Hemangiopericytoma is usually a solitary lesion occurring in the soft tissues or the axial skeleton and proximal long bones in middle-aged or older adult males. Histology reveals branching “staghorn” vascular spaces. The tumor cells resemble cells normally seen adjacent to capillaries. Treatment is wide excision.

Angiosarcoma of Bone. Angiosarcoma is a soft tissue malignancy usually seen in older adult males; chronic vascular stasis is a risk factor. Histology reveals vascular channels with anaplasia. Treatment is wide excision, or if the tumor is surgically inaccessible, radiation.

MISCELLANEOUS TUMORS

Giant Cell Tumor of Bone

Giant cell tumor is a benign aggressive tumor. Fifty percent of these tumors occur around the knee, especially at the distal femur and the proximal tibia. Giant cell tumors may also occur in the distal radius, proximal humerus, and pelvis (especially the sacrum ala) in women 20 to 40 years of age. Presenting complaints include pain and pathologic fracture. Imaging reveals eccentric, epimetaphyseal lytic lesions eroding the subchondral bone. Histology reveals multinucleate giant cells and mononuclear stromal cells. An abundance of giant cells in the field can help establish the diagnosis, and the nuclei of giant cells appear the same as the stroma cells (all nuclei look similar) (Fig. 43-46). Giant cell tumors must be differentiated from the Brown tumor of hyperparathyroidism. While both have giant cells, hyperparathyroidism affects multiple areas, and the serum calcium is not normal. Epiphyseal lesions such as chondroblastoma should also be part of the differential diagnosis. These tumors can occasionally metastasize to the chest. Primary malignant giant cell tumor has a poor prognosis. Treatment of giant cell tumors is with curettage and high-speed burr. Recurrence rates are high with simple curettage, and the use of adjuvants such as cryosurgery, phenol, or polymethylmethacrylate bone cement may help decrease recurrence rates. After pathologic fractures, wide excision with reconstruction or amputation may be required.

Figure 43-46. Giant cell tumor.

Adamantinoma and Osteofibrous Dysplasia

Adamantinomas are low-grade malignant tumors usually seen in the tibia (Fig. 43-47). Adamantinomas are capable of metastasizing to the lung. The patient may present with pain and/or bowing of the tibia. X-ray reveals multiple lucent lesions on the cortex of the tibia. Histology reveals a biphasic tumor with nests of epithelial cells and fibrous stroma (see Fig. 43-46). Osteofibrous dysplasia is considered the precursor to adamantinoma and should be part of the differential diagnosis. Osteofibrous dysplasia is a benign lesion, usually occurring in children, at the anterior tibia, which is treated with observation. The treatment of adamantinoma is with wide surgical excision.

Figure 43-47. Typical location of adamantinoma.

Primary Lymphoma of Bone

Primary lymphoma accounts for about 5% of all neoplasms of bone. Long bone involvement is more frequent than spine. Lymphoma of bone typically occurs in males in their forties. Histology reveals large B cell lymphomas. Treatment is a combination of chemotherapy and radiation. Surgery may be required for stabilization of pathologic fractures.

Chordoma

Chordoma arises from notochordal remnants in the sacrum. It is usually midline in location. These tumors are found in middle-aged to older men and presents with bladder and bowel symptoms due to involvement of the cauda equina. Visualization of the lesion may be difficult because of the bowel gas shadow. Diagnosis may be delayed. An MRI shows a destructive extensile midline lesion with a large soft tissue mass. Histology shows epithelioid cells arranged in cords with vacuolated foamy physaliferous cells. These cells are keratin positive. Treatment is surgical excision and muscle flaps and a mesh for reconstruction. Urinary diversion and colostomy may be needed for loss of bladder and bowel control. Local recurrence is common.

Multiple Myeloma

Myeloma, the most common primary bone malignancy, is a proliferative disorder of B cells with plasma cells producing immunoglobins. These plasma cells have a classic eccentric nucleus giving a “signet ring” appearance (Fig. 43-48). Evidence of monoclonal protein in the serum and/or urine (Bence Jones proteinuria), and hypercalcemia, renal insufficiency, anemia, or bone disease are usually present.

Presenting symptoms in myeloma range from bone pain and osteopenia to focal lytic lesions with pathologic fractures and hypercalcemia. Myeloma protein $1-\alpha$ stimulates osteoclast formation. Osteoclast activating factors increase receptor activator of nuclear factor κ B ligand (RANKL) in the bone marrow. RANKL induces osteoclast differentiation and activation. Myeloma cells inhibit osteoblast differentiation and activity. Serum and urine electrophoresis detect the M protein. Workup also includes complete blood cell count, erythrocyte sedimentation rate, calcium levels, renal function assessment, β 2-microglobulin levels, and a skeletal survey. X-ray will show multiple punched out lytic lesions. Bone scans may be cold in about 30% of cases. The SPEP, UPEP, and bone marrow biopsy are helpful in diagnosis. Histology will show atypical plasma cells with eccentric nuclei, its appearance resembles a “signet

Figure 43-48. Signet ring.

Figure 43-49. Multiple Myeloma showing the eccentric nuclei and the signet appearance of cells.

ring (Fig. 43-49).” Plasmacytoma is a solitary tumor with a negative bone marrow biopsy, usually treated with radiation to the lesion. Myeloma is treated with bisphosphonates, chemotherapy, stem cell transplantation, and radiation therapy. Surgical stabilization and irradiation is done for pathologic fractures or impending fractures. Many patients with myeloma develop a vertebral compression fracture. Kyphoplasty can be useful in providing pain relief. The risks of cement extravasation and related complications are lower with kyphoplasty than with vertebroplasty. If there is instability or if there is neural compression, surgical stabilization may be required.

METASTATIC BONE TUMORS

Metastatic bone tumors are more common than primary bone tumors. Metastatic tumors affect the lung, liver, and bone. Cancers that commonly metastasize to bone are breast, lung, thyroid, kidney, and prostate. In patients older than 40 years of age, metastases and myeloma are the most common causes of destructive lesions in bone. The most common site of involvement is the axial skeleton, especially the thoracic spine, and proximal ends of long bones, especially the proximal femur. Lung and renal cell carcinomas can metastasize distal to the knee and elbow. Malignant cells are able to detach from one location and set up a focus at a distant site. The tumor activates osteoclasts and causes destruction of the bone, a mechanism that involves the RANK/RANKL pathway. The patient may present with pain, pathologic fractures, or the manifestation of hypercalcemia. Workup of a patient with a suspected metastatic disease to bone and an unknown primary tumor should include CT of the chest, abdomen, and pelvis. The extent of the disease is evaluated by bone scans (myeloma and thyroid are usually cold in bone scans), mammography, tumor markers, serum, and urine electrophoresis (SPEP and UPEP). A biopsy may be necessary to rule out primary bone lesions if the primary site is not identified. Treatment of bone tumors depends on the diagnosis, as metastatic tumors are treated differently than primary bone tumors. Metastatic tumors are usually treated by bisphosphonates and by surgical stabilization with postoperative radiation if warranted. Primary bone tumors are usually treated by wide excision with chemotherapy in high-grade tumors (chondrosarcoma are treated only with wide excision). Radiation therapy can be used in Ewing’s.

Birth Injuries

Neonatal Brachial Plexus Palsy. Injury of the brachial plexus during delivery occurs in 2 births in every 1000. Large birth weight, forceps delivery, breech presentation, and prolonged second stage of labor with shoulder dystocia are risk factors. Brachial plexus injury usually represents a stretch injury on the nerve roots of the upper or lower plexus.

Upper plexus injuries (Erb-Duchenne) are lesions manifested by weakness of shoulder abductors and external rotators as well as the elbow flexors (Fig. 43-50). The hand is not involved. It has a good prognosis, if the biceps function is present early.

In *lower plexus injury*, the hand is involved, with deformity of the fingers. An ipsilateral Horner’s Syndrome consisting of ptosis, myosis, anhidrosis, and enophthalmos may occur indicating a preganglionic injury of the T1 cervical sympathetic nerve. This condition has a poor prognosis.

Management is therapy and gentle, passive range-of-motion exercises to preserve motion in the shoulder and prevent muscle contractures and joint incongruency in the early neonatal period while awaiting return of neurologic function and motor reinnervation. Early surgical intervention for the brachial plexus is indicated in infants who did not recover elbow flexion by 3 months of age, as they are anticipated to have a poor chance of full recovery.

Surgical intervention includes microsurgical repair procedures in the form of neurolysis, nerve transfer, or nerve grafts. Later orthopedic reconstruction such as muscle rebalancing procedures may be considered to improve function around the shoulder.

Cerebral Palsy. Cerebral palsy results from an injury to the brain, which may be associated with mental impairment. Cerebral palsy is classified as spastic, athetotic, or ataxic and may present with spasticity, hemiplegia, diplegia, or scoliosis. The typical cerebral palsy patient is hyperreflexic with increased muscle tone and spasm. Treatment includes tendon lengthening procedures, release of contractures, and tendon transfers to maintain motion and function.

Hip dislocation or subluxation results from unbalanced muscle forces in many cerebral palsy patients. Early treatment consists of soft tissue releases in the form of adductor tendon releases, iliopsoas releases, and immobilization in an abduction brace.

In older children with severe deformity, bony procedures in the form of open reduction and femoral or acetabular osteotomies are usually required. Femoral head resection is considered to be a salvage procedure in nonambulatory patients with painful dislocated hips.

Knee flexion contractures are treated with hamstring muscle lengthenings and immobilization in knee extension braces.

Foot and ankle deformities are treated even in nonambulatory patients to facilitate shoe wear. The most common foot deformity in cerebral palsy is an equinovalgus foot caused by heel cord contracture and peroneal spasm. Tendon balancing is usually necessary, and bony reconstruction may also be needed in severe cases.

Skeletal Growth

Injury, inflammatory disease, and developmental disorders in actively growing bones requires special attention to preserve the growth plates. The pediatric skeleton is incompletely ossified making the diagnosis of an injury difficult, since significant portions of the skeleton are invisible on radiographs. The epiphysis, generally containing an articular surface, is found at the ends of the long bone. The physis, or growth plate, is found beneath the epiphysis. The physis is divided into specific zones: the *reserve zone*, the *zone of proliferation*, and the *hypertrophic zone*. The hypertrophic zone has three phases: the *maturation zone*, the *degenerative zone*, and the *zone of calcification* (Fig. 43-51).

Injury or insult to the growth plate can lead to premature growth arrest or angular deformity of the limb. Surrounding the metaphyseal and diaphyseal bone is the periosteum. This metabolically active layer of tissue synthesizes new bone onto the diaphyseal and metaphyseal bone and provides circumferential growth of the bones.

Ossification centers in the epiphysis appear in a predictable order and can help determine “bone age.”

Figure 43-50. Erb’s point.

Figure 43-51. Different zones of the growth plate.

Figure 43-52. Classification of growth plate injuries.

Pediatric Fractures

In a pediatric patient, the epiphyseal growth plate is unossified and weak and is at risk of fracture. Reduction and stabilization of epiphyseal fractures is critical to minimize permanent growth disturbances and deformity. Fractures near the growth plate have significant potential to remodel. For example, 80% of the growth of the humerus occurs from the proximal humeral growth plate; therefore, severely displaced proximal humeral fracture can remodel in the younger age group.

Classification of Growth Plate Injuries

Salter and Harris described a useful classification for epiphyseal fractures (Fig. 43-52). A Salter-Harris type I injury is a simple transverse fracture through the physis. A Salter-Harris type II fracture contains a component of fracture through the growth plate in continuity with a fracture of the metaphysis. A Salter-Harris type III fracture occurs through the epiphysis and exits through the growth plate, while a Salter-Harris type IV fracture extends through the physis from the metaphysis into the epiphysis. A Salter-Harris type V fracture is a crushing injury to the physis. Type III and type IV involve the joint.

Treatment of growth plate fracture requires anatomic reduction of the fragments, closed or open. If internal fixation is used, avoid placing the hardware across the growth plate to minimize the chance of injury and premature growth plate closure. When hardware needs to be placed across the physis, it should be limited to smooth K-wires. The most common complication is a physal arrest resulting in leg length discrepancy (LLD) and/or angular deformity. Complete arrest will lead to LLD. Partial arrest will result in angulation in the area of the bar, bridge, and fusion. If less than 50% of the physis is involved and the patient has two years of growth remaining, the bar is usually resected with interposition of fat graft. If the bar (fusion area) is more than 50%, the surgeon will complete the arrest on the same side and will do a contralateral epiphysiodesis on the other extremity.

Distal femur physal fractures are known to have a high rate of leg length discrepancy and angular deformity. The injury will need an anatomical reduction and close follow-up. Parents need to be counseled about the poor prognosis associated with these fractures.

Diaphyseal Injuries in a Pediatric Patient

Long bone diaphyseal fractures are generally treated closed. Pediatric patients are capable of extensive remodeling so that

an angular deformity within the plane of an adjacent joint is often completely remodeled by the growth of the child. Older children do not remodel as well. A 10° angulation in both bones of the forearm in a child over an age of 10 years may cause significant limitation of rotation of the forearm. When internal fixation of a diaphyseal fracture is required, fixation through the physis is avoided.

Fractures of the Pediatric Hip

Fractures of the pediatric hip can occur with high-energy trauma, and there is a high rate of avascular necrosis. Pediatric patients with hip fractures may be treated with a spica cast. The spica cast includes the abdomen, lower back, pelvis, and lower limb, and derives its name from the resemblance of the plaster wrap over the hip to wheat “spica.” Closed or open reduction and internal fixation is done in fractures with severe displacement. Avascular necrosis is the most common complication after hip fractures. The incidence depends on the age of the patient and the type of the fracture. Children between 3 and 8 years old with very proximal fractures such as transphyseal fractures have the highest incidence of avascular necrosis.

Fractures of the Femoral Shaft

Consider child abuse if a femoral shaft fracture occurs before the walking age. Femoral shaft fractures in a child younger than 6 months are usually treated by a Pavlik harness or spica cast. A child between 6 months and 5 years with an acceptable shortening of the femur is usually treated by an immediate spica cast. The child between 5 years and 11 years is usually treated by surgery. If the fracture is transverse, flexible IM nails may be used, especially if the child weighs less than 100 lbs (45 kg). If the fracture is too proximal or too distal, or if the fracture is comminuted and unstable, a submuscular bridge plate is usually used; alternatively, an external fixator may also be used, especially in multiple trauma patients. If the patient is older than 11 years, an interlocking IM rod with a lateral trochanteric entry is used. Insertion of IM rod in younger children can cause avascular necrosis of the femoral head due to interruption of the blood supply. Refracture of the femur is a risk after using an external fixator. Overgrowth of the injured femur with leg length discrepancy can occur in children between 2 and 10 years of age.

Figure 43-53. Triplane fracture of the ankle in children.

Pediatric Ankle Fractures

Pediatric ankle fractures include several types. Salter-Harris type I and type II usually involve the fibula, and the fracture may not be apparent. The patient may present with pain and swelling. Salter-Harris type III usually involves fracture of the medial malleolus or avulsion of the anterior inferior tibiofibular ligament from the tibia. It is called a Tillaux fracture. Tillaux fractures occur because the lateral part of the ankle is not fused and it is weak. Triplane fractures are complex ankle fractures in older children as a result of partial closure of the growth plate, and they appear as a Salter II in the lateral view and as a Salter III in an AP view (Fig. 43-53). Salter-Harris I and II fractures are usually managed with casting. Salter-Harris III or IV fractures are usually managed by closed or open reduction and internal fixation. Smooth percutaneous pins or screws are utilized, avoiding the physis.

Pediatric Elbow Fractures

Management of pediatric elbow fractures is complex. Familiarity with the timing of the ossification centers' appearance aids in diagnosis. Distal humeral physal separation can occur from child abuse and can be mistaken for an elbow dislocation. A lateral condylar fracture of the elbow is a significant injury, and when it is displaced it will need anatomical surgical reduction. Medial epicondyle fractures of the elbow are usually treated conservatively unless they are severely displaced. It is associated with elbow dislocation in 50% of cases. When the elbow is reduced, the fragment may lodge in the joint itself and must be removed and fixed. In supracondylar fractures of the humerus (Fig. 43-54), the neurovascular status of the extremity must be assessed carefully before, during, and after treatment. The anterior interosseous nerve could be injured, and the patient may not be able to make an "OK sign" (Fig. 43-55). The brachial artery may also be injured. Closed reduction, possible open reduction, and percutaneous pinning is usually done for these fractures. The procedure should be done emergently if there is concern about the vascular status of the extremity. Close follow-up for maintenance of reduction and neurovascular status is needed.

DEVELOPMENTAL DISEASE

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) involves a spectrum of disease that includes dysplasia, subluxation, or dislocation

Figure 43-54. Supracondylar fracture of the humerus.

of the hip. Teratologic hip dislocation is a different entity in which the hip is dislocated in utero and irreducible on neonatal examination, usually associated with neuromuscular conditions and genetic syndromes. Developmental dysplasia of the hip is most often seen in firstborn females with a positive family history or with breech birth.

Untreated hip dislocations can lead to a dysplastic acetabulum, and they should be recognized and treated early. Newborns are examined for hip instability within the first 72 hours

Figure 43-55. Unable to make the "OK" sign due to interosseous nerve injury.

of life. Ortolani's test consists of gentle elevation and abduction of the femur causing a palpable click in the relocation of a dislocated hip. Barlow's test is gentle adduction and depression of the femur, which causes a palpable click as the hip slips into a dislocated position. In older infants (older than 3 months), limited abduction of the involved hip is an important finding. Infants with a dislocated or dislocatable hip will have apparent length discrepancies of the femur when the hip is positioned at 90° (Galeazzi test).

Since the bones are not ossified at birth, X-ray images of the acetabulum and femoral head are not reliable for diagnosis. Ultrasound is the imaging modality of choice in the neonatal period and can often demonstrate a dislocated or dislocatable hip.

Treatment of DDH

The main goal in the treatment of DDH is to achieve stable concentric reduction of the hip.

- **Neonate to 6 months:** Early treatment with abduction and flexion in a Pavlik harness for 6 to 12 weeks is usually sufficient. Avoid severe abduction and flexion in the Pavlik harness to avoid the risk of avascular necrosis of the femoral head and femoral nerve palsy.
- **Children 6 to 18 months:** Closed reduction and application of hip spica cast is indicated in this age group and in those children who failed Pavlik harness treatment.
- **Children older than 18 months:** Open reduction and capsulorrhaphy is indicated in this age group. A variety of procedures, including femoral shortening and pelvic osteotomies, are done in older age groups and in more severe cases. Osteonecrosis of the femoral head is a possible complication of treatment and can result in pain and decreased range of motion.

Legg-Calvé-Perthes Disease

Osteonecrosis of the proximal femoral epiphysis can cause flattening of the femoral head called *Legg-Calvé Perthes disease*. The age at presentation is between 4 and 8 years of age and occurs more in males, usually affecting one side. Younger age at presentation (less than 6 years old) will have a better prognosis. The patient presents with groin or knee pain, decreased hip motion, and a limp. Treatment includes traction, physical therapy, abduction exercises, and crutches. Restoration of range of motion is important. Femoral and pelvic osteotomies may be needed in extreme cases and in older children.

Slipped Capital Femoral Epiphysis

Children ages 10 to 16 years can develop displacement of the epiphysis on the femoral neck with no history of injury. The slippage occurs through the weak zone (hypertrophic zone) of the growth plate. When slippage occurs in young patients, check for endocrine disorders such as hypothyroidism, renal osteodystrophy, and growth hormone deficiency. Slipped capital femoral epiphysis (SCFE) is associated with African-American heritage and obesity, and it is more common in boys than in girls. One-quarter of cases are bilateral. In patients with endocrine etiology, the condition is usually bilateral. Patients generally present with groin and anterior thigh pain, and the patient may have antalgic gait and a limp.

Patient may present with knee pain that can lead to missing the diagnosis. In pediatric patients with knee pain, the ipsilateral hip should be assessed as well.

Examination of the patient will show obligatory external rotation with flexion and loss of internal rotation of the hip. Obtain AP and frog leg lateral views of both the hips.

Slipped epiphysis is classified as either *stable* or *unstable* on the basis of the patient's ability to bear weight. It is classified as stable if the patient is able to bear weight and the risk of osteonecrosis is less than 10%. It is classified as unstable if the patient is unable to bear weight even with crutches, and the incidence of avascular necrosis is high.

Treatment for slipped capital femoral epiphysis patients is percutaneous screw fixation through the femoral neck to engage the epiphysis, causing the growth plate to close. Reduction of the slipped epiphysis is not recommended because of an increased risk of avascular necrosis. One screw is usually adequate to prevent further slip.

Lower Extremity Rotational Abnormalities

Intoeing can result from femoral anteversion, tibial torsion, and metatarsus adductus. Mild degree of intoeing is normal in young children 3 to 5 years of age.

Excessive internal rotation of the femur will usually correct by age 8. Severe rotation with functional impairment that does not correct by age 10 or 11 may require rotational femoral osteotomy.

Tibial torsion is the most common cause of intoeing in toddlers and could be bilateral. The condition usually resolves without treatment.

Metatarsus adductus in infants will also resolve spontaneously in most cases.

Congenital Talipes Equinovarus (Clubfoot)

Clubfoot is a congenital disorder, and its etiology is not known. Clubfoot is a common problem associated with contractures of the medial tendons of the foot, a tight Achilles tendon, and contractures of the ankle, hindfoot, and midfoot. The foot is usually small, and it is in the equinus, varus, cavus, and adduction position. Talipes equinovarus can be corrected by sequential corrective casting of the foot. The serial manipulation and the casting technique is called the Ponseti technique, and it has a high success rate. A successful program of casting may be complete in 1 to 5 months. In patients with severe disease or who initiate treatment after 9 months of age, surgical release of contracted soft tissues may be necessary. The procedure is called *posteromedial soft tissue release and tendon lengthening*.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a common problem most often seen in athletically active adolescents, especially in sprinters and jumpers. It is a traction apophysitis of tibial tubercle (Figs. 43-56 and 43-57). One must know the difference between the epiphysis, apophysis, and physis. This disorder is characterized by ossification in the distal patellar tendon at the point of its tibial insertion, and it is thought to result from mechanical stress on the tendinous insertion. The disease presents with severe local pain and tenderness in the area of the tibial tubercle. Radiographs may show calcified ossicles within the tendon at its insertion.

Figure 43-56. Osgood Schlatter lesion.

Treatment for the disease is activity restriction and anti-inflammatory drugs. The majority of patients improve with conservative treatment, and athletic participation can be resumed. Usually, symptoms regress after skeletal maturity or after activity modification. In refractory cases, surgery in the form of ossicle excision is rarely done.

INTRODUCTION

The highly mobile, functional, and strong hand is a major distinguishing point between humans and the nonhuman primates. The hand is an essential participant for activities of daily living, vocation, and recreational activities. The hand is even adaptable enough to read for the blind and speak for the mute. The underlying goal of all aspects of hand surgery is to maximize mobility, sensibility, stability, and strength while minimizing pain. These goals are then maximized to the extent possible given the patient's particular pathology. Hand surgery is a regional specialty.

1▶ Hand surgeons integrate components of neurologic, orthopedic, plastic, and vascular surgery in the care of patients with disorders of the upper extremities.

ANATOMY OF THE HAND AND WRIST

In order to understand any disorder of the hand, one must understand the anatomy of the underlying structures. Examination of the hand is based on demonstrating the function or lack thereof of each of these structures.

Bones

The hand is highly mobile in space to allow maximum flexibility in function. As such, a number of directions particular to the hand are necessary in order to properly describe position, motion, and so on.¹ Palmar (or volar) refers to the anterior surface of the hand in the anatomic position; dorsal refers to the posterior surface in the anatomic position. The hand can rotate at the wrist level; rotation to bring the palm down is called

Key Points

- 1▶ Surgery of the hand is a regional specialty, integrating components of neurologic, orthopedic, plastic, and vascular surgery.
- 2▶ Understanding hand anatomy is the key to proper diagnosis of injury, infection, and degenerative disease of the hand.
- 3▶ After evaluation and/or treatment, patients should be splinted to protect the injured digits and keep the collateral ligaments of the injured joints on tension (metacarpophalangeal joints flexed, interphalangeal joints extended).
- 4▶ Healing of an injured or diseased structure in the hand is not the endpoint of treatment; the goal of any intervention must be to obtain structure healing, relief of pain, and maximization of function.
- 5▶ If a patient managed conservatively for cellulitis does not improve within 24 to 48 hours of appropriate intravenous antibiotics, abscess must be suspected.
- 6▶ Clinical examination, particularly noting the area of greatest tenderness and/or inflammation, is the most useful diagnostic tool for hand infections.

pronation, and rotation to bring the palm up is called supination. Because the hand can rotate in space, the terms *medial* and *lateral* are avoided. *Radial* and *ulnar* are used instead as these terms do not vary with respect to the rotational position of the hand. *Abduction* and *adduction*, when used on the hand, refer to movement of the digits away from and toward the middle finger, respectively (Fig. 44-1).

The hand is comprised of 19 bones arranged in five rays.² A *ray* is defined as a digit (finger or thumb) from the metacarpal base to the tip of the digit (Fig. 44-2A). The rays are numbered 1 to 5, beginning with the thumb. By convention, however, they are referred to by name: thumb, index, middle, ring, and small. There are five metacarpals, comprising the visible palm of the hand. Each digit has a proximal and a distal phalanx, but only the fingers have a middle phalanx as well. The metacarpophalangeal (MP) joint typically allows 90° of flexion with a small amount of hyperextension. In addition, the fingers can actively abduct (move away from the middle finger) and adduct (move toward the middle finger). The thumb, in contrast, moves principally in the flexion-extension arc at the MP joint. Although there can be laxity in the radial and ulnar direction, the thumb cannot actively move in these directions at the MP level. The proximal interphalangeal joint (PIP) is the critical joint for finger mobility. Normal motion is 0° to 95° (full extension to flexion). The distal interphalangeal joint (DIP) also moves only in a flexion-extension plane from 0° to 90° on average. The thumb interphalangeal joint (IP) also moves only in a flexion-extension plane. Its normal motion is highly variable between individuals, but averages 0° to 80°.

Each of the MP and IP joints has a radial and ulnar collateral ligament to support it. The IP joint collateral ligaments are on tension with the joint fully extended. For the fingers, the MP joint collateral ligaments are on tension with the joint bent 90°. Collateral ligaments have a tendency to contract when not placed on tension; this becomes relevant when splinting the hand (see later “Trauma” section on splinting).

The wrist consists of eight carpal bones divided into two rows (see Fig. 44-2B).² The proximal row consists of the scaphoid, lunate, and triquetrum. The lunate is the principle axis of motion of the hand onto the forearm. It bears approximately 35% of the load of the wrist onto the forearm. The scaphoid is shaped like the keel of a boat and bears 55% of the load of the hand onto the forearm, but it also serves as the principle link between the proximal and distal rows, allowing for motion while maintaining stability. Both the scaphoid and the lunate

articulate with the radius. The triquetrum resides ulnar to the lunate. It does not interact with the ulna proximally; rather, it interacts with a cartilage suspended between the ulnar styloid and the distal radius called with triangular fibrocartilage complex (TFCC) (see Fig. 44-2B). The remaining 10% of load of the hand onto the forearm is transmitted through the TFCC.³

The distal row consists of four bones. The trapezium resides between the scaphoid and the thumb metacarpal. Distally, it has a saddle-shaped surface, which interacts with a reciprocally saddle-shaped base of the thumb metacarpal to allow for high mobility of the thumb carpometacarpal (CMC) joint in radial-ulnar and palmar-dorsal directions and opposition (Fig. 44-1B). The trapezoid rests between the scaphoid and the index finger metacarpal. The capitate, the largest carpal bone and first to ossify in a child, lies between the lunate and the middle finger metacarpal, but it also interacts with the scaphoid on its proximal radial surface. The index and middle finger CMC joints are highly stable and have minimal mobility. The hamate is the ulnar-most bone in the distal row, sitting between the triquetrum proximally and the ring and small finger metacarpals distally. The ring and small finger CMC joints are mobile, principally in the flexion-extension direction.

The pisiform is a carpal bone only by geography. It is a sesamoid bone within the FCU tendon (see following section). It does not bear load and can be excised, when necessary, without consequence.

Muscles Affecting the Hand and Wrist

The wrist is moved by multiple tendons that originate from the forearm and elbow. The digits of the hand are moved by both intrinsic (originating within the hand) and extrinsic (originating in the forearm) muscles. All of these muscles are innervated by the median, radial, or ulnar nerves (or their branches) (Fig. 44-3).

Three muscles flex the wrist, all of which originate from the medial epicondyle of the humerus. The flexor carpi radialis (FCR, median nerve) inserts on the volar base of the index finger metacarpal. The flexor carpi ulnaris (FCU, ulnar nerve) also originates from the proximal ulna and inserts on the volar base of the small finger metacarpal. The palmaris longus (PL) tendon does not insert on a bone; it inserts on the palmar fascia, located deep to the skin in the central proximal palm, and is absent in up to 15% of patients. The FCR also deviates the wrist radially, whereas the FCU deviates the wrist ulnarly.

All three wrist extensors are innervated by the radial nerve or its branches. The extensor carpi radialis longus (ECRL)

Figure 44-1. Directions of finger, hand, and wrist motion. **A.** Finger abduction (*white arrows*) and adduction (*black arrows*). **B.** Thumb radial (*black arrow*) and palmar (*white arrow*) abduction. **C.** Thumb and small finger opposition. **D.** Hand/wrist pronation (*black arrow*) and supination (*white arrow*).

originates from the distal shaft of the humerus and inserts on the dorsal base of the index finger metacarpal. The extensor carpi radialis brevis (ECRB) originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the middle finger metacarpal. The extensor carpi ulnaris (ECU) also originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the small finger metacarpal. The ECRL deviates the wrist radially, whereas the ECU deviates the wrist ulnarly.

The long flexors of the fingers all originate from the medial epicondyle of the humerus. The flexor digitorum superficialis (FDS) inserts on the base of the middle phalanx of each finger and primarily flexes the PIP joint. The flexor digitorum profundus (FDP) inserts on the base of the distal phalanx and primarily flexes the DIP joint. The flexor pollicis longus (FPL) originates more distally, from the ulna, radius, and interosseous

membrane between them in the forearm. It inserts on the base of the distal phalanx of the thumb and primarily flexes the IP joint. All of these tendons can also flex the more proximal joint(s) in their respective rays. All of these muscles are innervated by the median nerve (or its branches) except the FDP to the ring and small fingers, which are innervated by the ulnar nerve.

The extrinsic extensors of the fingers and thumb are all innervated by the posterior interosseous nerve (PIN, branch of the radial nerve). The extensor digitorum communis (EDC) originates from the lateral epicondyle of the humerus and extends the MP joints of the fingers. Unlike most tendons that attach directly into a bone, the EDC tendons do not insert on the dorsal base of the proximal phalanx, but rather into a soft tissue sling called the sagittal hood, which surrounds the proximal phalanx base and pulls up on the volar surface in a

Figure 44-2. Bony architecture of the hand and wrist. **A.** Bones of the hand and digits. All rays have metacarpophalangeal (MP) joints. The fingers have proximal and distal interphalangeal joints (PIP and DIP), but the thumb has a single interphalangeal (IP) joint. **B.** Bones of the wrist. The proximal row consists of the scaphoid, lunate, and capitate. The distal row bones articulate with the metacarpals: the trapezium with the thumb, the trapezoid with the index, the capitate with the middle, and the hamate with the ring and small. The pisiform bone is a sesamoid within the flexor carpi ulnaris tendon. It overlaps the triquetrum and hamate but does not contribute to a carpal row. CMC = carpometacarpal; TFCC = triangular fibrocartilage complex.

hammock-like manner. More distally in the dorsal forearm, the extensor indices proprius (EIP) and extensor digiti quinti (EDQ) originate from the ulna, radius, and posterior interosseous membrane and insert on the sagittal hood of the index and small fingers, respectively.

The thumb has three separate extrinsic extensors. All of these originate from the dorsal ulna in the mid-forearm and are innervated by the PIN. The abductor pollicis longus (APL) inserts on the radial base of the thumb metacarpal to produce some extension, but mostly abduction. The extensor pollicis

Figure 44-3. Cross-section of the wrist at the midcarpal level. The relative geography of the neurologic and tendinous structures can be seen. The transverse carpal ligament (TCL) is the roof of the carpal tunnel, passing volar to the median nerve and long flexor tendons. The TCL is also the floor of the ulnar tunnel, or Guyon's canal, passing dorsal to the ulnar artery and nerve. The wrist and digital extensor tendons are also seen, distal to their compartments on the distal radius and ulna. Bones: C = capitate; H = hamate; P = pisiform; S = scaphoid. Tendons (flexor digitorum superficialis is volar to flexor digitorum profundus within the carpal tunnel): 2 = index finger; 3 = middle finger; 4 = ring finger; 5 = small finger. A = artery; APL = abductor pollicis longus; ECRB = extensor carpi radialis brevis; ECRL = extensor carpi radialis longus; ECU = extensor carpi ulnaris; EDC = extensor digitorum communis; EDQ = extensor digiti quinti; EIP = extensor indices proprius; EPB = extensor pollicis brevis; EPL = extensor pollicis longus; FCR = flexor carpi radialis; FPL = flexor pollicis longus; N = nerve.

brevis (EPB) inserts on the base of the thumb proximal phalanx. The extensor pollicis longus (EPL) inserts on the base of the thumb distal phalanx.

The intrinsic muscles of the hand are what allow humans fine, subtle movements of the hand. Microsurgery, typing, and even video gaming would be difficult, if not impossible, without them.

The thenar muscles originate from the volar radial surface of the scaphoid and trapezium and the flexor retinaculum. The abductor pollicis brevis (APB) inserts on the radial base of the thumb proximal phalanx and abducts the thumb in a radial and volar direction. The opponens pollicis (OP) inserts on the radial distal aspect of the thumb metacarpal and draws the thumb across the palm toward the small finger. The flexor pollicis brevis (FPB) inserts on the base of the thumb proximal phalanx and flexes the thumb MP joint. The APB, OP, and superficial head of the FPB are all innervated by the thenar motor branch of the median nerve.

The lumbrical muscles are unique in the body in that they originate from a tendon. Each finger's lumbrical originates from the FDP tendon in the palm. The lumbrical tendon passes along the radial aspect of the digit to flex the MP and extend the IP joints. The index and middle lumbricals are median nerve innervated, and the ring and small finger lumbricals are ulnar nerve innervated.

The hypothenar muscles originate from the pisiform, hamate, and flexor retinaculum and insert on the ulnar base of the small finger proximal phalanx. The abductor digiti quinti (ADQ) abducts the small finger. The opponens digiti quinti (ODQ) brings the small finger across the palm in reciprocal motion to the OP. The flexor digiti quinti (FDQ) flexes the small finger metacarpal. All of these muscles are innervated by the ulnar nerve.

The interosseous muscles occupy the space between the metacarpal bones. Their tendons insert on the bases of the proximal phalanges. All act to flex the MP joints and extend the IP joints. The three palmar interosseous muscles adduct the fingers. The four dorsal interosseous muscles abduct the fingers. The adductor pollicis originates from the middle finger metacarpal and inserts on the ulnar base of the thumb proximal phalanx. It acts to adduct the thumb. All of these muscles, as well as the deep head of the FPB, are innervated by the ulnar nerve.

Tendons and Pulleys

Multiple pulleys pass over or surround the extrinsic tendons en route to or within the hand. Their purpose is to maintain tendon position near the bone, allowing maximal translation of tendon excursion into joint motion.

The most well known of the wrist-level pulleys is the flexor retinaculum, also known as the transverse carpal ligament. It attaches to the scaphoid tubercle and trapezium radially and the hook of the hamate bone and pisiform ulnarly. Deep to this ligament, between the scaphoid (radially) and the hamate (ulnarly), pass the FDS, FDP, and FPL tendons as well as the median nerve. This area is also known as the carpal tunnel (see Fig. 44-3).

On the dorsum of the wrist, the extensor retinaculum is divided into six compartments. Beginning on the radial aspect of the radius, the first compartment contains the APL and EPB tendons. The second holds the ECRL and ECRB tendons. The EPL passes through the third compartment. The fourth compartment contains the EIP and EDC tendons, the fifth the EDQ,

and the sixth the ECU. The sixth compartment is located on the ulnar aspect of the distal ulna. Although the compartments end at the radiocarpal/ulnocarpal joints, the relative geography of the tendons is preserved over the carpal bones (see Fig. 44-3).

In the hand, the pulleys maintain the long flexor tendons in close apposition to the fingers and thumb. There are no extensor pulleys within the hand. Each finger has five annular and three cruciate pulleys (Fig. 44-4). The second and fourth (A2 and A4) pulleys are the critical structures to prevent bowstringing of the finger.³ The remaining pulleys can be divided as needed for surgical exposure or to relieve a stricture area.

Vascular

Two major arteries serve the hand. The radial artery travels under the brachioradialis muscle in the forearm. At the junction of the middle and distal thirds of the forearm, the artery becomes superficial and palpable, passing just radial to the FCR tendon. At the wrist level, the artery splits into two branches. The smaller, superficial branch passes volarly into the palm to contribute to the superficial palmar arch. The larger branch passes dorsally over the scaphoid bone, under the EPL and EPB tendons (known as the anatomic snuffbox) and back volarly between the proximal thumb and index finger metacarpals to form the superficial palmar arch.

The ulnar artery travels deep to the FCU muscle in the forearm. When the FCU becomes tendinous, the ulnar artery resides deep and slightly radial to it. At the wrist, the artery travels between the hamate and pisiform bones superficial to the transverse carpal ligament (known as Guyon's canal) into the palm. The larger, superficial branch forms the superficial

Figure 44-4. Drawing of anteroposterior and lateral view of the pulley system.

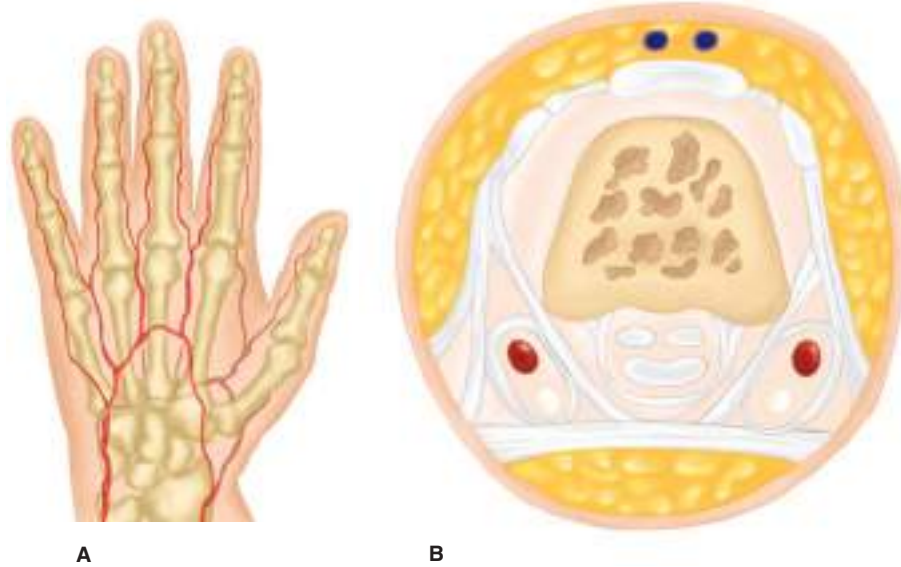

Figure 44-5. Arteries of the hand and finger. **A.** Relative position of the superficial and deep palmar arches to the bony structures and each other; note the radial artery passes dorsal to the thumb metacarpal base, through the first web space, and anterior to the index metacarpal base as it forms the deep arch. **B.** The neurovascular bundles lay volar to the midaxis of the digit with the artery dorsal to the nerve; Grayson's ligament (volar) and Cleland's ligament (dorsal) connect the bone to the skin surrounding the bundle.

palmar arch. The deeper branch contributes to the deep palmar arch (Fig. 44-5A). In 97% of patients, at least one of the deep or superficial palmar arches is intact, allowing for the entire hand to survive on the radial or ulnar artery.⁵

Each digit receives a radial and ulnar digital artery. For the thumb, the radial digital artery may come from the deep palmar arch or the main body of the radial artery. The larger ulnar digital artery comes off the deep arch as either a discrete unit, the princeps pollicis artery, or less frequently as the first common digital artery, which then splits into the radial digital artery to the index finger and the ulnar digital artery to the thumb. The second, third, and fourth digital arteries typically branch off the superficial palmar arch and pass over the similarly named interosseous spaces respectively, ultimately dividing into two proper digital arteries each. The ulnar digital artery of the small finger comes off as a separate branch from the superficial arch. Within the finger, the proper digital arteries travel lateral to the bones and tendons, just palmar to the midaxis of the digit, but dorsal to the proper digital nerves (Fig. 44-5B).

Nerve

Three principal nerves serve the forearm, wrist, and hand: the median, radial, and ulnar nerves. The most critical of these from a sensory standpoint is the median nerve. The median nerve begins as a terminal branch of the medial and lateral cords of the brachial plexus. It receives fibers from C5–T1. The palmar cutaneous branch of the median nerve separates from the main body of the nerve 6 cm proximal to the volar wrist crease and serves the proximal, radial-sided palm. The main body of the median nerve splits into several branches after the carpal tunnel: a radial digital branch to the thumb, an ulnar digital nerve to the thumb, and a radial digital nerve to the index finger (sometimes beginning as a single first common digital nerve); the second common digital nerve that branches into the ulnar digital nerve to the index finger and the radial digital nerve to the middle finger; and a third common digital nerve that branches into the ulnar digital

nerve to the middle finger and a radial digital nerve to the ring finger. The digital nerves provide volar-sided sensation from the metacarpal head level to the tip of the digit. They also, through their dorsal branches, provide dorsal-sided sensation to the digits from the midportion of the middle phalanx distally via dorsal branches. The thenar motor branch of the median nerve most commonly passes through the carpal tunnel and then travels in a recurrent fashion back to the thenar muscles. Less commonly, the nerve passes through or proximal to the transverse carpal ligament en route to its muscles.

In the forearm, the median nerve gives motor branches to all of the flexor muscles except the FCU, and the ring and small finger portions of the FDP. Distal median motor fibers (with the exception of those to the thenar muscles) are carried through a large branch called the anterior interosseous nerve.

The ulnar nerve is a terminal branch of the medial cord of the brachial plexus. It receives innervation from C8 and T1 roots. The FCU and FDP (ring/small) receive motor fibers from the ulnar nerve. In the distal forearm, 5 cm above the head of the ulna, the nerve gives off a dorsal sensory branch. Once in the hand, the nerve splits into the motor branch and sensory branches. The motor branch curves radially at the hook of the hamate bone to innervate the intrinsic muscles, as described earlier. The sensory branches become the ulnar digital nerve to the small finger and the fourth common digital nerve, which splits into the ulnar digital nerve to the ring finger and the radial digital nerve to the small finger. The sensory nerves provide distal dorsal sensation similar to the median nerve branches.

The radial nerve is the larger of two terminal branches of the posterior cord of the brachial plexus. It receives fibers from C5–T1 nerve roots. It innervates all of the extensor muscles of the forearm and wrist through the PIN branch except for the ECRL, which is innervated by the main body of the radial nerve in the distal upper arm. There is no ulnar nerve contribution to extension of the wrist, thumb, or finger MP joints. As noted earlier, the ulnar innervated intrinsic hand muscles are the principle

extensors of the finger IP joints, although the long finger extensors (EDC, EIP, EDQ) make a secondary contribution to this function.

In the proximal dorsal forearm, the superficial radial nerve (SRN) is the other terminal branch of the radial nerve. It travels deep to the brachioradialis muscle until 6 cm proximal to the radial styloid, where it becomes superficial. The SRN provides sensation to the dorsal hand and the radial three and a half digits up to the level of the mid-middle phalanx (where the dorsal branches of the proper digital nerves take over, as described earlier). The dorsal branch of the ulnar nerve provides sensation to the ulnar one and a half digits and dorsal hand in complement to the SRN.

HAND EXAMINATION

Emergency Department/Inpatient Consultation

A common scenario in which the hand surgeon will be introduced to the patient is in trauma or other acute situations. The patient is evaluated by inspection, palpation, and provocative testing.

On inspection, one should first note the position of the hand. The resting hand has a normal cascade of the fingers, with the small finger flexed most and the index finger least (Fig. 44-6). Disturbance of this suggests a tendon or skeletal problem. Also note any gross deformities or wounds and what deeper structures, if any, are visible in such wounds. Observe for abnormal coloration of a portion or all of the hand (this can be confounded by ambient temperature or other injuries), edema, and/or clubbing of the fingertips.

Palpation typically begins with the radial and ulnar artery pulses at the wrist level. Pencil Doppler examination can supplement this and evaluate distal vessels. A pulsatile signal is normally detectable by pencil Doppler in the pad of the finger at the center of the whorl of creases. Discrepancies between digits should be noted. If all other tests are inconclusive, pricking the involved digit with a 25-gauge needle should produce bright red capillary bleeding. If an attached digit demonstrates inadequate or absent blood flow (warm ischemia), the urgency of completing the evaluation and initiating treatment markedly increases.

Sensation must be evaluated prior to any administration of local anesthetic. At a minimum, light and sharp touch sensation should be documented for the radial and ulnar aspects of the tip of each digit. Beware of writing “sensation intact” at the conclusion of this evaluation. Rather, one should document what was tested (e.g., “light and sharp touch sensation present and symmetric to the tips of all digits of the injured hand”). For a more detailed evaluation of hand sensation, two-point discrimination may be assessed using a bent paperclip or monofilament. In the setting of a sharp injury, sensory deficit implies a lacerated structure until proven otherwise. Once sensation has been evaluated and documented, the injured hand can be anesthetized for patient comfort during the remainder of the examination (see below).

Ability to flex and extend the wrist and digital joints is typically examined next. At the wrist level, the FCR and FCU tendons should be palpable during flexion. The wrist extensors are not as readily palpated due to the extensor retinaculum. Ability to flex the DIP joint (FDP) is tested by blocking the finger at the middle phalanx level. To test the FDS to each finger, hold the remaining three fingers in slight hyperextension

A

B

Figure 44-6. In the normal resting hand, the fingers assume a slightly flexed posture from the index finger (least) to the small finger (most). **A.** Anteroposterior view. **B.** Lateral view.

and ask the patient to flex the involved digit (Fig. 44-7). This maneuver makes use of the fact that the FDP tendons share a common muscle belly. Placing the remaining fingers in extension prevents the FDP from firing, and allows the FDS, which has a separate muscle belly for each tendon, to fire. Strength in grip, finger abduction, and thumb opposition is tested and compared to the uninjured side. Range of motion for the wrist, MP, and IP joints should be noted and compared to the opposite side.

If there is suspicion for closed space infection, the hand should be evaluated for erythema, swelling, fluctuance, and localized tenderness. The dorsum of the hand does not have fascial septae; thus, dorsal infections can spread more widely than palmar ones. The epitrochlear and axillary nodes should be palpated for enlargement and tenderness. Findings for specific infectious processes will be discussed in the “Infections” section.

Figure 44-7. The examiner holds the untested fingers in full extension, preventing contracture of the flexor digitorum profundus. In this position, the patient is asked to flex the finger, and only the flexor digitorum superficialis will be able to fire.

Additional exam maneuvers and findings, such as those for office consultations, will be discussed with each disease process covered later in this chapter.

HAND IMAGING

Plain X-Rays

Almost every hand evaluation should include plain X-rays of the injured or affected part. A standard, anteroposterior, lateral, and oblique view of the hand or wrist (as appropriate) is rapid, inexpensive, and usually provides sufficient information about the bony structures to achieve a diagnosis in conjunction with the symptoms and findings.⁶

Lucencies within the bone should be noted. Most commonly, these represent fractures, but they can on occasion represent neoplastic or degenerative processes. Great care should be taken to evaluate the entire X-ray, typically beginning away from the area of the patient's complaint. Additional injuries can be missed, which might affect the treatment plan selected and eventual outcome.

Congruency of adjacent joints should also be noted. The MP and IP joints of the fingers should all be in the same plain on any given view. Incongruity of the joint(s) of one finger implies fracture with rotation. At the wrist level, the proximal and distal edge of the proximal row and proximal edge of the distal row should be smooth arcs, known as Gilula's arcs (Fig. 44-8A). Disruption of these implies ligamentous injury or possibly dislocation (Fig. 44-8B).⁷

Computed Tomography

Computed tomography (CT) scanning of the hand and wrist can provide additional bony information when plain X-rays are insufficient. Comminuted fractures of the distal radius can be better visualized for number and orientation of fragments. Scaphoid fractures can be evaluated for displacement and comminution preoperatively as well as for the presence of bony bridging postoperatively (Fig. 44-9). Recent studies have suggested that in the setting of suspected scaphoid fractures with negative radiographs, the use of CT scans may decrease the healthcare costs and patient morbidity.⁸ CT scans are also useful for CMC fractures of the hand where overlap on a plain X-ray lateral view may make diagnosis difficult.

Unlike the trunk and more proximal extremities, CT scans with contrast are less useful to demonstrate abscess cavities due to the small area of these spaces.

Ultrasonography

Ultrasonography has the advantages of being able to demonstrate soft tissue structures and being available on nights and weekends. Unfortunately, it is also highly operator dependent. In the middle of the night when magnetic resonance imaging (MRI) is not available, ultrasound may be able to demonstrate a

Figure 44-8. Gilula's arcs are seen shown in this normal patient (A) and in a patient with a scaphoid fracture and perilunate dislocation (B).

A

B

Figure 44-9. A. Preoperative images demonstrate a nonunion of a scaphoid fracture sustained 4 years earlier. B. Postoperatively, cross-sectional imaging with a computed tomography scan in the coronal plan demonstrates bone crossing the previous fracture line. This can be difficult to discern on plain X-rays due to overlap of bone fragments.

Figure 44-10. T1-weighted magnetic resonance imaging shows perfused bone as white. In this patient, there is the absence of whiteness where the scaphoid should be (*dashed circle*), consistent with avascular necrosis.

large deep infection in the hand but is rarely more useful than a thorough clinical examination. Additionally, the use of dynamic ultrasound may be used to evaluate tendon motion and aid in the diagnosis of tendon pathology or injury.⁹

Magnetic Resonance Imaging

MRI provides the best noninvasive visualization of the soft tissue structures. With contrast, MRI can demonstrate an occult abscess. Unfortunately, it is often not available on an urgent basis for hand issues when this information is often needed. MRI can also demonstrate soft tissue injuries such as cartilage or ligament tears or tendonitis (usually by demonstrating edema in the area in question). It can demonstrate occult fractures that are not sufficiently displaced to be seen on X-ray or CT (again, by demonstrating edema). MRI can also demonstrate vascular disturbance of a bone, as in a patient with avascular necrosis of the scaphoid (Fig. 44-10).

Angiography

Angiography of the upper extremity is rarely used. In many centers, MRI and CT angiography provide sufficient resolution of the vascular structures to make traditional angiography unnecessary. Also, primary vascular disease of the upper extremity is relatively uncommon. In the trauma setting, vascular disturbance usually mandates exploration and direct visualization of the structures in question, and angiography is thus obviated.

For a patient with vascular disease of the upper extremity, angiography of the upper extremity is usually performed through a femoral access much like with the leg. An arterial catheter can be used to deliver thrombolytic drugs to treat a thrombotic process.

TRAUMA

The upper extremity–injured patient may have additional injuries to other parts of the body. All injured patients should receive an appropriate trauma survey to look for additional injuries.

The patient with upper extremity trauma is evaluated as described in the “Hand Examination” section. Sensory examination should be performed early. Once sensory status has been documented, administration of local anesthesia can provide comfort to the patient during the remainder of the evaluation

and subsequent treatment. Patients with nonclean wounds who received fewer than three prior doses of tetanus toxoid (or more than 5 years since last tetanus vaccination) or have an unknown history of prior doses should receive tetanus immunoglobulin as well as tetanus vaccination.¹⁰

Fractures and Dislocations

For dislocations and displaced fractures, a visible deformity is often present. Nondisplaced fractures may not show a gross deformity but will have edema and tenderness to palpation at the fracture site. A fracture is described by its displacement, rotation, and angulation. A fracture is also described in terms of comminution and the number and complexity of fracture fragments. Displacement is described as a percentage of the diameter of the bone; rotation is described in degrees of supination or pronation with respect to the rest of the hand; angulation is described in degrees. To avoid confusion, it is useful to describe which direction the angle of the fracture points. All injuries should be evaluated for nearby wounds (open) that may introduce bacteria into the fracture site or joint space.

Once the initial force on the fracture ceases, the tendons passing beyond the fracture site provide the principal deforming force. Their force is directed proximally and, to a lesser extent, volarly. Based on this, the stability of a fracture can be determined by the orientation of the fracture with respect to the shaft of the bone. Transverse fractures are typically stable. Oblique fractures typically shorten. Spiral fractures typically rotate as they shorten and thus require surgical treatment.

Fractures of the tuft of the distal phalanx are common. Catching of a finger in a closing door is a common causative mechanism. These fractures are often nondisplaced and do not require treatment beyond protection of the distal phalanx from additional trauma while the fracture heals.

Displaced transverse fractures of the phalanges can usually be reduced with distraction. The distal part is pulled away from the main body of the hand and then pushed in the direction of the proximal shaft of the finger, and then distraction is released. Postreduction X-rays should routinely be performed to document satisfactory reduction. Oblique and spiral fractures usually are unstable after reduction. The involved digit(s) should be splinted until appropriate surgical intervention can be performed.

Articular fractures of the IP and MP joints are worrisome because they may compromise motion. Chip fractures must be evaluated for instability of the collateral ligaments. If the joint is stable, the patient should initially be splinted for comfort. Motion therapy should be instituted early (ideally within the first week) to prevent stiffness. For larger fractures, the patient should be splinted until surgical treatment can be performed. In surgery, the fracture is typically internally fixated to allow for early motion, again with the goal of preventing stiffness.^{11,12}

Dislocations of the PIP joints produce traction on the neurovascular structures but usually do not lacerate them. In general, the patient should not be sent home with a joint that remains dislocated. Most commonly, the distal part is dorsal to the proximal shaft and sits in a hyperextended position. For this patient, the examiner gently applies pressure to the base of the distal part until it passes beyond the head of the proximal phalanx. Once there, the relocated PIP joint is gently flexed, confirming the joint is in fact reduced. The joint is splinted in slight flexion to prevent redislocation. On occasion, the head of the proximal phalanx may pass between the two slips of the

Figure 44-11. The Jahss maneuver. The surgeon fully flexes the patient's small finger into the palm and secures it in his distal hand. The proximal hand controls the wrist and places the thumb on the patient's fracture apex (the most prominent dorsal point). The examiner distracts the fracture, pushes dorsally with the distal hand (*up arrow*), and resists dorsal motion with the proximal hand (*down arrow*).

FDS tendon. For these patients, the joint may not be reducible in a closed fashion.

Angulated fractures of the small finger metacarpal neck ("boxer's fracture") are another common injury seen in the ER. Typical history is that the patient struck another individual or rigid object with a hook punch. These are often stable after reduction using the Jahss maneuver (Fig. 44-11).¹³

Fractures of the thumb metacarpal base are often unstable. The Bennett fracture displaces the volar-ulnar base of the bone. The remainder of the articular surface and the shaft typically dislocate dorsoradially and shorten. The thumb often appears grossly shortened, and the proximal shaft of the metacarpal may reside at the level of the trapezium or even the scaphoid on X-ray. In a Rolando fracture, a second fracture line occurs between the remaining articular surface and the shaft. These fractures nearly always require open reduction and internal fixation.

Most nondisplaced fractures do not require surgical treatment. The scaphoid bone of the wrist is a notable exception to this rule. Due to peculiarities in its vascular supply, particularly vulnerable at its proximal end, nondisplaced scaphoid fractures can fail to unite in up to 20% of patients even with appropriate immobilization. Recent developments in hardware and surgical technique have allowed stabilization of the fracture with minimal surgical exposure. One prospective randomized series of scaphoid wrist fractures demonstrated shortening of time to union by up to 6 weeks in the surgically treated group, but no difference in rate of union.¹⁴ Surgery may be useful in the younger, more active patient who would benefit from an earlier return to full activity.

Ligament injuries of the wrist can be difficult to recognize. Patients often present late and may not be able to localize their pain. In severe cases, the ligaments of the wrist can rupture to the point of dislocation of the capitate off the lunate or even the lunate off the radius. Mayfield and colleagues classified the progression of this injury into four groups.¹⁵ In the most severe group, the lunate dislocates off the radius into the carpal tunnel. In some circumstances, the scaphoid bone may break rather than

the scapholunate ligament rupturing. Attention to the congruency or disruption of Gilula's arcs will help the examiner to recognize this injury. For patients with type 4 (most severe) and some with type 3 injury, the examiner should also evaluate for sensory disturbance in the median nerve distribution because this may indicate acute carpal tunnel syndrome and necessitate more urgent intervention. Although the Mayfield pattern of injury is most common, force can also transmit along alternate paths through the carpus.¹⁶

After reduction of fractures and dislocations (as well as after surgical repair of these and many other injuries), the hand must be splinted in a protected position. For the fingers, MP joints should be splinted 90°, and the IP joints at 0° (called the intrinsic plus position). The wrist is generally splinted at 20° extension because this puts the hand in a more functional position.

3▶ This keeps the collateral ligaments on tension and helps prevent secondary contracture. In general, one of three splints should be used for the emergency department (ED) patient (Fig. 44-12). The ulnar gutter splint uses places plaster

Figure 44-12. Commons splints used for hand injuries/surgeries. **A.** Ulnar gutter splint. The ring and small fingers are included and maintain an interphalangeal (IP) joint extension and metacarpophalangeal (MP) joint flexion to 90°. **B.** Dorsal four-finger splint. As with the ulnar gutter splint, finger MP joints are flexed to 90° with IP joints kept fully extended. **C.** Thumb spica splint. One easy method to fabricate is to place one slab of plaster radially over the wrist and thumb with a second square of plaster over the thenar eminence, which joins the first. **D.** Sugar tong splint. This dorsal and volar slab splints immobilizes the wrist and elbow in neutral and 90° positions, respectively.

around the ulnar border of the hand. It is generally appropriate for small finger injuries only. Dorsal plaster splints can be used for injuries of any of the fingers. Plaster is more readily contoured to the dorsal surface of the hand than the volar surface, particularly in the setting of trauma-associated edema. For thumb injuries, the thumb spica splint is used to keep the thumb radially and palmarly abducted from the hand. Lastly, sugar tong splints include a volar and dorsal slab that includes the elbow in order to prevent supination and pronation. Sugar tong splints are most often used in the setting of acute distal radius or ulna fractures.

Tendons

Injuries to the flexor and extensor tendons compromise the mobility and strength of the digits. On inspection, injury is normally suspected by loss of the normal cascade of the fingers. The patient should be examined as described earlier to evaluate for which tendon motion is deficient. If the patient is unable to cooperate, extension of the wrist will produce passive flexion of the fingers and also demonstrate a deficit. This is referred to as the *tenodesis maneuver*.

Flexor tendon injuries are described based on zones (Fig. 44-13). Up until 40 years ago, zone 2 injuries were always reconstructed and never repaired primarily due to concern that the bulk of repair within the flexor sheath would prevent tendon glide. The work of Dr. Kleinert and colleagues at the University of Louisville changed this “axiom” and established the principle of primary repair and early controlled mobilization postoperatively.¹⁷ Flexor tendon injuries should always be repaired in the operating room. Although they do not need to be repaired on the day

Figure 44-13. The zones of flexor tendon injury. I. Flexor digitorum superficialis insertion to the flexor digitorum profundus insertion. II. Start of the A1 pulley to the flexor digitorum superficialis insertion. III. End of the carpal tunnel to the start of the A1 pulley. IV. Within the carpal tunnel. V. Proximal to the carpal tunnel.

of injury, the closer to the day of injury they are repaired, the easier it will be to retrieve the retracted proximal end in surgery. The laceration should be washed out and closed at the skin level only using permanent sutures. The hand should be splinted as described earlier; one notable difference is that the wrist should be splinted at slight flexion (about 20°) to help decrease the retracting force on the proximal cut tendon end.

Extensor tendons do not pass through a sheath in the fingers. As such, bulkiness of repair is less of a concern. With proper supervision/experience and equipment, primary extensor tendon repair can be performed in the ED.

Very distal extensor injuries near the insertion on the dorsal base of the distal phalanx may not have sufficient distal tendon to hold a suture. Closed injuries, called mallet fingers, can be treated with extension splinting of the DIP joint for 6 continuous weeks. For patients with open injuries, a dermatotenodesis suture is performed. A 2-0 or 3-0 suture is passed through the distal skin, tendon remnant, and proximal tendon as a mattress suture. Using a suture of a different color than the skin closing sutures will help prevent removing the dermatotenodesis suture(s) too soon. The DIP joint is splinted in extension.

More proximal injuries are typically repaired with a 3-0 braided permanent suture. Horizontal mattress or figure-of-eight sutures should be used, two per tendon if possible. Great care should be used to ensure matching the appropriate proximal and distal tendon ends. The patient is splinted with IP joints in extension and the wrist in extension per usual. MP joints should be splinted in 45° flexion, sometimes less. Although this position is not ideal for MP collateral ligaments, it is important for taking tension off of the tendon repairs.

Nerve Injuries

In the setting of a sharp injury, a sensory deficit implies a nerve laceration until proven otherwise. For blunt injuries, even displaced fractures and dislocations, nerves are often contused but not lacerated and are managed expectantly. Nerve repairs require appropriate microsurgical equipment and suture; they should not be performed in the ED. As with tendons, nerve injuries do not require immediate exploration. However, earlier exploration will allow for easier identification of structures and less scar tissue to be present. The nerve must be resected back to healthy nerve fascicle prior to repair. Delay between injury and repair can thus make a difference between the ability to repair a nerve primarily or the need to use a graft. The injured hand should be splinted with MPs at 90° and IPs at 0°, as described earlier.

Vascular Injuries

Vascular injuries have the potential to be limb or digit threatening. A partial laceration of an artery at the wrist level can potentially cause exsanguinating hemorrhage. Consultations for these injuries must be evaluated urgently.

Initial treatment for an actively bleeding wound should be direct local pressure for no less than 10 continuous minutes. If this is unsuccessful, an upper extremity tourniquet inflated to 100 mmHg above the systolic pressure should be used. One should keep this tourniquet time to less than 2 hours to avoid tissue necrosis. Once bleeding is controlled well enough to evaluate the wound, it may be cautiously explored to evaluate for bleeding points. One must be very cautious if attempting to ligate these to ensure that adjacent structures such as nerves are not included in the ligature.

The hand must be evaluated for adequacy of perfusion to the hand as a whole as well as the individual digits. Capillary

refill, turgor, Doppler signal, and bleeding to pinprick all provide useful information regarding vascular status. The finger or hand with vascular compromise requires urgent operative exploration. Unlike the complete amputation, in which the amputated part can be cold preserved (see later section, “Amputation and Replantation”), devascularization without amputation produces warm ischemia, which is tolerated only for a matter of hours.

For the noncritical vascular injury, two treatment options exist. Simple ligation will control hemorrhage. At least one of the palmar arterial arches is intact in 97% of patients, so this will usually not compromise hand perfusion.⁵ Each digit also has two arterial inflows and can survive on one (see “Amputations and Replantation” section). In the academic hospital setting, however, consideration should be given to repairing all vascular injuries. Instructing a resident in vascular repair in the noncritical setting will produce a more skilled and prepared resident for when a critical vascular injury does arise.

ANESTHESIA

Local Anesthesia

Anesthetic blockade can be administered at the wrist level, digital level, or with local infiltration as needed. Keep in mind that all local anesthetics are less effective in areas of inflammation.

The agents most commonly used are lidocaine and bupivacaine. Lidocaine has the advantage of rapid onset, whereas bupivacaine has the advantage of long duration (average 6–8 hours).¹⁸ Although bupivacaine can produce irreversible heart block in high doses, this is rarely an issue with the amounts typically used in the hand. For pediatric patients, the tolerated dose is 2.5 mg/kg. This can be easily remembered by noting that when using 0.25% bupivacaine, 1 mL/kg is acceptable dosing.

A commonly held axiom is that epinephrine is unacceptable to be used in the hand. Several recent large series have dispelled this myth.¹⁹ Epinephrine should not be used in the fingertip and not in concentrations higher than 1:100,000 (i.e., what is present in commercially available local anesthetic with epinephrine). Beyond that, its use is acceptable and may be useful in an ED where tourniquet control may not be available. Also, because most ED procedures are done under pure local anesthesia, many patients will not tolerate the discomfort of the tourniquet beyond 30 minutes.²⁰ Epinephrine will provide hemostasis and also prolong the effect of the local anesthetic.

Studies have reported that the addition of sodium bicarbonate (NaHCO₃) in order to buffer local anesthetic solutions and decrease the pain experienced during the administration of local anesthetic.²¹ This decrease in pain has been attributed to decreasing the acidity of local anesthetic solutions. In the clinical setting, the mixing of 8.4% sodium bicarbonate with 1% lidocaine with 1:100,000 epinephrine in a 1:9 ratio is adequate to provide a decrease in pain during the injection of local anesthetic.²²

Simple lacerations, particularly on the dorsum of the hand, can be anesthetized with local infiltration. This is performed in the standard fashion.

Blocking of the digital nerves at the metacarpal head level is useful for volar injuries distal to this point and for dorsal injuries beyond the midpoint of the middle phalanx (via dorsal branches of the proper digital nerves). Fingertip injuries are particularly well anesthetized by this technique. A digit can be anesthetized via a flexor sheath approach or via the dorsal web space (Fig. 44-14A,B).

Figure 44-14. Local anesthesia can be administered at the digital or the wrist level. **A.** A single injection into the flexor tendon sheath at the metacarpal head level provides complete anesthesia for the digit. **B.** Alternatively, one can inject from a dorsal approach into the web space on either side. **C.** The superficial radial nerve is blocked by infiltrating subcutaneously over the distal radius from the radial artery pulse to the distal radioulnar joint. The dorsal sensory branch of the ulnar nerve is blocked in similar fashion over the distal ulna. **D.** To block the ulnar nerve, insert the needle parallel to the plane of the palm and deep to the flexor carpi ulnaris tendon; aspirate to confirm the needle is not in the adjacent ulnar artery. **E.** To block the median nerve, insert the needle just ulnar to the palmaris longus tendon into the carpal tunnel. One should feel two points of resistance: one when piercing the skin, the second when piercing the antebrachial fascia.

Blocking one or more nerves as they cross the wrist can provide several advantages: anesthesia for multiple injured digits, avoiding areas of inflammation where the local anesthetic agent may be less effective, and avoiding injection where the volume of fluid injected may make treatment harder (such as fracture reduction). Four major nerves cross the wrist: the median nerve, SRN, ulnar nerve, and dorsal sensory branch of the ulnar nerve (Fig. 44-14C–E). When blocking the median and ulnar nerves, beware of intraneural injection, which can cause irreversible neural scarring. If the patient complains of severe paresthesias with injection or high resistance is encountered, the needle should be repositioned.

Hand Surgery Under Local Anesthesia

Wide awake hand surgery is surgery that is performed under surgeon-administered local anesthesia with field sterility but without the use of sedation or a tourniquet. A major benefit of this approach is the reduction of healthcare costs due to the elimination of an anesthesia provider and postoperative monitoring because only local anesthesia is used. Further benefits of sedation-free surgery include decreased time spent in the hospital for surgery and the ability of patients to follow instructions during surgery. This advantage is evident during flexor tendon repairs, where intraoperative active movement allows direct visualization of the tendon repair under active movement.²³ Perceived weaknesses of sedation-free surgery include patient intraoperative anxiety and fear of pain during the administration of local anesthetic. A study by Davison et al, however, found that patients undergoing carpal tunnel release under wide awake local had no difference in anxiety or pain compared to patients undergoing carpal tunnel release with sedation.²⁴

Postoperative Pain Management

Since the recognition of pain as the fifth vital sign in the early 2000s, the number of opioid prescriptions has risen dramatically. Accordingly, over the last decade, the United States has seen an increase in the number of deaths due to prescription opioid overdose. Deaths due to opioid overdose now exceeds the number of deaths caused by heroin and cocaine combined. As healthcare providers, it is essential that we adequately treat postoperative pain with the minimal amount of narcotics necessary. A recent study by Rodgers et al identified that the majority of patients undergoing elective hand surgery used prescription pain medication for only 2 or fewer days after surgery. Many patients achieved adequate pain control with over-the-counter pain medication and were often left with unused opioid analgesics.²⁵

Accordingly, there has been increased emphasis on educating prescribers on the recognition of opioid abuse and guidelines for appropriate opioid prescribing. Approaches such as multimodal pain management and opioid prescription protocols have shown to achieve adequate pain control while also reducing excess opioid prescriptions.²⁶

SPECIAL CONSIDERATIONS

Amputations and Replantation

After replantation was first reported, replantation was attempted for nearly all amputations.²⁷ Over the ensuing decades, more stringent guidelines have been established regarding what should be replanted. Indications for replantation include amputations of the thumb, multiple digit amputations, and amputations in children. Relative contraindications to replantation

include crush injuries, injuries to a single digit distal to the PIP joint, and patients who are unable to tolerate a long surgical procedure. As with all guidelines, one should evaluate the particular needs of the injured patient.

In preparation for replantation, the amputated part and proximal stump should be appropriately treated. The amputated part should be wrapped in moistened gauze and placed in a sealed plastic bag. This bag should then be placed in an ice water bath. Do not use dry ice, and do not allow the part to contact ice directly; frostbite can occur in the amputated part, which will decrease its chance of survival after replantation. Bleeding should be controlled in the proximal stump by as minimal a means necessary, and the stump should be dressed with a nonadherent gauze and bulky dressing.

For digital amputations deemed unsalvageable, revision amputation can be performed in the ED if appropriate equipment is available. Bony prominences should be smoothed off with a rongeur and/or rasp. Great care must be taken to identify the digital nerves and resect them back as far proximally in the wound as possible; this helps decrease the chance of painful neuroma in the skin closure. Skin may be closed with permanent or absorbable sutures; absorbable sutures will spare the patient the discomfort of suture removal several weeks later. For more proximal unsalvageable amputations, revision should be performed in the operating room to maximize vascular and neural control.

Prostheses can be made for amputated parts. The more proximal the amputation, the more important to function the prosthesis is likely to be. Although finger-level prostheses are generally considered cosmetic, patients with multiple finger amputations proximal to the DIP have demonstrable functional benefit from their prosthesis as well.²⁸

Fingertip Injuries

Fingertip injuries are among the most common pathologies seen in an ED. The usual history is that a door closed on the finger (commonly the middle, due to its increased length) or something heavy fell on the finger.

Initial evaluation should include: wound(s) including the nail bed, perfusion, sensation, and presence and severity of fractures. For the common scenario, complex lacerations with minimally displaced fracture(s) and no loss of perfusion, the wound is cleansed, sutured, and splinted in the ED. To properly assess the nail bed, the nail plate (hard part of the nail) should be removed. A Freer periosteal elevator is well suited for this purpose. Lacerations are repaired with 6-0 fast gut suture. Great care must be taken when suturing because excessive traction with the needle can further lacerate the tissue. After repair, the nail folds are splinted with the patient's own nail plate (if available) or with aluminum foil from the suture pack. This is done to prevent scarring from the nail folds down to the nail bed that would further compromise healing of the nail.

In some situations, tissue may have been avulsed in the injury and be unavailable for repair. Choice of treatment options depends on the amount and location of tissue loss (Fig. 44-15). Historically, wounds less than 1 cm² with no exposed bone can be treated with local wound care and secondary intention. Recently, studies have reported that wounds with an average size of 1.75 cm² have healed well with excellent functional and aesthetic results.²⁹ For larger wounds or wounds with bone exposed, one must decide if the finger is worth preserving at the current length or if shortening to allow for primary closure is a

Figure 44-15. Treatment algorithm for management of fingertip injuries. See text for description of flaps.

better solution. A useful guideline is the amount of fingernail still present; if greater than 50% is present, local or regional flap coverage may be a good solution.

If sufficient local tissue is present, homodigital flaps can be considered. A wide range of antegrade and retrograde homodigital flaps can be mobilized to cover the defect. Some carry sensation or can receive nerve coaptation to recover sensation over time.³⁰ For the thumb only, the entire volar skin including both neurovascular bundles can be raised and advanced distally up to 1.5 cm².³¹ The thumb receives separate vascularity to its dorsal skin from the radial artery. This flap is not appropriate for the fingers. Patients retain full sensibility in the advanced skin and can be mobilized within days of surgery (Fig. 44-16A–C).

For wounds too large to cover with homodigital tissue, regional flaps can be considered. The skin from the distal radial thenar eminence can be raised as a random pattern flap (Fig. 44-16D–F). The finger is maintained in flexion for 14 to 21 days until division of the flap pedicle and inset of the flap. Some authors have reported prolonged stiffness in patients over 30 years old, but careful flap design helps minimize this complication.³² Alternatively, the skin from the dorsum of the middle phalanx of an adjacent digit can be raised as a flap to cover the volar P3 (Fig. 44-16G–I). The flap is inset at 14 to 21 days. Long-term studies have shown this flap develops sensation over time.³³

Patients with fingertip injuries must be assessed for the possibility of salvage of the injured digit(s) taken within the context of the patient's recovery needs and goals. The surgeon then matches the available options to the particular patient needs.

High-Pressure Injection Injuries

High-pressure devices are commonly used for cleaning and applications of liquids such as lubricants and paint. Most commonly, the inexperienced worker accidentally discharges the device into his nondominant hand at the base of the digit.

Severity of injury depends on the amount and type of liquid injected; hydrophobic compounds cause greater damage.³⁴

These injuries are typically quite innocuous to inspection. They are, however, digit-threatening emergencies. The patient should be informed of the severity of the injury, and exploration is ideally performed within 6 hours of injury. Up to 50% of such injuries result in loss of the digit, but early recognition and treatment are associated with increased chance of digit survival.³⁵ Early frank discussion with the patient and initiation of appropriate treatment produce the best results and medicolegal protection.

Compartment Syndrome

Compartment syndromes can occur in the forearm and/or the hand. As in other locations, these are potentially limb-threatening issues. Principle symptoms are pain in the affected compartments, tense swelling, tenderness to palpation over the compartment, and pain with passive stretch of the muscles of the compartment.³⁶ Pulse changes are a late finding; normal pulses do not rule out compartment syndrome.

There are three compartments in the forearm and four groups of compartments in the hand. The volar forearm is one compartment. On the dorsum of the forearm, there is the dorsal compartment as well as the mobile wad compartment, beginning proximally over the lateral epicondyle. In the hand, the thenar and hypothenar eminences each represent a compartment. The seven interosseous muscles each behave as a separate compartment.

Compartment syndrome can be caused by intrinsic and extrinsic causes. Intrinsic causes include edema and hematoma due to fracture. Extrinsic causes include splints and dressings that are circumferentially too tight and intravenous infiltrations. Infiltrations with hyperosmolar fluids such as X-ray contrast are particularly dangerous, because additional water will be drawn in to neutralize the hyperosmolarity.

Measurement of compartment pressures can be a useful adjunct to assessment of the patient. The Stryker pressure measurement device or similar device is kept in many operating rooms for this purpose. The needle is inserted into the compartment in question, a gentle flush with 0.1 to 0.2 cc of saline clears the measurement chamber, and a reading is obtained. Studies have disagreed about whether the criterion is a measured pressure (30–45 mmHg, depending on the series) or within a certain amount of the diastolic blood pressure.³⁷

Compartment releases are performed in the operating room under tourniquet control. Release of the volar forearm compartment includes release of the carpal tunnel. As the incision travels distally, it should pass ulnar and then curve back radially just before the carpal tunnel. This avoids a linear incision across a flexion crease and also decreases the chance of injury to the palmar cutaneous branch of the median nerve. One dorsal forearm incision can release the dorsal compartment and the mobile wad. In the hand, the thenar and hypothenar compartments are released each with a single incision. The interosseous compartments are released with incisions over the index and ring metacarpal shafts. Dissection then continues radial and ulnar to each of these bones and provides release of all the muscle compartments. Any dead muscle is debrided. Incisions are left open and covered with a nonadherent dressing. The wounds are reexplored in 2 to 3 days to assess for muscle viability. Often the incisions can be closed primarily, but a skin graft may be needed for the forearm.

Figure 44-16. (Continued)

If the examiner feels the patient does not have a compartment syndrome, elevation and serial examination are mandatory. When in doubt, it is safer to release an early compartment syndrome than wait to release and risk muscle necrosis. Progression of compartment syndrome can lead to Volkmann's ischemic contracture with muscle loss and scarring that may compress nerves and other critical structures. Medicolegally, it is far easier to defend releasing an early compartment syndrome than delaying treatment until the process has progressed to necrosis and/or deeper scarring.

COMPLICATIONS

Nonunion

Any fractured bone has the risk of failing to heal. Fortunately, in the fingers and hand, this is a rare problem. Tuft injuries, where soft tissue interposes between the fracture fragments, have relatively higher risk of this problem. The nonunited tuft can be treated with debridement and bone grafting or revision amputation depending on the needs and goals of the patient. Phalangeal and metacarpal nonunions are also quite rare. They can similarly be treated with debridement of the nonunion, grafting, and rigid fixation.³⁸ More proximally, the scaphoid bone of the wrist has a significant risk of nonunion even if nondisplaced (see Fig. 44-9A). Any patient suspected of a scaphoid injury, namely those with tenderness at the anatomic snuffbox, should be placed in a thumb spica splint and reevaluated within 2 weeks even if initial X-rays show no fracture. Scaphoid nonunions can be quite challenging to repair, and immobilization at the time of injury in a thumb spica splint is essentially always warranted.³⁹

Stiffness

The desired outcome of any hand injury is a painless, mobile, functional hand. Multiple factors can contribute to decreased mobility, including complex injuries of soft tissue and bone, noncompliance of the patient with postoperative therapy, and inappropriate splinting. The surgeon performing the initial evaluation can greatly impact this last factor. The goal of splinting is to keep the collateral ligaments on tension (MPs at 90°, IP joints straight). For severe cases of stiffness, mobilization surgeries such as tenolysis and capsulotomies can be performed, but these rarely produce normal range of motion.⁴⁰ Prevention of joint contractures with appropriate splinting and early, protected mobilization is the best option to maximize mobility at the end of healing. Healing of an injured or diseased structure in the hand is not the endpoint of treatment; the goal of any intervention must be to obtain structure healing, relief of pain, and maximization of function.

Neuroma

Any lacerated nerve will form a neuroma. A neuroma consists of a ball of scar and axon sprouts at the end of the injured nerve.⁴¹ In unfavorable circumstances, this neuroma can become painful. The SRN is particularly notorious for this problem. By providing proximal axon sprouts a target, nerve repair is an excellent preventive technique. In some circumstances, such as injuries requiring amputation, this is not possible. As mentioned earlier, the surgeon should resect the nerve stump as far proximally in the wound as possible to avoid the nerve stump healing in the cutaneous scar to minimize this risk.

For the patient who develops a painful neuroma, nonsurgical treatments are initiated first. The neuroma can be identified

by the presence of a Tinel's sign. Therapy techniques of desensitization, ultrasound, and electrical stimulation have all proven useful. Corticosteroid injection to the neuroma has also proven useful in some hands.

When these techniques fail, surgery is contemplated. The neuroma can be resected, but a new one will form to replace it. The nerve ending can be buried in muscle or even bone to prevent the neuroma from residing in a superficial location where it may be impacted frequently.

Regional Pain Syndromes

Injuries to the upper extremity can occasionally result in the patient experiencing pain beyond the area of initial injury. Reflex sympathetic dystrophy and sympathetic mediated pain are two terms that have been used in the past to describe this phenomenon. Both are inaccurate, as the sympathetic nervous system is not always involved. Current terminology for this condition is complex regional pain syndrome (CRPS). Type I occurs in the absence of a documented nerve injury; type II occurs in the presence of one.⁴²

CRPSs manifest as pain beyond the area of initial injuries. There is often associated edema and changes in hair and/or sweat distribution. Comparison to the unaffected side is useful to better appreciate these findings. There are currently no imaging studies that can be considered diagnostic for CRPS.⁴³

For the patient in whom the diagnosis of CRPS is not clear, no definitive diagnostic study exists. Patients suspected of CRPS should be referred for aggressive hand therapy. Brief trials of oral corticosteroids have been successful in some series. Referral to a pain management specialist including a trial of stellate ganglion blocks is also frequently employed.

NERVE COMPRESSION

Nerves conduct signals along their axonal membranes toward their end organs. Sensory axons carry signals from distal to proximal; motor axons from proximal to distal. Myelin from Schwann cells allows faster conduction of signals. Signals jump from the start of one Schwann cell to the end of the cell (a location called a gap junction) and only require the slower membrane depolarization in these locations.

Nerve compression creates a mechanical disturbance of the nerve.⁴⁴ In early disease, the conduction signal is slowed across the area of compression. When compression occurs to a sufficient degree for a sufficient time, individual axons may die. On a nerve conduction study, this manifests as a decrease in amplitude. Muscles receiving motor axons may show electrical disturbance on electromyogram (EMG) when sufficiently deprived of their axonal input.

Compression of sensory nerves typically produces a combination of numbness, paresthesias (pins and needles), and pain. Knowledge of the anatomic distribution of the peripheral nerves can aid in diagnosis. Sensory disturbance outside an area of distribution of a particular nerve (e.g., volar and dorsal radial-sided hand numbness for median nerve) makes compression of that nerve less likely. Diseases that cause systemic neuropathy (e.g., diabetes) can make diagnosis more difficult.

Nerve compression can theoretically occur anywhere along a peripheral nerve's course. The most common sites of nerve compression in the upper extremity are the median nerve at the carpal tunnel, ulnar nerve at the cubital tunnel, and ulnar nerve at Guyon's canal. Other, less common locations of nerve

compression are described as well. In addition, a nerve can become compressed in scar due to a previous trauma.

Carpal Tunnel Syndrome

The most common location of upper extremity nerve compression is the median nerve at the carpal tunnel, called carpal tunnel syndrome (CTS). The carpal tunnel is bordered by the scaphoid bone radially, the lunate and capitate bones dorsally, and the hook of the hamate bone ulnarly (see Fig. 44-3). The transverse carpal ligament, also called the flexor retinaculum, is its superficial border. The FPL, four FDS, and four FDP tendons pass through the carpal tunnel along with the median nerve. Of these 10 structures, the median nerve is relatively superficial and radial to the other nine.

An estimated 53 per 10,000 working adults have evidence of CTS. The National Institute for Occupational Safety and Health website asserts, "There is strong evidence of a positive association between exposure to a combination of risk factors (e.g., force and repetition, force and posture) and CTS."⁴⁵ There is disagreement among hand surgeons regarding whether occurrence of CTS in a patient who does repetitive activities at work represents a work-related injury.

Initial evaluation of the patient consists of symptom inventory: location and character of the symptoms, sleep disturbance due to symptoms, history of dropping objects, and difficulty manipulating small objects such as buttons, coins, or jewelry clasps.⁴⁶

Physical examination should begin with inspection. Look for evidence of wasting of the thenar muscles. Tinel's sign should be tested over the median nerve from the volar wrist flexion crease to the proximal palm, although this test has significant interexaminer variability.⁴⁷ Applying pressure over the carpal tunnel while flexing the wrist has been shown in one series to have the highest sensitivity when compared to Phalen's and Tinel's signs.⁴⁸ Strength of the thumb in opposition should also be tested.

Early treatment of CTS consists of conservative management. The patient is given a splint to keep the wrist at 20° extension worn at nighttime. Many patients can have years of symptom relief with this management. As a treatment and diagnostic modality, corticosteroid injection of the carpal tunnel is often employed. Mixing local anesthetic into the solution provides the benefit of early symptom relief (corticosteroids often take 3–7 days to provide noticeable benefit), and report of postinjection anesthesia in the median nerve distribution confirms the injection went into the correct location. Multiple authors have shown a strong correlation to relief of symptoms with corticosteroid injection and good response to carpal tunnel release.⁴⁹

When lesser measures fail or are no longer effective, carpal tunnel release is indicated. Open carpal tunnel release is a time-tested procedure with documented long-term relief of symptoms. A direct incision is made over the carpal tunnel, typically in line with where the ring finger pad touches the proximal palm in flexion. Skin is divided followed by palmar fascia. The carpal tunnel contents are visualized as they exit the carpal tunnel. The transverse carpal ligament is divided with the median nerve visualized and protected at all times. Improvement in symptoms is typically noted by the first postoperative visit, although symptom relief may be incomplete for patients with long-standing disease or systemic nerve-affecting diseases such as diabetes.

Endoscopic techniques have been devised to address CTS. All involve avoidance of incising the skin directly over the

carpal tunnel. In experienced hands, endoscopic carpal tunnel release provides the same relief of CTS with less intense and shorter lasting postoperative pain. After 3 months, however, the results are equivalent to open release.⁵⁰ In inexperienced hands, there may be a higher risk of injury to the median nerve with the endoscopic techniques; this procedure is not for the occasional carpal tunnel surgeon.

Cubital Tunnel Syndrome

The second most common location of upper extremity nerve compression is the ulnar nerve where it passes behind the elbow at the cubital tunnel. The cubital tunnel retinaculum passes between the medial epicondyle of the humerus and the olecranon process of the ulna. It stabilizes the ulnar nerve in this location during elbow motion. Over time, or sometimes after trauma, the ulnar nerve can become less stabilized in this area. Motion of the elbow then produces trauma to the nerve as it impacts the retinaculum and medial epicondyle.

Cubital tunnel syndrome may produce sensory and motor symptoms.⁵¹ The small finger and ulnar half of the ring fingers may have numbness, paresthesias, and/or pain. The ulnar nerve also innervates the dorsal surface of the small finger and ulnar side of the ring finger, so numbness in these areas can be explained by cubital tunnel syndrome. The patient may also report weakness in grip due to effects on the FDP tendons to the ring and small fingers and the intrinsic hand muscles. Patients with advanced disease may complain of inability to fully extend the ring and small finger IP joints.

Physical examination for cubital tunnel syndrome begins with inspection. Look for wasting in the hypothenar eminence and the interdigital web spaces. When the hand rests flat on the table, the small finger may rest in abduction with respect to the other fingers; this is called *Wartenberg's sign*. Tinel's sign is often present at the cubital tunnel. Elbow flexion and the shoulder internal rotation tests are affective maneuvers to aid in the diagnosis of cubital tunnel syndrome.⁵² Grip strength and finger abduction strength should be compared to the unaffected side. Froment's sign can be tested by placing a sheet of paper between the thumb and index finger and instructing the patient to hold on to the paper while the examiner pulls it away without flexing the finger or thumb (this tests the strength of the adductor pollicis and first dorsal interosseous muscles). If the patient must flex the index finger and/or thumb (FDP-index and FPL, both median nerve supplied) to maintain traction on the paper, this is a positive response.

Early treatment of cubital tunnel syndrome begins with avoiding maximal flexion of the elbow. Splints are often used for this purpose. Corticosteroid injection is rarely done for this condition; unlike in the carpal tunnel, there is very little space within the tunnel outside of the nerve. Injection in this area runs a risk of intraneural injection, which can cause permanent scarring of the nerve and dysfunction.

When conservative management fails, surgery has been contemplated. Treatment options include releasing the cubital tunnel retinaculum with or without transposing the nerve anterior to the elbow. While some authors advocate anterior transposition into the flexor-pronator muscle group with the goal of maximizing nerve recovery, recent studies have demonstrated equivalent results between transposition and in situ release of the nerve even in advanced cases. For this reason, the simpler in situ release, either open or endoscopic, is preferred by many surgeons.⁵³

Other Sites of Nerve Compression

All nerves crossing the forearm have areas described where compression can occur.⁵¹ The median nerve can be compressed as it passes under the pronator teres. The ulnar nerve can be compressed as it passes through Guyon's canal. The radial nerve, or its posterior interosseous branch, can be compressed as it passes through the radial tunnel (distal to the elbow where the nerve divides and passes under the arch of the supinator muscle). The SRN can be compressed distally in the forearm as it emerges from under the brachioradialis tendon, called *Wartenberg's syndrome*. As mentioned previously, any nerve can become compressed in scar at the site of a previous trauma.

DEGENERATIVE JOINT DISEASE

As with other joints in the body, the joints of the hand and wrist can develop degenerative changes. Symptoms typically begin in the fifth decade of life. Symptoms consist of joint pain and stiffness and often are exacerbated with changes in the weather. Any of the joints can become involved. As the articular cartilage wears out, pain typically increases and range of motion decreases. The patient should always be asked to what degree symptoms are impeding activities.

Physical findings are documented in serial fashion from the initial visit and subsequent visits. Pain with axial loading of the joint may be present. Decreased range of motion may be a late finding. Instability of the collateral ligaments of the joint is uncommon in the absence of inflammatory arthritis.

Plain X-rays are typically sufficient to demonstrate arthritis. Initially, the affected joint has a narrower radiolucent space between the bones. As joint degeneration progresses, the joint space further collapses. Bone spurs, loose bodies, and cystic changes in the bone adjacent to the joint all may become apparent. X-ray findings do not always correlate with patient symptoms. Patients with advanced X-ray findings may have minimal symptoms, and vice versa. Treatment is initiated and progressed based on the patient's symptoms regardless of imaging findings.

Initial management begins with rest of the painful joint. Splints are often useful, but may significantly impair the patient in activities and thus are frequently used at nighttime only. Oral nonsteroidal anti-inflammatory medications such as ibuprofen and naproxen are also useful. Patients on anticoagulants and antiplatelet medications may not be able to take these, and some patients simply do not tolerate the gastric irritation side effect even if they take the medication with food.

For patients with localized disease affecting only one or a few joints, corticosteroid injection may be contemplated. Needle insertion can be difficult since these joint spaces are quite narrow even before degenerative disease sets in. Also, many corticosteroid injections are suspensions, not solutions; injected corticosteroid will remain in the joint space and can be seen as a white paste if surgery is performed on a joint that has been previously injected.

Small Joints (Metacarpophalangeal and Interphalangeal)

When conservative measures fail, two principal surgical options exist: arthrodesis and arthroplasty. The surgeon and patient must decide together as to whether conservative measures have failed. Surgery for arthritis, whether arthrodesis or arthroplasty, is performed for the purpose of relieving pain. Arthrodesis, fusion of a joint can be performed with a tension band or axial

compression screw techniques.⁵⁴ Both methods provides excellent relief of pain and is durable over time. However, it comes at the price of total loss of motion.

Silicone implant arthroplasty has been available for over 40 years.⁵⁵ Rather than a true replacement of the joint, the silicone implant acts as a spacer between the two bones adjacent to the joint. This allows for motion without bony contact that would produce pain. Long-term studies have shown that all implants fracture over time, but usually continue to preserve motion and pain relief.⁵⁶

In the past 15 years, resurfacing implant arthroplasties have become available for the small joints of the hand. Multiple different materials have been used to fabricate such implants. These are designed to behave as a true joint resurfacing (as knee and hip arthroplasty implants are) and have shown promising outcomes in short- and intermediate-term studies.⁵⁶ Neither the silicone nor the resurfacing arthroplasties preserve (or restore) full motion of the MP or PIP joints.

Wrist

The CMC joint of the thumb, also called the basilar joint, is another common location of arthritis pain. Pain in this joint particularly disturbs function because the CMC joint is essential for opposition and cylindrical grasp. Patients will typically complain of pain with opening a tight jar or doorknob and strong pinch activities such as knitting. Conservative management is used first, as described earlier. Prefabricated, removable thumb spica splinting can provide excellent relief of symptoms for many patients.

Multiple surgical options exist for thumb CMC arthritis. Many resurfacing implants have been used in the past; often they have shown good short- and intermediate-term results and poor long-term results. Resection of the arthritic trapezium provides excellent relief of pain; however, many authors feel that stabilization of the thumb metacarpal base is necessary to prevent shortening and instability.⁵⁷ Some surgeons have demonstrated excellent long-term results from resection of the trapezium without permanent stabilization of the metacarpal base.⁵⁸ For both of these operations, the thumb base may not be sufficiently stable to withstand heavy labor. For these patients, fusion of the thumb CMC in mild opposition provides excellent pain relief and durability. The patient must be warned preoperatively that he will not be able to lay his hand flat after the surgery. This loss of motion can be problematic when the patient attempts to tuck in clothing or reach into a narrow space.⁵⁹

Degenerative change of the radiocarpal and midcarpal joints is often a consequence of scapholunate ligament injury. Often the initial injury goes untreated, with the patient believing it is merely a "sprain"; the patient is first diagnosed with the initial injury when he presents years later with degenerative changes.

Degenerative wrist changes associated with the scapholunate ligament follow a predictable pattern over many years, called *scapholunate advanced collapse* or *SLAC wrist*.⁶⁰ Because of this slow progression (Fig. 44-17A), patients can usually be treated with a motion-sparing procedure. If there is truly no arthritic change present, the scapholunate ligament can be reconstructed.

If arthritis is limited to the radiocarpal joint, two motion-sparing options are available. The proximal carpal row (scaphoid, lunate, and triquetrum) can be removed (proximal row carpectomy [PRC]). The lunate facet of the radius then

Figure 44-17. Arthritis of the hand and wrist. **A.** This patient injured her scapholunate ligament years prior to presentation. The scapholunate interval is widened (*double arrow*), and the radioscaphoid joint is degenerated (*solid oval*), but the radiolunate and lunocapitate joint spaces are well preserved (*dashed ovals*). **B.** This patient has had rheumatoid arthritis for decades. The classic volar subluxation of the metacarpophalangeal joints of the fingers (*dashed oval*) and radial deviation of the fingers are apparent.

articulates with the base of the capitate, whose articular surface is similar in shape to that of the base of the lunate. Studies have shown maintenance of approximately 68% of the wrist flexion-extension arc and 72% of hand strength compared to the contralateral side.⁶¹ Alternatively, the scaphoid can be excised, and four-bone fusion (lunate, capitate, hamate, and triquetrum) can be performed. This maintains the full length of the wrist and the lunate in the lunate facet of the radius. Some series have

shown better strength but less mobility with this technique, others have shown equivalent results to the PRC.⁶² The four-bone fusion does appear to be more durable for younger patients and/or those who perform heavy labor.

If the patient presents with pancarpal arthritis or motion-sparing measures have failed to alleviate pain, total wrist fusion is the final surgical option. The distal radius is fused, through the proximal and distal carpal rows to the third metacarpal, typically with a dorsal plate and screws. Multiple long-term studies have shown excellent pain relief and durability; this comes at the cost of total loss of wrist motion. This is surprisingly well tolerated in most patients, especially if the other hand/wrist is unaffected. The only activity of daily living that cannot be done with a fused wrist is personal toileting.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an inflammatory arthritis that can affect any joint in the body. Inflamed synovium causes articular cartilage breakdown with pain and decreased range of motion. The goals of hand surgery for the RA patient are relief of pain, improvement of function, slowing progression of disease, and improvement in appearance.⁶³ In addition, swelling of the joint due to the inflammation can cause laxity and even failure of the collateral ligaments supporting the joints. Recent advances in the medical care of RA have made the need for surgical care of these patients far less common than in previous decades.

MP joints of the fingers are commonly affected. The base of the proximal phalanx progressively subluxates and eventually dislocates volarly with respect to the metacarpal head. The collateral ligaments, particularly on the radial side, stretch out and cause the ulnar deviation of the fingers characteristic of the rheumatoid hand. In more advanced cases, the joint may not be salvageable (Fig. 44-17B). For these patients, implant arthroplasty is the mainstay of surgical treatment. Silicone implants have been used for over 40 years with good results.⁶⁴ The silicone implant acts as a spacer between proximal and distal bone, rather than as a true resurfacing arthroplasty. The radial collateral ligament must be repaired to appropriate length to correct the preoperative ulnar deviation of the MP joint. Extensor tendon centralization is then performed, as needed, at the end of the procedure.

For MP joint and PIP joint disease, fusion is an option. However, since RA usually affects multiple joints, fusion is typically avoided due to impaired function of adjacent joints, which would leave a severe motion deficit to the finger.

Failure of the support ligaments of the distal radioulnar joint (DRUJ) leads to the caput ulnae posture of the wrist with the ulnar head prominent dorsally. As this dorsal prominence becomes more advanced, the ulna head, denuded of its cartilage to act as a buffer, erodes into the overlying extensor tendons. Extensor tenosynovitis, followed ultimately by tendon rupture, begins ulnarly and proceeds radially. Rupture of the ECU tendon may go unnoticed due to the intact ECRL and ECRB tendons to extend the wrist. EDQ rupture may go unnoticed if a sufficiently robust EDC tendon to the small finger exists. Once the fourth compartment (EDC) tendons begin to fail, the motion deficit is unable to be ignored by the patient.

Surgical solutions must address the tendon ruptures as well as the DRUJ synovitis and instability and ulna head breakdown that led to them.⁶⁵ Excision of the ulna head removes the bony prominence. The DRUJ synovitis must also be resected.

Alternatively, the DRUJ can be fused and the ulna neck resected to create a pseudoarthrosis to allow for rotation. For both procedures, the remaining distal ulna must be stabilized. Multiple techniques have been described using portions of FCU, ECU, wrist capsule, and combinations thereof.

The ruptured extensor tendons are typically degenerated over a significant length. Primary repair is almost never possible, and the frequent occurrence of multiple tendon ruptures makes repair with graft less desirable due to the need for multiple graft donors.

Strict compliance with postoperative therapy is essential to maximizing the surgical result. Due to the chronic inflammation associated with RA, tendon and ligament repairs will be slower to achieve maximal tensile strength. Prolonged nighttime splinting, usually for months, helps prevent recurrence of extensor lag. Finally, the disease may progress over time. Reconstructions that were initially adequate may stretch out or fail over time. Medical management is the key to slowing disease progression and maximizing the durability of any surgical reconstruction.

DUPUYTREN'S CONTRACTURE

In 1614, a Swiss surgeon named Felix Plater first described contracture of multiple fingers due to palpable, cord-like structures on the volar surface of the hand and fingers. The disease state he described would ultimately come to be known as *Dupuytren's contracture*. Dupuytren's name came to be associated with the disease after he performed an open fasciotomy of a contracted cord before a class of medical students in 1831.⁶⁶

The palmar fascia consists of collagen bundles in the palm and fingers. These are primarily longitudinally oriented and reside as a layer between the overlying skin and the underlying tendons and neurovascular structures. There are also connections from this layer to the deep structures below and the skin above. Much is known about the progression of these structures from their normal state (called bands) to their contracted state (called cords), but little is known on how or why this process begins.

Increased collagen deposition leads to a palpable nodule in the palm. Over time, there is increased deposition distally into the fingers. This collagen becomes organized and linearly oriented. These collagen bundles, with the aid of myofibroblasts, contract down to form the cords, which are the hallmark of the symptomatic patient. Detail of the molecular and cell biology of Dupuytren's disease is beyond the scope of this chapter but is available in multiple hand surgery texts.⁶⁷

Most nonoperative management techniques will not delay the progression of disease. Corticosteroid injections may soften nodules and decrease the discomfort associated with them but are ineffective against cords. Splinting has similarly been shown not to retard disease progression.

Recently, several minimally invasive treatment approaches have been described for the treatment of Dupuytren's disease.⁶⁸ Disruption of the cord with a needle is an effective means of releasing contractures, particularly at the MP joint level. Long-term studies have demonstrated more rapid recovery from needle fasciotomy, as the procedure is called, but more durable results with fasciectomy.⁶⁹ Injectable clostridial collagenase was approved by the U.S. Food and Drug Administration in 2009, and although it has shown good early results, treatment costs remain high.⁷⁰

For patients with advanced disease including contractures of the digits that limit function, surgery is the mainstay of therapy. Although rate of progression should weigh heavily in the decision of whether or not to perform surgery, general guidelines are MP contractures greater than or equal to 30° and/or PIP contractures greater than or equal to 20°.⁷¹

Surgery consists of an open approach through the skin down to the involved cords. Skin is elevated off of the underlying cords. Great care must be taken to preserve as much of the subdermal vascular plexus with the elevated skin flaps to minimize postoperative skin necrosis. All nerves, tendons, and blood vessels in the operative field should be identified. Once this is done, the involved cord is resected while keeping the critical deeper structures under direct vision. The skin is then closed, with local flap transpositions as needed, to allow for full extension of the fingers that have been released (Fig. 44-18).

Alternative cord resection techniques include removal of the skin over the contracture (dermatofasciectomy). This requires a skin graft to the wound and should only be done if skin cannot be separated from the cords and local tissue cannot be rearranged with local flaps to provide closure of the wound.

Complications of surgical treatment of Dupuytren's disease occur in as many as 24% of cases.⁷² Problems include digital nerve laceration, digital artery laceration, buttonholing of the skin, hematoma, swelling, and pain, including some patients with CRPS (see earlier section on CRPS). Digital nerve injury can be quite devastating, producing annoying numbness at best or a painful neuroma in worse situations.

Hand therapy is typically instituted within a week of surgery to begin mobilization of the fingers and edema control. The therapist can also identify any early wound problems because he or she will see the patient more frequently than the surgeon. Extension hand splinting is maintained for 4 to 6 weeks, with nighttime splinting continued for an additional 6 to 8 weeks. After this point, the patient is serially followed for evidence of recurrence or extension of disease.

INFECTIONS

Trauma is the most common cause of hand infections. Other predisposing factors include diabetes, neuropathies, and immunocompromised patients. Proper treatment consists of incision and drainage of any collections followed by debridement, obtaining wound cultures, antibiotic therapy, elevation, and immobilization. *Staphylococcus* and *Streptococcus* are the offending pathogens in about 90% of hand infections. Infections caused by intravenous drug use or human bites and those associated with diabetes will often be polymicrobial, including gram-positive and gram-negative species. Heavily contaminated injuries require anaerobic coverage. Although α -hemolytic *Streptococcus* and *Staphylococcus aureus* are the most commonly encountered pathogens in human bites, *Eikenella corrodens* is isolated in up to one-third of cases and should be considered when choosing antimicrobial therapy. Ziehl-Neelsen staining and cultures at 28°C to 32°C in Lowenstein-Jensen medium must be performed if there is a suspicion for atypical mycobacteria.⁷³

Cellulitis

Cellulitis is characterized by a nonpurulent diffuse spreading of inflammation characterized by erythema, warmth, pain, swelling, and induration. Skin breakdown is a frequent cause, but

Figure 44-18. Dupuytren's disease. **A.** This patient has cords affecting the thumb, middle, ring, and small fingers. **B.** The resected specimens are shown. **C.** Postoperatively, the patient went on to heal all his incisions and, with the aid of weeks of hand therapy, recover full motion.

often no inciting factor is identified. Group A α -hemolytic *Streptococcus* is the most common offending pathogen and causes a more diffuse spread of infection. *S aureus* is the second most common offending pathogen and will cause a more localized cellulitis. The diagnosis of cellulitis is clinical. Septic arthritis, osteomyelitis, an abscess, a deep-space infection, and necrotizing fasciitis are severe infectious processes that may initially mimic cellulitis. These must be ruled out appropriately before initiating treatment, and serial exams should be conducted to ensure proper diagnosis. Treatment of cellulitis consists of elevation, splint immobilization, and antibiotics that

5► cover both *Streptococcus* and *Staphylococcus*. Intravenous antibiotics are usually initiated for patients with severe comorbidities and those who fail to improve on oral antibiotics after 24 to 48 hours. Failure to improve after 24 hours indicates a need to search for an underlying abscess or other infectious cause.⁷³

Abscess

An abscess will present much like cellulitis, but they are two clinically separate entities. The defining difference is an area of fluctuance. Skin-puncturing trauma is the most common cause. *S aureus* is the most common pathogen, followed by *Streptococcus*. Treatment consists of incision and drainage with appropriate debridement, wound cultures, wound packing, elevation, immobilization, and antibiotics. The packing should be removed in 12 to 24 hours or sooner if there is clinical concern, and warm soapy water soaks with fresh packing should be initiated. Most should be allowed to heal secondarily. Delayed primary closure should only be performed after repeat washouts for larger wounds where complete infection control has been achieved.

Collar-Button Abscess

This is a subfascial infection of a web space and is usually caused by skin trauma that becomes infected; it often occurs in

Figure 44-19. Collar-Button abscess **A.** The fingers surrounding the involved (second) web space rest in greater abduction than the other fingers. **B.** Dorsal and volar drainage incisions are made, separated by a bridge of intact web skin; a Penrose drain prevents the skin from closing too early.

laborers. The adherence of the palmar web space skin to the palmar fascia prevents lateral spread, so the infection courses dorsally, resulting in both palmar web space tenderness and dorsal web space swelling and tenderness. The adjacent fingers will be held in abduction with pain on adduction (Fig. 44-19). Incision and drainage, often using separate volar and dorsal incisions, is mandatory, and follows the same treatment as for any abscess or deep-space infection.

Osteomyelitis

Osteomyelitis in the hand usually occurs due to an open fracture with significant soft tissue injury. The presence of infected hardware, peripheral vascular disease, diabetes, and alcohol or drug abuse are also predisposing factors. Presentation includes persistent or recurrent swelling with pain, erythema, and possible drainage. It will take 2 to 3 weeks for periosteal reaction and osteopenia to be detected on radiographs. Bone scans and MRI

are useful modalities to aid in diagnosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) have low specificity but are useful for monitoring the progress of treatment, with CRP being more reliable. Treatment consists of antibiotics alone in the early stage as long as there is favorable response. All necrotic bone and soft tissue, if present, must be debrided. Initial intravenous antibiotic therapy should cover *S aureus*, the most common pathogen, and should then be adjusted according to bone cultures. Antibiotic therapy is continued for 4 to 6 weeks once the patient clinically improves and there is no further need for debridement. For osteomyelitis in the setting of an acute fracture with internal fixation in place, the hardware should be left in place as long as it is stable and the fracture has not yet healed. If the hardware is unstable, it must be replaced. An external fixation device may be useful in this setting. If osteomyelitis occurs in a healed fracture, all hardware and necrotic bone and soft tissue must be removed.⁷⁴

Pyogenic Arthritis

Infection of a joint will progress quickly to severe cartilage and bony destruction if not addressed quickly. Direct trauma and local spread of an infection are the most common causes. Hematogenous spread occurs most commonly in patients who are immunocompromised. *S aureus* is the most common pathogen, followed by *Streptococcus* species. *Neisseria gonorrhoeae* is the most common cause of atraumatic septic arthritis in an adult less than 30 years of age. Presentation includes exacerbation of pain with any joint movement, severe pain on axial load, swelling, erythema, and tenderness. Radiographs may show a foreign body or fracture, with widened joint space early in the process and decreased joint space late in the process due to destruction. Joint aspiration with cell count, Gram stain, and culture is used to secure the diagnosis. Treatment of nongonococcal septic arthritis includes open arthrotomy, irrigation, debridement, and packing the joint or leaving a drain in place. Intravenous antibiotics are continued until there is clinical improvement, followed by 2 to 4 weeks of additional oral or intravenous antibiotics. Gonococcal septic arthritis is usually treated nonoperatively. Intravenous ceftriaxone is first-line therapy. Joint aspiration may be used to obtain cultures and decrease joint pressure.⁷⁵

Necrotizing Infections

Necrotizing soft tissue infections occur when the immune system is unable to contain an infection, leading to extensive spread with death of all involved tissues. This is different from an abscess, which forms when a functioning immune system is able to “wall off” the infectious focus. Necrotizing infections can result in loss of limb or life, even with prompt medical care.

Bacteria spread along the fascial layer, resulting in the death of soft tissues, which is in part due to the extensive blood vessel thrombosis that occurs. An inciting event is not always identified. Immunocompromised patients and those who abuse drugs or alcohol are at greater risk, with intravenous drug users having the highest increased risk. The infection can be mono- or polymicrobial, with group A β -hemolytic *Streptococcus* being the most common pathogen, followed by α -hemolytic *Streptococcus*, *S aureus*, and anaerobes. Prompt clinical diagnosis and treatment are the most important factors for salvaging limbs and saving life. Patients will present with pain out of proportion with findings. Appearance of skin may range from normal to erythematous or maroon with edema, induration, and blistering. Crepitus may occur if a gas-forming organism

is involved. “Dirty dishwasher fluid” may be encountered as a scant grayish fluid, but often there is little to no discharge. There may be no appreciable leukocytosis. The infection can progress rapidly and can lead to septic shock and disseminated intravascular coagulation. Radiographs may reveal gas formation, but they must not delay emergent debridement once the diagnosis is suspected. Intravenous antibiotics should be started immediately to cover gram-positive, gram-negative, and anaerobic bacteria. Patients will require multiple debridements, and the spread of infection is normally wider than expected based on initial assessment.⁷³

Necrotizing myositis, or myonecrosis, is usually caused by *Clostridium perfringens* due to heavily contaminated wounds. Unlike necrotizing fasciitis, muscle is universally involved and found to be necrotic. Treatment includes emergent debridement of all necrotic tissue along with empirical intravenous antibiotics.

Wet gangrene is most common in diabetics with renal failure and an arteriovenous shunt. It is usually polymicrobial. Patients will present with a necrotic digit that is purulent and very malodorous, with rapidly evolving pain, swelling, skin discoloration, and systemic collapse. Emergent treatment is the same as for other necrotizing infections, and amputation of the involved digit or extremity must often be performed.

Infectious Flexor Tenosynovitis

Flexor tenosynovitis (FTS) is a severe pathophysiologic state causing disruption of normal flexor tendon function in the hand. A variety of etiologies are responsible for this process. Most acute cases of FTS are due to purulent infection. FTS also can occur secondary to chronic inflammation as a result of diabetes, RA, crystalline deposition, overuse syndromes, amyloidosis, psoriatic arthritis, systemic lupus erythematosus, and sarcoidosis.

The primary mechanism of infectious FTS usually is penetrating trauma. Most infections are caused by skin flora, including both *Staphylococcus* and *Streptococcus* species. Bacteria involved vary by etiology of the infection: bite wounds (*Pasteurella multocida*—cat, *E corrodens*—human); diabetic patients (*Bacteroides*, *Fusobacterium*, *Haemophilus* species, gram-negative organisms); hematogenous spread (*Mycobacterium tuberculosis*, *N gonorrhoeae*); or water-related punctures (*Vibrio vulnificus*, *Mycobacterium marinum*). Infection in any of the fingers may spread proximally into the wrist, carpal tunnel, and forearm, also known as *Parona’s space*.⁷⁶

Suppurative FTS has the ability to rapidly destroy a finger’s functional capacity and is considered a surgical emergency. Suppurative FTS results from bacteria multiplying in the closed space of the flexor tendon sheath and culture-rich synovial fluid medium causing migration of inflammatory cells and subsequent swelling. The inflammatory reaction within the closed tendon sheath quickly erodes the paratenon, leading to adhesions and scarring, as well as increase in pressures within the tendon sheath that may lead to ischemia. The ultimate consequences are tendon necrosis, disruption of the tendon sheath, and digital contracture.

Patients with infectious FTS present with pain, redness, and fever (Fig. 44-20). Physical examination reveals Kanavel’s “cardinal” signs of flexor tendon sheath infection: finger held in slight flexion, fusiform swelling, tenderness along the flexor tendon sheath, and pain over the flexor sheath with passive extension of the digit.⁷⁷ Kanavel’s signs may be absent in patients who are immunocompromised, have early manifestations of

A

B

C

infection, have recently received antibiotics, or have a chronic, indolent infection.

If a patient presents with suspected infectious FTS, empiric intravenous antibiotics should be initiated. Prompt medical therapy in early cases may prevent the need for surgical drainage. For healthy individuals, empiric antibiotic therapy should cover *Staphylococcus* and *Streptococcus*. For immunocompromised patients (including diabetics) or infections associated with bite wounds, empiric treatment should include coverage of gram-negative organisms as well.⁷⁸

Adjuncts to antibiotics include splint immobilization (intrinsic plus position preferred) and elevation until infection is under control. Hand rehabilitation (i.e., range-of-motion exercises and edema control) should be initiated once pain and inflammation are under control.

If medical treatment alone is attempted, then initial inpatient observation is indicated. Surgical intervention is necessary if no obvious improvement has occurred within 12 to 24 hours.

Several surgical approaches can be used to drain infectious FTS. The method used is based on the extent of the infection. Michon developed a classification scheme that can be useful in guiding surgical treatment (Table 44-1).⁷⁹ Figure 44-20 (B and C) demonstrates drainage of a stage II FTS. A Brunner incision allows better initial exposure but may yield difficulties with tendon coverage if skin necrosis occurs. A 16-gauge catheter or 5-French pediatric feeding tube then is inserted into the tendon sheath through the proximal incision. The sheath is copiously irrigated with normal saline. Avoid excessive fluid extravasation into the soft tissue because the resulting increase in tissue pressure can lead to necrosis of the digit. The catheter is removed after irrigation. The incisions are left open. Some surgeons prefer a continuous irrigation technique for a period of 24 to 48 hours. The catheter is sewn in place, and a small drain is placed at the distal incision site. Continuous or intermittent irrigation every 2 to 4 hours with sterile saline can then be performed through the indwelling catheter.

After surgery, an intrinsic plus splint is applied, the hand is elevated, and the appropriate empiric antibiotic coverage is instituted while awaiting culture results. The hand is reexamined the following day. Whirlpool therapy and range of motion are begun. Drains are removed before discharge from the hospital. The wounds are left open to heal by secondary intention. In severe cases, repeat irrigation and operative debridement may be required.

Table 44-1

Michon's stages of suppurative flexor tenosynovitis and appropriate treatment

STAGE	FINDINGS	TREATMENT
I	Increased fluid in sheath, mainly a serous exudate	Catheter irrigation
II	Purulent fluid, granulomatous synovium	Minimal invasive drainage ± indwelling catheter irrigation
III	Necrosis of the tendon, pulleys, or tendon sheath	Extensive open debridement and possible amputation

Antibiotic therapy is guided by culture results as well as clinical improvement. Once there is no further need for debridement, a 7- to 14-day course of oral antibiotics is generally prescribed. Consultation with an infectious disease specialist should be considered early in order to maximize efficiency and efficacy of therapy.

Felon

A felon is a subcutaneous abscess of the fingertip and is most commonly caused by penetrating trauma. *S aureus* is the most common pathogen. The fingertip contains multiple septa connecting the distal phalanx to the skin. These septa are poorly compliant, and presence of an abscess will increase pressure and lead to severe pain and tissue death. Patients will experience erythema, swelling, and tenderness of the volar digital pad. Oral antibiotics may resolve the infection if diagnosed very early, but incision and drainage is indicated when fluctuance is identified. A digital block should be performed, followed by a longitudinal incision over the point of maximal fluctuance (Fig. 44-21). Transverse and lateral incisions should be avoided, and the incision should never extend across the distal phalangeal joint crease. Deep incision should not be performed as this may cause seeding of bacteria into the flexor tendon sheath. The wound is irrigated and packed, with warm soapy water soaks and packing changes initiated within 24 hours and performed two to three times daily until secondarily healed. Antibiotic coverage should cover for *Staphylococcus* and *Streptococcus* species.⁷³

Paronychia

Paronychia is an infection beneath the nail fold. The nail plate can be viewed as an invagination into the dorsal skin extending down to the distal phalanx periosteum. Predisposing factors include anything that causes nail trauma, such as manicures, artificial nails, or nail biting. The infection may spread around

Figure 44-21. Felon. **A.** Lateral view of the digit showing fluctuance between the skin of the pad and the underlying distal phalanx bone. **B.** The authors prefer to drain felons with a longitudinal incision (dashed line) directly over the area of maximal fluctuance.

Figure 44-22. Paronychia. **A.** Fluctuance in the nail fold is the hallmark of this infection. **B.** The authors prefer to drain a paronychia using the bevel of an 18-gauge needle inserted between the nail fold and the nail plate at the location of maximal fluctuance.

the nail plate from one side to the other, or it may extend into the pulp and result in a felon. An acute paronychia is usually caused by *S aureus* or *Streptococcal* species. Patients report pain, erythema, swelling, and possibly purulent drainage involving the periungual tissue. Treatment consists of warm water soaks and oral antibiotics if diagnosed early. If purulence or fluctuance is present, then a freer elevator or 18-gauge needle can be passed along the involved nail fold to decompress the collection (Fig. 44-22). If the infection involves the eponychial fold, a

small proximally based flap of eponychium is created by using a scalpel, followed by irrigation and packing. The nail plate must be removed if the infection extends beneath the nail plate. Packing is kept in place for 24 to 48 hours, followed by warm water soaks and local wound care. Usually, the wound cannot be repacked once the dressing is removed.⁷³

A chronic paronychia is most commonly caused by *Candida* species and is most often found in patients who perform jobs involving the submersion of their hands in water or other moist environments. These develop into thickened nails with callus-like formation along the nail folds and may occasionally become red and inflamed. They do not respond to antibiotic treatment, and nail plate removal with marsupialization of the skin proximal to the eponychial fold will allow the wound to heal secondarily. The environmental factors leading to the chronic paronychia must also be corrected in order for treatment to be successful.

All hand infections other than cellulitis will require surgical management. Clinical examination, particularly noting the area of greatest tenderness and/or inflammation, is the single most useful diagnostic tool to localize any purulence requiring drainage. Specific recommendations for differentiating among the possible locations of hand infection are included in the diagnostic algorithm shown in Fig. 44-23.

TUMORS

Tumors of the hand and upper extremity can be classified as benign soft tissue tumors; malignant soft tissue tumors (subclassified into cutaneous and noncutaneous malignancies); benign bony tumors; malignant bony tumors; and secondary metastatic tumors. Initial investigation for any mass starts with a complete

Figure 44-23. Diagnostic algorithm. Diagnostic workup for a patient with hand inflammation to evaluate for infection. See text for details about particular infectious diagnoses. Abx = antibiotics; FTS = flexor tenosynovitis; IF MC = index finger metacarpal; MRI = magnetic resonance imaging; SF MC = small finger metacarpal.

history and physical exam. Hand and/or wrist X-rays should be obtained in every patient presenting with a mass unless clearly not indicated (e.g., a superficial skin lesion with no aggressive/malignant features). The workup proceeds in an orderly fashion until a diagnosis is obtained. Once a benign diagnosis is secured (by strong clinical suspicion in an experienced hand surgeon, radiographic evidence, or tissue biopsy), further workup is not needed; this may occur at any point in the workup of a mass.

Most hand masses are benign and can be readily diagnosed without advanced imaging or tissue biopsy. When necessary, additional workup may include baseline laboratory studies, CT and/or MRI of the involved region, and a bone scan or positron emission tomography (PET) scan. Staging of a malignant tumor may occur before biopsy if a malignancy is strongly suspected, or it may occur after formal biopsy. Staging includes a chest X-ray and CT with intravenous contrast of the chest, abdomen, and pelvis to detect possible metastasis. Biopsy of the mass is always the last step of a workup and should occur only after all other available information has been gathered. Any mass that is over 5 cm in size, is rapidly increasing in size (as judged by an experienced surgeon or oncologist), is symptomatic or painful, or has an aggressive clinical or radiographic appearance warrants workup and biopsy to rule out malignancy.

CT scans are useful for detecting bony tumor extension across planes and identifying tumors of small bones, such as the carpal bones. MRI is useful for evaluating soft tissue tumor involvement (e.g., which muscle compartments are involved) as well as intramedullary lesions. Most soft tissue tumors will appear dark on T1-weighted images and bright on T2-weighted images. Hematomas, hemangiomas, lipomas, liposarcomas, and adipose tissue will appear bright on T1-weighted images and dark on T2-weighted images. Scintigraphy uses methylene diphosphonate attached to technetium-99m. This complex will attach to hydroxyapatite. Immediate uptake is seen in areas of increased vascularity, such as infection, trauma, and neoplasia. Increased uptake 2 to 3 hours later is seen in “pooled” areas where new bone formation has occurred. This modality is useful for detecting areas of tumor invasion or metastases not otherwise seen on prior CT, MRI, or radiographs.

Biopsy is reserved for masses that cannot be diagnosed as benign based on prior clinical and radiographic exams. Needle biopsy is not reliable for primary diagnosis, but it can be useful for recurrent or metastatic disease. Open excisional (if mass is less than 5 cm in size) or incisional (if mass is greater than 5 cm in size) biopsy is the most common biopsy method. Proper surgical oncologic technique is strictly adhered to in order to prevent tumor spread into uninvolved tissues or compartments. This includes making all incisions longitudinally using sharp dissection and meticulous hemostasis; carrying the incision directly down to the tumor with no development of tissue planes (i.e., making a straight-line path from skin to tumor); incising through the fewest number of muscle compartments; and avoiding critical neurovascular structures. The CT or MRI images will help determine the best surgical approach for biopsy or resection in order to avoid uninvolved compartments and critical structures.⁸⁰

Benign Soft Tissue Tumors

Ganglion Cyst. This is the most common soft tissue tumor of the hand and wrist, comprising 50% to 70% of all soft tissue tumors in this region. They can occur at any age but are most common in the second to fourth decades with a slight

predilection toward females. Patients may report a slow-growing soft mass that may fluctuate in size and can sometimes be associated with mild pain. Compressive neuropathies may be seen if they occur in Guyon’s canal or the carpal tunnel, but they are uncommon. There are no reports of malignant degeneration. History and physical exam are usually sufficient to establish a diagnosis. Occurrence by location is as follows: 60% to 70% occur on the dorsal wrist between the third and fourth extensor compartments and are connected by a stalk to the scapholunate ligament (Fig. 44-24); 18% to 20% occur on the volar wrist; and 10% to 12% occur in the digits as volar retinacular or flexor tendon sheath cysts. The cyst transilluminates. There is always a stalk that communicates with the underlying joint or tendon sheath. The cyst wall is composed of compressed collagen fibers with no epithelial or synovial cells present. Clear viscous mucin fills the cyst and is composed of glucosamine, albumin, globulin, and hyaluronic acid. The etiology is unclear. The most accepted theory currently is Angelides’ who proposed that repeated stress of a joint, ligament, or tendon sheath causes an increase of mucin-producing cells and subsequent mucin production. The increased mucin production dissects superficially and coalesces into a cyst. The successful treatment of dorsal ganglion cysts by excising only the stalk supports this theory.⁸⁰

Treatment consists of observation if asymptomatic. If symptoms exist or the patient desires removal for cosmetic appearance, aspiration of the cyst may be performed with a

Figure 44-24. Dorsal wrist ganglion cyst. These typically occur between the third and fourth dorsal extensor compartments and have a stalk connecting the base of the cyst to the scapholunate ligament.

successful cure rate ranging from 15% to 89%. The benefit of injected steroids is inconclusive. Aspiration of a volar wrist ganglion cyst can be dangerous due to the potential of injuring neurovascular structures. Open excision and arthroscopic excision of the cyst stalk are surgical options for cysts that are not amendable to aspiration. A recent meta-analysis reported recurrence rates after either needle aspiration, open excision, and arthroscopic excision as 59%, 21%, and 6%, respectively.⁸¹

Mucous Cyst. A mucous cyst is a ganglion cyst of the DIP joint. They occur most commonly in the fifth to seventh decades, and the underlying cause is associated osteoarthritis of the DIP joint. They are slow growing and usually occur on one side of the terminal extensor tendon between the DIP joint and the eponychium. The earliest clinical sign is often longitudinal grooving of the involved nail plate followed by a small enlarging mass and then attenuation of overlying skin. X-rays will show signs of osteoarthritis within the DIP joint. Heberden nodes (osteophytes within the DIP joint) are often seen on X-ray.

Possible treatment includes observation, aspiration, or excision. If the cyst is not draining and the overlying skin is intact, the patient may be offered reassurance. A draining cyst poses risk of DIP joint infection due to the tract communicating with the DIP joint and should be excised. If the cyst is symptomatic, painful, or the patient desires removal for cosmetic purposes, excision should be performed. Any osteophytes in the DIP joint must be removed to reduce recurrence. Aspiration is an option for treatment, but this poses the risk of DIP joint infection through seeding of bacteria into the joint or by the development of a draining sinus tract. It is generally not performed.

Giant Cell Tumor of the Tendon Sheath. Also known as a xanthosarcoma, fibrous xanthoma, localized nodular synovitis, sclerosing hemangioma, or pigmented villonodular tenosynovitis, giant cell tumor of the tendon sheath is the second most common soft tissue mass of the hand and wrist. It is a benign lesion with no clear pathogenesis. The tumor is a growth of polyclonal cells with no risk of malignant transformation. Despite the similarity in name, it is not histopathologically related to giant cell tumor of the bone.⁸²

Giant cell tumor of the tendon sheath occurs as a firm slow-growing painless mass over months to years and will often feel bumpy or nodular, which is a distinguishing characteristic helpful for diagnosis. It has a predilection for occurring in close proximity to joints along flexor surfaces of the wrist, hands, and digits (especially the PIP joints of the radial digits) and occurs most commonly between the second and fifth decades (Fig. 44-25A). These tumors do not transilluminate. Direct extension into joints and ligaments can make complete excision difficult. Gross appearance of the tumor will show a well-circumscribed nodular firm mass with a deep brown color due to the large amount of hemosiderin content, which is easily detected on histologic staining (Fig. 44-25B). Multinucleated giant cells and hemosiderin-laden macrophages are characteristic.⁸⁰

This tumor is not visible on radiographs. Approximately 20% will show extrinsic cortical erosion on X-ray. This is a risk factor for recurrence, and removal of the cortical shell should be considered. MRI is useful for delineating involvement with tendons, ligaments, and joints.

The standard treatment is marginal excision. These tumors will often grow next to or around neurovascular bundles, and an Allen's test should always be performed preoperatively to confirm adequate blood supply by both ulnar and radial arteries as

A

B

Figure 44-25. Giant cell tumor of tendon sheath. **A.** The mass produces lobulated enlargement of the external finger. **B.** The excised giant cell tumor has a multilobulated, tan-brown appearance.

well as dual blood supply to an involved digit via the ulnar and radial proper digital arteries. It is important to completely excise the stalk because this will greatly reduce tumor recurrence even in the setting of residual tumor. If tumor is suspected to have extended into the joint, the joint must be opened and all tumor removed. Despite this being a benign lesion, local recurrence is varies widely from 4% to 44%. Some variants can mimic more aggressive processes, and malignancy must be considered if aggressive features are identified, such as direct bony invasion.⁸²

Lipoma. Lipomas of the hand and wrist may occur in multiple anatomic locations, including subcutaneous tissues; intramuscularly (especially thenar or hypothenar muscles); deep spaces; carpal tunnel or Guyon's canal; and rarely bone or nerve. They typically present as a painless, slow-growing, soft, and mobile mass over a period of months to years. Painful findings suggest close approximation to a neurovascular structure or, less commonly, a malignant lesion such as liposarcoma. Lipomas do not transilluminate. They resemble mature fat histologically. X-rays typically reveal no abnormality. MRI is a helpful imaging modality to evaluate a lipoma and will show signal characteristics that are suggestive of adipose tissue.⁸⁰

Asymptomatic lesions with no aggressive findings may be observed. Marginal excision is recommended for symptomatic, painful, or enlarging lipomas or those that cause dysfunction. MRI is recommended for deep lipomas to evaluate proximity or involvement of critical structures, followed by marginal excision if MRI findings are consistent with a lipoma. If MRI findings are not consistent with a lipoma, incisional biopsy is warranted. Recurrence after marginal excision is rare.⁸⁰

Figure 44-26. Schwannomas grow as a firm, round, well-encapsulated mass within the epineurium of a peripheral nerve. Schwannomas are able to be separated from the nerve fascicles relatively easily because they do not infiltrate between them (unlike neurofibromas).

Schwannoma. A schwannoma, also known as a neurilemmoma, is a type of benign peripheral nerve sheath tumor. It is the most common benign peripheral nerve sheath tumor of the upper extremity.⁸³ The majority occur as single solitary masses. Patients with neurofibromatosis type 1 (NF1) or 2 (NF2) may develop multiple schwannomas involving large peripheral nerve trunks or bilateral acoustic schwannomas, respectively. These tumors arise from the Schwann cell and occur most often in the middle decades of life. They grow as painless, slow-growing, firm, round, well-encapsulated masses with a predilection toward flexor surfaces of the forearm and palm (given their presence of large nerves). Schwannomas grow from the peripheral nerve sheath and are usually connected by a pedicled stalk. The tumor is well demarcated and can be readily separated from the nerve fascicles (Fig. 44-26). Unlike neurofibromas, they do not grow within the nerve. Paresthesias or other neurologic findings may occur, but they are usually absent, as is the Tinel's sign. Findings such as pain, paresthesias, or numbness should raise concern for a tumor causing a compressive neuropathy or a tumor that is malignant.⁸³

Histologic exam reveals Antoni type A palisades of spindle cells with large oval nuclei with interlacing fascicles. Less cellular regions appear as Antoni type B areas. Mutations of the *schwannomin* gene on chromosome 22 are found in 50% of sporadic cases and 100% of acoustic schwannomas in patients with NF2.⁸⁴

Surgical treatment is reserved for symptomatic tumors and those that require biopsy to rule out a malignant process. An MRI should be obtained prior to surgery to confirm that the tumor is not located within the nerve (i.e., a neurofibroma) and that it is consistent with a schwannoma. Operative treatment involves excisional biopsy. If the tumor is adherent to adjacent soft tissue or not encapsulated, incisional biopsy is performed and excision is delayed pending pathology results. Malignant degeneration is exceedingly rare.⁸³

Malignant Soft Tissue Tumors—Cutaneous

Squamous Cell Carcinoma. Squamous cell carcinoma (SCC) is the most common primary malignant tumor of the hand, accounting for 75% to 90% of all malignancies of the hand.

Eleven percent of all cutaneous SCC occurs in the hand.⁸⁵ It is the most common malignancy of the nail bed. Risk factors include sun exposure, radiation exposure, chronic ulcers, immunosuppression, xeroderma pigmentosa, and actinic keratosis. Marjolin's ulcers represent malignant degeneration of old burn or traumatic wounds into an SCC and are a more aggressive type. Transplant patients on immunosuppression have a fourfold increased risk, and patients with xeroderma pigmentosa have a 65 to 200-fold increased risk of developing an SCC.⁸⁶ They often develop as small, firm nodules or plaques with indistinct margins and surface irregularities ranging from smooth to verruciform or ulcerated (Fig. 44-27). They are locally invasive, with 2% to 5% lymph node involvement. Metastasis rates of up to 20% have been reported in radiation or burn wounds. Standard treatment is excision with 0.5- to 1.0-cm margins. Other treatment options include curettage and electrodesiccation, cryotherapy, and radiotherapy.⁸⁵

Basal Cell Carcinoma. Basal cell carcinoma (BCC) is the second most common primary malignancy of the hand, accounting for 3% to 12%; 2% to 3% of all BCCs occur on the hand. Risk factors are similar for SCC and include chronic sun exposure, light complexion, immunosuppression, inorganic arsenic exposure, and Gorlin's syndrome. Presentation includes a small, well-defined nodule with a translucent, pearly border and overlying telangiectasias (Fig. 44-28). Metastasis is very rare. Standard treatment is excision with 5-mm margins. Other treatment options include curettage and electrodesiccation, cryotherapy, and radiotherapy.

Melanoma. Melanoma accounts for approximately 4% of skin cancers and is responsible of 80% of all deaths from skin cancer. Approximately 2% of all cutaneous melanomas occur in the hand.⁸⁷ Risk factors include sun exposure (especially blistering sunburns as a child), dysplastic nevi, light complexion, family history of melanoma, immunosuppression, and congenital

Figure 44-27. Squamous cell carcinoma involving the nail fold and nail bed. Note the wart-like and ulcerated appearance.

Figure 44-28. Basal cell carcinoma of the dorsal hand with surrounding telangiectasia.

nevi. Pigmented lesions with irregular borders, color changes, increase in growth, or change in shape are suggestive of melanoma. Breslow thickness is the most important factor in predicting survival for a primary melanoma. Melanoma in situ lesions should be surgically excised with 0.5 cm margins. For lesions up to 1 mm in thickness, 1-cm margins should be used. Two centimeter margins should be used for lesions over 1 mm in thickness.⁸⁸ Sentinel lymph node biopsy is done for lesions over 1 mm in thickness or for any lesion that is over 0.76 mm in thickness and exhibits ulceration or high mitotic rate.⁸⁹ Any clinically palpable lymph node requires a formal lymph node dissection of the involved basin, as do sentinel lymph nodes positive for melanoma. Lymph node dissection has not been shown to offer any long-term survival benefit, but the information gained from sentinel lymph node biopsy (or lymph node dissection) does offer valuable staging information that is important for prognosis. For cases of subungual melanomas, DIP amputation is the current standard of care. A recent study reported similar recurrence and survival rates when comparing patients treated with either DIP amputations or wide local excision; however, there was insufficient evidence to conclude if one treatment was superior to another.⁹⁰

Malignant Soft Tissue Tumors—Noncutaneous

Primary soft tissue sarcomas of the upper extremity are very rare. Approximately 12,000 new cases of sarcomas are diagnosed each year and of those, only 15% occur in upper extremity.⁸⁰ Statistical inference is limited due to the rare occurrence of these tumors, but mortality rate is very high despite the aggressive treatments. Fewer than 5% of soft tissue sarcomas of the upper extremity will develop lymph node metastasis. Cutaneous malignancies must be considered in the differential

diagnosis for any patient with palpable lymph nodes in the setting of any upper extremity mass. Any lesion of the upper extremity that is over 5 cm in diameter, rapidly enlarges, or is painful should be considered malignant until proven otherwise.⁹¹

Treatment for soft tissue sarcomas can range from palliative debulking to attempted curative resection. Many muscles of the upper extremity and their compartments cross joints (e.g., forearm flexors). Any malignancy within a compartment mandates complete resection of that compartment, and therefore, amputations must often be performed at levels much more proximal than the level of the actual tumor. Many soft tissue sarcomas are not responsive to radiation or chemotherapy, and use of these adjuvant treatments must be decided upon after discussion with medical and radiation oncologists in a multidisciplinary team. Several studies have shown higher mortality rates in patients who undergo initial tumor biopsy of sarcomas at institutions from which they do not ultimately receive treatment. These studies recommend biopsy be performed at the institution at which definitive treatment will be provided.⁹² Institutions best suited for such treatment should have pathologists familiar with soft tissue sarcomas, medical and radiation oncologists, surgical oncologists, and a multidisciplinary tumor board.

An in-depth review of each type of soft tissue sarcoma is beyond the scope of this chapter. Epithelioid sarcoma is the most common primary soft tissue sarcoma of the upper extremity and usually presents as a benign-like slow-growing mass during the third or fourth decades. It has a propensity for the forearm, palm, and digits. Spread to lymph nodes has been reported. It typically spreads along fascial planes.⁸⁰ Synovial sarcoma is argued by some to be the most common primary soft tissue sarcoma of the hand and wrist, but the paucity of case reports is inconclusive. It is a high-grade malignancy that is painless and slow-growing and usually occurs adjacent to, but not involving, joints. It is most common in the second to fifth decades of life. Tumor size (greater than 5 cm) is positively correlated with mortality. Other sarcomas include malignant fibrous histiocytoma, liposarcoma, fibrosarcoma, dermatofibrosarcoma protuberans, and malignant peripheral nerve sheath tumors, and more information can be found in further selected reading.⁹³ The majority of metastases to the hand involve secondary bone tumors and are discussed later in the section, “Secondary Metastatic Tumors.”

Benign Bone Tumors

Primary benign bone tumors of the hand and wrist make up a total of 7% of all primary benign bone tumors in the body. Benign tumors of cartilage origin comprise 79% of all primary benign bone tumors of the hand and wrist.⁹⁴

Enchondroma. This is the most common primary benign bone tumor of the hand and wrist and is of cartilage origin. Up to 90% of all bone tumors in the hand and wrist are enchondromas, with 35% to 54% of all enchondromas occurring in the hand and wrist. They are often found incidentally on X-rays taken for other reasons (e.g., hand trauma). They are usually solitary and favor the diaphysis of small tubular bones and are most common in the second and third decades of life. The most common location is in the proximal phalanges, followed by the metacarpals and then middle phalanges. Enchondroma has never been reported in the trapezoid. Presentation is usually asymptomatic, but pain may occur if there is a pathologic fracture or impending fracture. The etiology is believed to be from a fragment of cartilage from the central physis. Histology shows well-differentiated hyaline cartilage with lamellar bone and calcification.⁹⁴

Two variants of enchondroma include Ollier's disease (multiple enchondromatosis) and Maffucci's syndrome (multiple enchondromatosis associated with multiple soft tissue hemangiomas). Malignant transformation is very rare in the solitary form, but there is a 25% incidence by age 40 in Ollier's patients and a 100% life-time incidence in Maffucci's patients. When malignant transformation does occur, it is almost uniformly a chondrosarcoma with pain and rapid growth.⁹⁵

Diagnosis is usually made based on history, physical exam, and X-rays. There is a well-defined, multilobulated central lucency in the metaphysis or diaphysis that can expand causing cortical thinning or, sometimes, thickening (Fig. 44-29A). Further imaging is seldom needed, but a CT would be the study of choice.

Observation is indicated for asymptomatic enchondromas with no risk of impending fracture, followed by annual X-rays for 2 years. If a pathologic fracture is found, it is treated with immobilization until fracture union and then surgically treated. If there is any uncertainty as to whether it is an enchondroma, incisional biopsy is indicated, and definitive treatment is

postponed pending final pathology. Symptomatic lesions and those with impending fracture are treated surgically. Surgical treatment consists of an open incisional biopsy and confirmation by frozen section that it is well-differentiated hyaline cartilage. Curettage and high-speed burring are used to ablate the tumor. Intraoperative fluoroscopy is used to confirm complete ablation (Fig. 44-29B). The defect is then packed with bone graft or bone substitute. Recurrence ranges from 2% to 15%. X-rays should be obtained serially after surgery.⁹⁴

Periosteal Chondroma. Periosteal chondromas are benign bone tumors of cartilage origin that arise most commonly within or adjacent to periosteum at the metaphyseal-diaphyseal junction in phalanges. They occur usually in the second or third decade as solitary lesions with pain, swelling, deformity, and possible pathologic fracture. X-rays reveal a subperiosteal lytic, unilobular lesion with erosion into adjacent cortex. There is often a rim of sclerosis. Histologically, they appear as aggressive cartilage with atypia, and it can be difficult to differentiate these from chondrosarcomas.⁹⁴

Diagnosis involves X-rays with incisional biopsy to confirm the benign diagnosis and avoid unnecessary amputation. Treatment includes en bloc resection of periosteum and corticocancellous bone. Recurrence is less than 4%.

Osteoid Osteoma. This is a tumor of bone origin. Approximately 5% to 15% of all osteoid osteomas occur in the hand and wrist and are most often found in the proximal phalanx or carpus. They usually occur in the second or third decade and present with a deep, dull ache that is classically worse at night and relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). X-rays reveal a central lucency that is usually less than 1 cm in diameter surrounded by reactive sclerosis. Bone scan or CT is helpful to secure the diagnosis.⁹⁶

Treatment consists of NSAID therapy only, and resolution occurs at an average of 33 months. If the patient does not wish to undergo prolonged discomfort with conservative therapy, curettage or percutaneous ablation of the nucleus may be performed.⁹⁶

Giant Cell Tumor of Bone. Giant cell tumors of bone make up only 4% to 5% of all benign bone tumors in the body, and only 12% of these occur in the hand or wrist. Although its name is similar to that of "giant cell tumor of tendon sheath," they are two separate tumors and do not share the same clinical or histopathologic characteristics. Approximately 2% occur in the hand and 10% occur in the distal radius; those within the distal radius are more aggressive. They usually occur in the fourth decade with pain and swelling and possibly pathologic fracture.⁹⁷

Giant cell tumor of the bone is unique in that it is benign on histology but does have metastatic potential and can cause death. It should be considered a low-grade malignancy.⁹⁷ Workup includes a CT of the chest and total-body scintigraphy to evaluate for metastases and multifocal lesions and MRI to evaluate the extent of local tissue involvement. The recommended treatment consists of surgical resection of the involved phalanges or metacarpals and wide excision of entire carpal rows. Treatment with curettage and adjuvant treatments only results in a high rate of recurrence. Local and systemic surveillance must be done for at least 10 years because metastasis has been reported to occur as late as 10 years postoperatively.^{97,98}

Malignant Bone Tumors

Malignant primary and secondary bone tumors of the hand, like soft tissue malignancies, are exceedingly rare. An in-depth

A

B

Figure 44-29. Enchondroma. **A.** X-ray of the phalanx demonstrates a well-defined central lucency. Surrounding cortex may thin or thicken. Thinning of the cortex contributes to risk of pathologic fracture. **B.** Intraoperative fluoroscopy after curettage of the tumor. A radiopaque ribbon is used to occupy the defect to help ensure that there is no tumor (similarly radiolucent to the defect after curettage) left behind prior to bone grafting.

review is beyond the scope of this chapter. The same principles for soft tissue sarcomas of the upper extremity apply here with regard to evaluation, biopsy, and treatment.

Chondrosarcoma comprises 41% of all primary malignant bone tumors of the hand and wrist but only 1.5% of all chondrosarcomas overall. It is most likely to occur from malignant degeneration from a preexisting lesion, with enchondromatosis and osteochondromatosis being the most common. It usually presents as a slow-growing, painless mass in the fourth to sixth decades and can be difficult to differentiate from its benign counterparts. X-ray reveals endosteal erosion, cortical expansion, cortical destruction, and calcification. Metastasis has never been reported for chondrosarcomas of the hand. Chondrosarcomas are not responsive to chemotherapy or radiation.⁹⁹

Osteosarcoma of the hand is exceedingly rare; only 0.18% of osteosarcomas occur in the hand. It usually presents as a painful swelling with pathologic fracture in the fifth to eighth decades of life. Radiation exposure is believed to be a possible risk factor. X-ray findings vary widely, with 90% of tumors occurring at a metaphyseal location. Findings include an osteoblastic or osteolytic lesion, cortical breakthrough with soft tissue extension, a “sunburst” pattern radially, or periosteal elevation (Codman’s triangle). The presence or absence of metastasis is the most important prognostic factor, with a 5-year survival of 70% in the absence of metastases and a 5-year survival of 10% if present. Preoperative chemotherapy is usually given, but radiation therapy plays no role.¹⁰⁰

Secondary Metastatic Tumors

Metastases to the hand or wrist are rare, with only 0.1% of skeletal metastases occurring in the hand. The majority of metastases to the hand are bone lesions, but soft tissue metastases have been reported. The most common primary site is the lung (40%), followed by the kidney (13%) and the breast (11%). Approximately 16% will have no known diagnosis of cancer.¹⁰¹ The most common sites are the distal phalanges, followed by the proximal and middle phalanges, metacarpals, and carpus. Patients will present with pain, swelling, and erythema. Differential diagnosis includes felon, gout, osteomyelitis, trauma, RA, or skin cancer. Treatment of a hand or wrist metastatic lesion must not interfere with treatment of the primary cancer. Treatment is usually palliative (simple excision or amputation). The average life expectancy for these patients is less than 6 months.¹⁰¹

BURNS

The palm of the hand makes up approximately 1% of the total body surface area. A burn involving the entire hand and digits is unlikely to cause life-threatening injury or shock, but seemingly small burns to the hand may cause severe permanent loss of function if not treated appropriately. Burns to the hand can cause serious short- and long-term disability. All burns to the hand are considered severe injuries that warrant transfer to a dedicated burn center for specialized treatment. This management will include a multidisciplinary team consisting of hand surgeons, burn surgeons, burn-specialized nurses, occupational therapists, case managers, and social workers.

Superficial burns involve damage to the epidermis only and present with erythema, no blistering, and full sensation with blanching of skin. These will heal without scarring. Superficial partial-thickness burns involve damage to the papillary

dermis; all skin appendages are preserved, and therefore, these readily reepithelialize with minimal to no scarring. Superficial partial-thickness burns are sensate and present with pain, erythema, blistering, and blanching of skin. Topical dressings are the mainstay of treatment. Deep partial-thickness burns involve damage to the reticular dermis with damage to skin appendages, as well as the dermal plexus blood vessels and nerves. These have decreased sensation and no cap refill and appear pale or white. Blistering may be present. Damage to the skin appendages and blood supply in the dermal plexus precludes spontaneous healing without scar. Excision with skin grafting is needed. Third-degree burns involve full-thickness damage through the dermis and are insensate with no blistering. They appear dry, leathery, and even charred.

Acute Management

Advanced trauma life support guidelines should be followed. After primary survey, circulation to the hand should be assessed. Palpation and Doppler ultrasound should be used to evaluate blood flow within the radial and ulnar arteries, the palmar arches, and digital blood flow at the radial and ulnar aspect of each volar digital pad. A sensorimotor exam should be performed. Objective evidence of inadequate perfusion (i.e., deteriorating clinical exam with changes in or loss of pulse or Doppler signal) indicates the need for escharotomy, especially in the setting of circumferential burns. Escharotomy may be performed at bedside with scalpel or electrocautery under local anesthesia or intravenous sedation. In the forearm, axially oriented midradial and midulnar incisions are made for the entire extent of the burn. Escharotomy should proceed as distally as necessary into the wrist and hand to restore perfusion. Digital escharotomies are made via a midaxial (the middle of the longitudinal axis on sagittal view) incision over the radial aspects of the thumb and small finger and the ulnar aspects of the index, middle, and ring fingers.¹⁰² These locations for digital escharotomies avoid painful scars on the heavy-contact surfaces of each respective digit. After primary survey, vascular, and sensorimotor exams are complete, careful documentation should be made of all burns. This is best done with a Lund and Browder chart and includes location, surface area, and initial depth of burn.

The burns should be dressed as soon as examination is complete. Gauze moistened with normal saline is a good initial dressing because it is easy, readily available, and will not leave ointment or cream on the wounds, which can hinder frequent examinations in the initial period. It is critical that no dressing is wrapped in a circumferential manner around any body part. Edema and swelling can lead to extremity ischemia if a circumferential dressing is in place. It is important to maintain body temperature above 37°C, especially in burn patients who have lost thermoregulatory function of the skin and now have moist dressings in place. The hands should be elevated above heart level to decrease edema formation, which can hinder motion and lead to late scar contracture. The hand should be splinted in the intrinsic plus position with the MPs flexed to 90° (placing MP collateral ligaments under tension), the IPs in straight extension (prevents volar plate adhesion), and the wrist in approximately 15° of extension.¹⁰³ In rare cases, Kirschner wires or heavy steel wires/pins are needed to keep a joint in proper position. These are placed percutaneously through the involved joint and serve as a temporary joint stabilizer.

After the primary and secondary surveys are complete, the wound should be evaluated again. Devitalized tissue should be

debrided. Wounds should be cleansed twice daily, typically with normal saline. Second-degree superficial burns may be dressed with Xeroform gauze and bacitracin. Silver sulfadiazine cream is another option for any second- or third-degree wound. It covers gram-positive and gram-negative microbes, but it does not penetrate eschar. It should be applied at least one-sixteenth of an inch thick. Sulfamylon can be used in conjunction with silver sulfadiazine or alone. It deeply penetrates eschar and tissues and has good gram-positive coverage.

Surgical Management

Any burn wound will eventually heal with proper wound care. However, this may involve unacceptable scarring, deformity, contractures, pain, and unstable wounds that are prone to breakdown. The goal is to restore preinjury function as much as possible with a wound that is durable, supple, nonpainful, and allows the patient to return to society as an active member. Local wound care is the ideal treatment for wounds that can heal completely within 14 days while not sacrificing function. For deep partial-thickness or full-thickness burns, early surgical excision and skin grafting is necessary.¹⁰³

Considerable controversy surrounds the need, timing, and method of grafting burns. Careful consideration must be given to the patient's overall status, their preinjury state, and the type of work and recreational activities they enjoyed in order to have a better understanding of which issues should be addressed. Tangential excision of the wounds should be performed under tourniquet to minimize blood loss and is carried down to viable tissue. Avoid excising through fascia (epimysium) overlying muscles or exposing tendons, bone, joint capsules, or neurovascular structures. Tissues capable of receiving a skin graft include well-vascularized fat, muscle, perineurium, paratenon, perichondrium, and periosteum. Exposure of deep structures without an adequately graftable bed mandates further coverage before skin grafting can occur (discussed later in "Reconstruction").

Once there is an adequate bed, grafting is the next step. If there is any doubt as to whether the wound bed can support a skin graft, a temporary dressing such as Allograft (human cadaver skin) should be placed and the patient reexamined frequently for signs of granulation tissue and wound bed viability. It can remain in place for up to 14 days before rejection and can serve as a way of "testing" if a wound is ready to receive a skin graft. Skin grafts to the dorsum of the hand are typically split-thickness sheet grafts (not meshed), as sheet grafts have a superior aesthetic appearance. Skin grafts to the palmar aspects of the hand should be full-thickness in order to provide the dermal durability needed for daily functions. Skin grafts are secured with staples, sutures, fibrin glue, or even skin glue. It is important to bolster every skin graft. This prevents shearing loss and also keeps the skin graft in contact with the wound bed, preventing fluid collections that can lead to graft loss. A bolster may consist of a tie-over bolster and a splint or a negative-pressure dressing. The hand should be splinted in intrinsic plus for 7 days after skin grafting. Once the graft is adherent, hand therapy should begin, consisting of active and passive range-of-motion exercises and modalities.¹⁰³

Reconstruction

Reconstruction of burn wounds can begin as early as the acute setting and continue into the subacute and late stages. Burns may initially be superficial but later convert to deep burns

(especially with grease, oil, and alkali burns) due to infection, tissue desiccation, or continued trauma, or they may be deep from the outset of injury. Debridement or excision of burns may result in exposure of viable muscle, bone, tendon, cartilage, joints, and neurovascular structures, as well as loss of fascial layers that are required for overlying soft tissue to glide during movement. Simply skin grafting these exposed structures will result in unstable wounds that are prone to chronic breakdown. Soft tissue contractures will develop as the skin grafts adhere to the structures, effectively anchoring them in static position. This is especially true for tendons, where gliding capability is paramount for function. Flap coverage is required in these situations. The reversed radial forearm flap is a local flap and is often the first choice for flap coverage of the hand. If the zone of injury or size of defect precludes its use, other skin and fat flaps, including the free lateral arm, free anterolateral thigh, or even free parascapular flaps, may be useful, provided the patient can tolerate a free tissue transfer (see Chapter 45) operation (Fig. 44-30). The digits may also be buried subcutaneously in the lower abdominal skin or groin crease. Vascular ingrowth from the digits into the abdominal or groin skin occurs over 2 to 3 weeks, allowing division of the flap(s) and achieving full-thickness coverage of the wounds.¹⁰⁴

An acellular dermal regenerative substitute (e.g., Integra) may be used for wounds that have exposed structures and require more durability than is offered by a skin graft such as full-thickness loss overlying the extensor tendons of the wrist and hand.¹⁰⁵ Dermal substitute is a good option for wounds that are not extensive enough to warrant a flap and for patients who are poor candidates for an extensive surgery. Integra is composed of acellular cross-linked bovine tendon collagen and glycosaminoglycan with an overlying silicone sheet. It is applied much like a skin graft. After incorporation in 14 to 21 days, it is capable of accepting a skin graft (after removing the silicone sheet). Conceptually, it works by replacing the lost dermis and adds durability to a wound bed. It may be reapplied multiple times to the same area if thicker neodermis is desired. Although cultured autologous keratinocytes have been used, they are expensive, time-consuming, and do not provide prompt or durable coverage.

Web space contractures are the most common deformity resulting after hand burns. They may occur late despite the best efforts. In the normal web space, the leading edge of the volar

Figure 44-30. Free anterolateral thigh flap reconstruction of a large dorsal hand wound. Once wound coverage is stable, this flap will need to be surgically revised to achieve proper contour.

Figure 44-31. Z-plasty release of web space contracture. **A.** First web space burn contracture. **B.** Immediate postoperative result.

aspect of the web is distal to the dorsal aspect. This is reversed in web space contractures and limits digit abduction. Local modified Z-plasty (double-opposing Z-plasty) is the preferred treatment (Fig. 44-31).

Special Considerations

Chemical burns pose a risk to healthcare providers and should be considered hazardous material. They must also be removed from the patient or continued burn injury will occur. A complete discussion of all chemicals causing burns is beyond the scope of this chapter. Hydrofluoric acid produces a slow onset of severe pain and continues to penetrate deeper structures. It avidly binds tissue and circulating calcium and can lead to hypocalcemia and cardiac arrest. The wound should be irrigated copiously with water followed by topical or intra-arterial injection of calcium gluconate. Chronic acid burns should be treated with immediate

lavage, phosphate buffer soaks and immediate surgical excision. Cement can result in chemical burns and should be treated with immediate irrigation and topical antibacterial ointments. Alkaline and acid burns require copious irrigation with water, with alkali burns often requiring hours of irrigation. Phenol burns should be irrigated with dilute polyethylene glycol wash followed by high-flow water lavage.¹⁰⁶

VASCULAR DISEASE

Vascular disease encompasses a broad spectrum of disorders leading to compromised perfusion to the hand and digits and may potentially cause ischemia and necrosis. Chronic vascular disorders tend to develop slowly and are typically seen in older patients. This includes progressive thrombosis, aneurysms, systemic vasculopathy, and vasospastic disorders. Disorders unique or common to the hand are discussed in the following sections.

Progressive Thrombotic Disease

Hypothenar hammer syndrome involves occlusion of the ulnar artery at the wrist and is the most common occlusive vascular disorder of the upper extremity. The etiology is believed to be chronic trauma to the ulnar artery as it exits Guyon's canal. The classic example is a construction worker who frequently uses heavy equipment, such as jackhammers, that cause prolonged vibration and repetitive impact on the ulnar aspect of the palm. This causes periadventitial arterial damage that results in scarring and eventual compression, as well as medial and intimal damage.¹⁰⁷ The artery then becomes weakened and prone to aneurysm and/or thrombosis. If a thrombus forms, it may embolize, producing digital ischemia. Symptoms may be chronic or acute and include pain, numbness and tingling, weakness of grip, discoloration of the fingers, and even gangrene or ulcers of the fingertips.

If acute in onset, proximal occlusions may be extracted with a balloon catheter or, sometimes, under direct vision via an arteriotomy. Very distal embolism may require infusion of thrombolytics to dissolve clots and allow reperfusion. Large-vessel acute embolism and reperfusion may result in edema and compartment syndrome, requiring fasciotomy. A high index of suspicion must be maintained.

For the more common scenario of chronic, progressive occlusion, the involved segment of ulnar artery should be resected. There is disagreement in the literature regarding whether simple ligation and excision is sufficient for patients with sufficient distal flow or if all patients should undergo vascular reconstruction.¹⁰⁸ The authors' personal preference is to reconstruct all patients.

Systemic Vasculopathy

Buerger's disease (thromboangiitis obliterans) is an inflammatory occlusive disease affecting small and medium-sized arteries and veins. It is strongly influenced by smoking and will often resolve upon smoking cessation. The disease is classified into acute, intermediate, and chronic, depending on histologic progression of the disease. Migratory phlebitis occurs distal to the elbow, resulting in ischemia, rest pain, and ulceration and necrosis of the digits. It can continue to cause more proximal ischemia and ultimately lead to loss of the hands. Treatment must start with smoking cessation. Failure to stop smoking will make any surgical intervention unsuccessful. Arteriography is useful to determine arterial flow and whether bypass is possible.

If direct bypass is not possible, alternatives include arterIALIZATION of the venous system by connecting the dorsal venous network to the brachial artery or possible free microvascular omental transfer beneath the dorsal forearm or hand for indirect revascularization.¹⁰⁹

Vasospastic Disorders

Raynaud's syndrome results from excessive sympathetic nervous system stimulation. Perfusion is diminished and fingers often become cyanotic. Although the onset of the symptoms is benign, chronic episodes can result in atrophic changes and painful ulceration or gangrene of the digits. Raynaud's disease occurs without another associated disease. This disease predominantly affects young women and is often bilateral. The vascular system is structurally intact without any obstructions. There is no ulceration, gangrene, or digit loss. In contrast, Raynaud's phenomenon is associated with an underlying connective tissue disorder, such as scleroderma. Arterial stenosis is present due to disease changes in blood vessels as a result of the specific medical disorder.¹¹⁰

Scleroderma is an autoimmune connective tissue disorder resulting in fibrosis and abnormal collagen deposition in tissue. Many organs can be affected, with the skin most commonly and noticeably involved. In this disease, blood vessels are injured by intimal fibrosis leading to microvascular disease. The vessels become subject to Raynaud's phenomenon, and patients develop painful, ulcerated, and sometimes necrotic digits.^{109,110}

Sympathectomy can provide pain relief and healing of ulcers for patients with scleroderma and Raynaud's phenomenon. In this procedure, adventitia is stripped from the radial artery, ulnar artery, superficial palmar arch, and digital arteries in various combinations based on the affected digits being treated. The decrease in sympathetic tone allows for vasodilation and increased blood flow. If the patient notes significant distal pain relief and/or previously ischemic tissue improves in color after a test administration of local anesthetic, sympathectomy may provide the same results in a long-term fashion.¹¹¹ Recently, several studies have investigated the use of botulinum toxin on improving digital perfusion in patients with Raynaud's. Reports have shown improved objective measurements of hand function 8-12 weeks after injection.¹¹²

CONGENITAL DIFFERENCES

Congenital differences in a newborn can be particularly disabling as the child learns to interact with the environment by using the hands. The degree of anomaly can range from minor, such as a digital disproportion, to severe, such as total absence of a forearm bone. In recent years, increasing knowledge of the molecular basis of embryonic limb development has significantly enhanced the understanding of congenital differences. Congenital hand differences have an incidence of 1:1500 births. The two most common differences encountered are syndactyly and polydactyly.¹¹³

There are numerous classification systems for hand differences. The Swanson classification, adopted by the American Society for Surgery of the Hand, delineates seven groups organized based on anatomic parts affected by types of embryonic failures.^{114,115}

Failure of Formation

The failure of the formation of parts is a group of congenital differences that forms as a result of a transverse or longitudinal

arrest of development. Conditions in this group include radial club hand, a deformity that involves some or all of the tissues on the radial side of the forearm and hand, and ulnar club hand, which involves underdevelopment or absence of the ulnar-sided bones.

Failure of Differentiation

The failure of the differentiation of parts comprises conditions where the tissues of the hand fail to separate during embryogenesis. Syndactyly, in which two or more fingers are fused together, is the most common congenital hand deformity and occurs in 7 out of every 10,000 live births. There is a familial tendency to develop this deformity. This deformity often involves both hands, and males are more often affected than females. Syndactyly is classified as either simple (soft tissue only) or complex (bone and/or cartilage also involved), and complete (full length of the digits) or incomplete (less than the full length).

Surgical release of syndactyly requires the use of local flaps to create a floor for the interdigital web space and to partially surface the adjacent sides of the separated digits (Fig. 44-32). Residual defects along the sides of the separated fingers are covered with full-thickness skin grafts. Surgery usually is performed at 6 to 12 months of age.

Duplication

Duplication of digits is also known as polydactyly. Radial polydactyly is usually manifests as thumb duplication. Wassel described a classification system for thumb duplications based on the level of bifurcation.¹¹⁶ When two thumbs are present in the same hand, they are rarely both normal in size, alignment, and mobility. In the most common form of thumb duplication, a single broad metacarpal supports two proximal phalanges, each of which supports a distal phalanx. Optimal reconstruction requires merging of elements of both component digits. Usually the ulnar thumb is maintained. If the duplication occurs at the MP joint, the radial collateral ligament is preserved with the metacarpal and attached to the proximal phalanx of the retained ulnar thumb. Surgery is usually performed at 6 to 12 months of age. Ulnar-sided polydactyly may often be treated by simple excision of the extra digit.

Overgrowth

Overgrowth of digits is also known as macrodactyly, which causes an abnormally large digit. In this situation, the hand and the forearm also may be involved. In this rare condition, all parts of a digit are affected; however, in most cases, only one digit is involved, and it is usually the index finger. This condition is more commonly seen in males. Surgical treatment of this condition is complex, and the outcomes may be less than desirable. Sometimes, amputation of the enlarged digit provides the best functional result.

Constriction Band Syndrome

Underdeveloped fingers or thumbs are associated with many congenital hand deformities. Surgical treatment is not always required to correct these deformities. Underdeveloped fingers may include the following: small digits (brachydactyly), missing muscles, underdeveloped or missing bones, or absence of a digit.

Generalized Skeletal Anomalies and Syndromes

This is a rare and complex group of unclassified problems.

B

C

Figure 44-32. Syndactyly. **A.** Hand of a 1-year-old patient with complex syndactyly between the long and ring fingers. Complex syndactyly refers to fingers joined by bone or cartilaginous union, usually in a side-to-side fashion at the distal phalanges. **B.** Anteroposterior radiograph. **C.** The syndactyly is divided with interdigitating full-thickness flaps, a dorsal trapezoidal-shaped flap to resurface the floor of the web space, and full-thickness skin grafts. Note the skin grafts on the ulnar and radial sides of the new web space.

RECONSTRUCTIVE TRANSPLANTATION OF THE UPPER EXTREMITY

Hand transplantation was first performed in humans in the late 1990s both in Louisville, Kentucky, and Lyon, France.¹¹⁷ The treating surgeons were able to successfully remove an upper extremity from a brain-dead donor, attach it to an upper extremity amputee, and have the tissue survive. In the subsequent 15 years, many additional centers have achieved technical success with upper extremity transplantation as well.

The technical considerations of hand transplantation have proven to be only the beginning of challenges in bringing this treatment option to the general public. Replantation of an amputated limb was first reported by Malt in 1962.¹¹⁸ In a limb replantation, there is a zone of injury, and cold preservation of the amputated part does not begin immediately. In a limb transplant, the harvest can be done as proximally as necessary to ensure that only healthy tissue is present on both sides of the repair and to obviate the need for limb shortening, and cold preservation of the amputated part can begin immediately after harvest.

A major concern regarding the use of limb transplantation is the immunosuppression medications required to prevent rejection of the transplanted limb. Unlike organ transplantation, which provides a critical organ without which the recipient could not survive or would require chronic mechanical support (e.g., hemodialysis), the absence of one or even multiple limbs does not represent an immediate threat to a patient's survival. Multiple studies have documented the nephrotoxic and other side effects of tacrolimus (FK 506), the principle antirejection agent used in transplant immunomodulation protocols.^{119,120}

Due to these concerns, much research has been directed at minimizing the amount of antirejection medication as well as promoting tolerance or even chimerism. Donor bone marrow transplantation to the limb transplant recipient has been shown to be beneficial toward this purpose and is part of the limb transplant protocol in some centers.^{121,122} Recent research with donor bone marrow infusions has shown that lower levels of immunosuppressive drugs may be possible, as well as fewer immunosuppressive agents.¹²¹ Further research is needed in order to determine the efficacy and utility of donor bone marrow transfusions and how they impact transplant recipients in the short and long term.

The final challenge in consideration of a patient for limb transplantation is selection of an appropriate candidate. There are multiple patient factors that need to be considered to determine if a patient is an appropriate candidate for hand transplantation. These include medical concerns, such as immunologic issues (both antibodies and the presence of occult neoplasms or indolent viruses such as cytomegalovirus), hematologic issues including coagulopathies, and anatomic issues such as quality of skin envelope and amputation level of the bone and neuromuscular structures. Psychological and social factors must also be considered related to the recipient's ability to comply with postoperative medication and therapy protocols as well as to cope with a continuous visible presence of a limb originating from another person.¹²³

The promise of upper limb transplantation as a reconstructive technique remains high. Both civilian and military amputees stand to receive a marked functional benefit from this treatment. With the number of transplants performed worldwide

approaching 100 as well as decades of animal research, understanding of how best to use this technique from functional, patient safety, and cost-effectiveness standpoints continues to grow.

INTRODUCTION

Plastic and reconstructive surgery is a unique subspecialty of surgery that consists of a set of techniques intended to modify the amount, position, quality, or organization of tissues in order to restore function and appearance. The name of the field is derived from the Greek word *plastikos*, which means “to mold.” An object is considered plastic if its shape can be modified without destruction. In this sense, all human tissues have some degree of plasticity. They can be nondestructively modified if the surgeon adheres to certain principles. Understanding and applying these principles to solve clinical problems is the essence of plastic and reconstructive surgery. Although informal references to this type of surgery can be found in the modern literature as early as the 17th century, American surgeon John Staige Davis published the first textbook dedicated to the field in 1919, entitled *Plastic Surgery—Its Principles and Practice*. He coined the term that we have used to refer to the specialty ever since. Science has always evolved in a nonlinear fashion: seminal discoveries in different parts of the world have all collectively fueled progress and addressed an unmet need. The evolution of plastic and reconstructive surgery has followed the same path: the *Edwin Smith Papyrus*¹ (Egypt, 1600 B.C.) (Fig. 45-1) described facial reconstruction; the *Shushruta Samhita* (India, 1500 B.C.) (Fig. 45-2) described nasal reconstruction; and Aulus Cornelius Celsus (Rome, 1 A.D.) described operations for facial reconstruction. The underlying impetus for this evolution is the common unmet need for restoring defects, be they congenital, traumatic, or functional.

This strong thread of advances in reconstructive surgery continues even today. What does seem under-recognized is that the clinical practice of plastic and reconstructive surgery

touches on every other area of surgery. Enhanced reconstructive capabilities strengthen all other specialties significantly, such as the ability to safely perform radical cancer operations, salvage traumatic limbs, or extend the reach of neonatal medicine by congenital reconstruction. Each surgical specialty encounters problems that might be addressed by some form of tissue repair, modification, rearrangement, transfer, or replacement. Since its inception, plastic surgeons have routinely responded to the medical needs of the society and helped restore form and function. One of the most powerful examples of this response is the advances that occurred as a result of World Wars I and II. Walter Yeo, a sailor injured at the Battle of Jutland, is assumed to have received plastic surgery in 1917. The photograph shows him before (Fig. 45-3, *left*) and after (*right*) receiving a flap surgery performed by Gillies.

The Gulf war and the conflicts in the Middle East have prompted several revolutionary reconstructive surgical advances in limb salvage, microsurgery, supermicrosurgery, hand, face, and abdominal wall transplantation. Plastic surgeons have also targeted muscle reinnervation, tissue engineering, and regenerative medicine.

When society calls, plastic surgeons rise to the challenge and create novel methods to address its needs. For example, neurosurgeons at times must replace or stabilize bone in the cranium or spine, and healthy soft tissue coverage is essential for optimal healing. Head and neck surgeons face tissue replacement problems in order to restore normal function and appearance after major tumor ablation. Thoracic surgeons must manage bronchopleural fistulae, esophageal defects, or loss of chest wall integrity after trauma or tumor resection. Cardiologists and cardiac surgeons at times face complicated wound

Key Points

- 1▶ It is critical to understand the physiologic basis and rationale of wound healing in order to further assimilate surgical and nonsurgical care of wounds and methods of wound care.
- 2▶ Understanding the reconstructive choices in tissue repair cases is critical for any surgeon. The principles of soft tissue and skin repair are important for the reconstruction of defects, whether in a trauma situation or after excision of lesions.
- 3▶ Children with cleft and craniofacial differences have complex medical, surgical, and social needs. Coordinated, interdisciplinary team care is crucial to success.
- 4▶ Robin sequence, characterized by micrognathia, glossoposis, and airway obstruction, can be managed with prone positioning, tongue-lip adhesion, mandibular distraction osteogenesis, or tracheostomy.
- 5▶ The first-line treatment for high-risk hemangiomas is oral propranolol, which can induce rapid involution and has a more favorable side effect profile than systemic steroids.
- 6▶ The coordination of care for patients in a trauma department is an important part of a surgeon's role, whether that
- 7▶ role be as a trauma emergency department surgeon or a surgeon in practice.
- 7▶ The careful evaluation of a patient in a polytrauma involves a thorough assessment of internal and soft tissue injuries, planning of care, and the appropriate triage of reconstructive procedures. As a leader in a trauma bay of the trauma service, the surgeon typically assumes a captain's role in decision-making.
- 8▶ Principles of oncologic reconstruction have evolved significantly, and a deeper understanding of these reconstructive choices is essential for a surgeon who is often the first point of contact for cancer patients and responsible for making critical referrals.
- 9▶ The combined work of general surgeons and reconstructive plastic surgeons has revolutionized the care of abdominal wall defects, including ventral hernias, repair after tumor ablation, and bariatric surgery.
- 10▶ Any critical care unit or a medical surgical team that takes care of debilitated patients needs a detailed understanding of pressure sores, including their etiology and the reconstructive options that are available to these patients.

infections, sternal osteomyelitis, or failure of soft tissue coverage that leads to exposure and contamination of implanted devices such as left ventricular assist devices or cardiac pacemakers. Orthopedic surgeons managing segmental bone defects in the extremities at times require replacement by surgical transfer of vascularized bone segments rather than conventional bone grafts or alloplastic substitutes. Urologists, colorectal surgeons, and gynecologists who commonly perform surgery in the perineum encounter nonhealing wounds or fistulae. All of these problems may be managed or potentially prevented by judicious application of tissue methods developed and practiced by plastic and reconstructive surgeons.

Plastic and reconstructive surgery is a field characterized by innovation, and it has yielded important contributions to other surgical specialties. These include notable advances in hand and upper extremity surgery, craniofacial surgery, peripheral

nerve surgery, and reconstructive microsurgery. Entirely new fields have emerged from plastic surgery research. Joseph E. Murray, a Boston plastic surgeon, and his team performed the first renal transplantation procedures and laid the foundation for modern organ transplantation, an achievement for which he was awarded the Nobel Prize in Medicine in 1990 (Fig. 45-4). This spirit of innovation continues with ongoing active research by plastic surgeons in composite tissue allotransplantation, tissue engineering, biomaterials, cell transplantation, regenerative medicine, computer-assisted surgical planning, medical application of three-dimensional manufacturing methods, infection control, and outcomes research. Plastic and reconstructive surgery is a vibrant field that brings tremendous value to people's health and quality of life through life-changing reconstructive, restorative, and transformative surgeries.

PURPOSE

The purpose of this chapter is to inform about the general principles of plastic and reconstructive surgery, which apply to all areas of surgery, and to provide current examples of practice. Studying this chapter will help the reader to understand (a) the principles of plastic surgery that translate into other surgical specialties; (b) the kind of clinical problems that may be addressed using plastic surgery techniques; and (c) the types of research found in plastic and reconstructive surgery. It will make clearer the nature of the field and its role in the multidisciplinary care environment of modern healthcare.

GENERAL PRINCIPLES

General principles of plastic surgery relate to technical aspects of incision planning and wound repair. These principles apply to all surgical disciplines. As such, every surgeon can benefit from

Figure 45-4. Joseph E. Murray, MD, awarded the Nobel Prize in Medicine in 1990.

learning and applying them. Previously, tremendous emphasis was placed on simply understanding the nature of skin, which is completely justified; however, over the past few years plastic surgical focus has expanded to include the entire integument. Muscles, fascia, fat, skeletal framework, nerves, vascular networks, and their dynamic interactions have become far more important factors that are choreographed in most reconstructive processes.

Skin Incisions

From a surgical viewpoint, the skin is a multilayered tissue formed by dermis and epidermis. It is the largest organ in the human body and exists in a state of dynamic equilibrium from the balance of tension created by external and internal factors. Externally, skin and underlying subcutaneous tissue are acted on by gravity and clothing. Internal factors include skin elasticity, which is simply the ability to stretch and return to prestretch architecture upon removal of the stretch. The dermis is composed of different types of collagen and elastic protein fibers (elastin), and epidermis, composed primarily of cells anchored together in various stages of maturation. The skin serves important functions of thermoregulation, affording tactile sensation, and protection from foreign materials and microorganisms. Areas of skin exposed to view in normal clothing play a significant role in personal appearance and social interaction. As a result, even favorable scars from surgical incisions can have an undesirable effect on personal appearance. Thoughtful placement and performance of a surgical incision will minimize the risk of adverse consequences that can result in short- and long-term morbidity.

Human skin exists in a resting state of tension caused by gravity and its conformation over underlying structures between sites that are tethered by subcutaneous fibrous tissue, which secure the deep surface of the dermis to underlying points of fixation. When the skin is incised linearly, the wound edges separate in a predictable fashion forming an ellipse with the long axis perpendicular to the lines of greatest tension. These tension lines are often called “Langer’s lines,” after Carl Langer, a 19th century anatomist from Vienna who first described them based on studies in fresh cadavers (Fig. 45-5). Later, Borges described relaxed skin tension lines, which follow furrows formed when the skin is relaxed and are produced by pinching the skin. Incisions placed parallel to these lines often heal with less conspicuous scar because the skin often has natural wrinkles following these lines and there is less tension perpendicular to the orientation of the wound¹ (Fig. 45-6). Based on these principles,² a recommended pattern for incisions can be made (Fig. 45-7).

Using the proper technique for creating and repairing skin incisions ensures uncomplicated wound healing with few distorting surface scars. The epidermis and superficial dermis should be incised sharply with a scalpel. The incision is then continued through the deep dermis and subdermal plexus of blood vessels with electrocautery. This technique helps to minimize collateral tissue injury along the wound margins to facilitate prompt and reliable healing. It is essential to maintain the orientation of the scalpel or electrocautery blade perpendicular to the surface of the skin in order to facilitate accurate reapproximation during wound closure. As the incision is deepened through the subcutaneous tissue to expose underlying structures, it is important to avoid creating multiple pathways through the tissue, which can create focal areas of devitalized tissue that form a nidus of infection or lead to delayed wound healing. The

Figure 45-5. “Langer’s lines,” named after Carl Langer, a 19th century anatomist from Vienna.

surgeon should extend the incision through the subcutaneous fat by tracing the same line each time with the scalpel or electrocautery in order to reach the deeper structures.

Traumatic wounds do not permit the same careful planning that is possible with incisions made in undamaged skin. Nevertheless, optimum repair of traumatic lacerations involves similar principles applicable in nontraumatic circumstances. The surgeon must remove as much traumatized tissue as possible from the wound edges, converting the uncontrolled traumatic wound into a controlled surgical wound. All devitalized tissue is excised. The same principles of making incisions perpendicular to the skin surface and avoiding creating multiple pathways through the subcutaneous tissues apply. In this process, an attempt can be made to reorient the wound into a more favorable direction. A variety of methods are available

Figure 45-7. Planning of incisions based on lines of skin tension.

to perform this reorientation, and they often involve creating small local flaps of undamaged tissue using geometric tissue rearrangements. These techniques will be considered later in this chapter. Following these principles increases the likelihood of uncomplicated wound healing and reduces the need for later treatment of unfavorable scars. However, there are situations in which the direction of the incision has been preestablished, as in acute lacerations, burns, or old contracted and distorting scars. In these circumstances, the principles of proper incision placement can be combined with simple surgical techniques to reorient the scar and lessen the deformity.

When making an incision in an area of previous scarring, such as in a scar revision or a reoperation, it is preferable to completely excise the scar when making the skin incision and not simply make the incision through the old scar. Closing scarred wound edges increases the likelihood of delayed wound healing, infections, and unfavorable new scars. It only takes a few moments to make the skin incision outside of the area of scarring through unscarred skin. Once the skin incisions on each side of the previous scar reach into the subcutaneous tissue, then the surface scar can be removed completely at the subdermal level. This approach ensures that the final repair relies on undamaged tissues, thus facilitating uncomplicated healing and lowering the risk of an unfavorable scar.

Incision Repair

A well-performed skin incision sets the stage for an accurate repair that minimizes the risk of unfavorable scarring. An unfavorable scar is characterized by excessive amount of collagen

Figure 45-6. Lines of relaxed skin tension.

Hypertrophic Scar

Keloid

Figure 45-8. Hypertrophic scar (*left*) and keloid (*right*).

deposition,⁴ leading to hypertrophic scarring or keloid formation (Fig. 45-8). The difference between them is that a hypertrophic scar stops growing 6 months after the injury, whereas a keloid continues to grow, even growing well beyond its borders. Accurate approximation and stabilization of the skin edges helps to minimize the amount of collagen deposition required for skin healing. The most important layer to approximate is the dermis because this layer contains the healing elements such as blood supply and cellular elements that create the extracellular matrix necessary for healing. Optimal wound closure involves placing deep dermal sutures followed by superficial sutures that incorporate the upper layers of the dermis and epidermis. Absorbable deep dermal sutures have the advantage of disappearing over time; however, they can promote prolonged inflammation during this process. Nonabsorbable sutures minimize inflammation and might be indicated in individuals who are particularly prone to scar formation. A step-off between each side of the wound should be avoided because an uneven surface on each side of the wound can cause a shadow that accentuates the presence of the scar. Stability between the two wound edges is important because motion between the two sides of the wound prolongs the inflammatory phase of healing and requires additional collagen to be deposited. The timing of suture removal depends on the type of suture placed in the superficial closure. Sutures placed at the surface that go deep into the dermis can leave additional scarring at the entry and exit points of the suture material in addition to the incisional scar. Sutures like this should be removed within the first week. If the superficial sutures are placed more shallowly in the dermis, there is a reduced tendency to form additional scarring. A subcuticular suture may be used instead of simple sutures. This type of technique avoids the risk of additional scarring along the wound edge; however, it can be more difficult to accurately reapproximate the skin edges without a step-off between the two sides.

Wound Healing

In the United States, nonhealing wounds affect about 3 to 6 million people, with persons 65 years and older accounting for 85% of these events. The annual cost of this problem is estimated to be as high as \$25 billion for hospital admissions, antibiotics, and local wound care.³

Normal wound healing is achieved through four highly choreographed, overlapping biophysiologic phases: *hemostasis*, *inflammation*, *proliferation*, and *tissue remodeling or resolution*. Each phase initiates a cascading set of processes critical to the desired result of a healed wound.

Several factors impede wound healing and need to be understood so that they can be mitigated. Successful mitigation of these adverse factors requires precise, least-traumatic surgical technique that incorporates new methods of prevention and treatment of infection and an understanding of the role of microbial behavior, including the formation of biofilm. Because chronic diseases such as diabetes, vascular insufficiency, and obesity are on the rise, there must be a better understanding of chronic versus acute wounds and how comorbid conditions affect wound healing. Lastly, the impact of age, gender, and nutrition becomes more important as the population of aging patients increases.

Phases of Wound Healing

There are different processes that characterize healing in several types of tissue, such as skin, muscle, or bone, and there is a strong underlying mechanism that is best understood in terms of a simple skin injury. The process of wound healing is comprised of four integrated processes that overlap: (a) bleeding and hemostasis, (b) inflammation, (c) proliferation, and (d) tissue modeling or resolution (Fig. 45-9).

These processes occur in sequence over a 1-year duration, but they also significantly overlap and work in terms of a “continuum of processes” rather than discrete “stop-and-go” phases. As shown in Fig. 45-9, each phase is characterized by several

Figure 45-9. Phases of wound healing.

well-defined processes that are dominated by cellular as well as noncellular elements, such as platelets, macrophages, and cytokines, that act in concert.

Hemostasis. This phase of healing occurs immediately after tissue injury. The most important cells that play a role in the hemostatic process are platelets that degranulate and result in the formation of a clot. The extracellular matrix that supports the tissue framework and otherwise acts as a barrier is now open to the vascular compartment, resulting in the release of several factors into the wound. In addition, the release of proteins—otherwise stored within the extracellular matrix—and the president cells act as further stimulants that start the hemostatic process. Inflammatory plasma proteins and leukocytes also migrate into the wound. On the cellular level, the plasma membrane of each platelet contains several receptors for collagen (glycoprotein 1A and 2A). Once these receptors are activated, glycolated granules holding multiple factors that activate hemostasis and inflammation are disrupted, releasing bioactive factors that stimulate platelet aggregation, vasoconstriction, and the subsequent activation of the clotting cascade. As these initial platelet activation factors are released, there is a subsequent push that influences angiogenesis inflammation. These systemic immune response platelet-derived factors include biologically active proteins, such as PDGF, TGF- β , and VEGF, as well as other cytokines, such as PF4 and CD40L.

In addition to the release of these factors, the binding of selected proteins within the already developed fibroblasts and the combination of two elements within the extracellular matrix create a chemotactic gradient that activates cell recruitment, cell migration, and cell differentiation and promotes tissue repair. This has been demonstrated clinically in several instances, including orthopedic surgery, cardiac surgery, and certain types of skin repair, where autologous platelet transfusions have shown to accelerate the healing process.

The subsequent fate of the platelet plug is determined by the amount of circulating fibrinogen. The vascular system interacts with the sympathetic nervous system by eliciting vasoconstriction from the actions of cytokines, prostaglandins, and catecholamines. There is also an alteration of capillary permeability caused by histaminic responses and the mediation of VEGF, which is released from micelles and the damaged endothelium. This highly interactive process results in decreasing blood loss while simultaneously delivering bioactive proteins and cells into the wound environment that *kick start* the inflammatory process.

Inflammation. This is the second phase of wound healing and arguably overlaps the hemostatic face. Polymorphonuclear leukocytes (PMNs) and macrophages appear in the wound right after platelets, and their primary role is mainly to act as scavengers. They clear the wound environment of debris, foreign material, bacteria, dead tissue cells and any other devitalized issues that would otherwise impede the healing process. Both macrophages and PMNs aid in phagocytosis and the secretion of free articles that kill bacteria and reduce the bioburden. Cellular migration into the wound is highly controlled by bioactive agents within the wound and within the vascular compartment. These include cytokines, integrins, selection, and other collagen-derived substances that act in concert. Through antibody activation, polymorphonuclear cells also interact with the humoral system to facilitate the key functions of cell activation, recruitment, and proliferation, as well as migration from the

intravascular compartment to the extracellular matrix. Within 48 hours of tissue injury, PMNs and macrophages are recruited to the wound in very large numbers, heralding the inflammatory response. As described in other chapters in this text, macrophages possess a very large repertoire of functions, all of which are geared towards removing the nonviable elements in the wound and recruiting other cell types into the wound that facilitate angiogenesis, fibroblast function, and subsequent repair. A summary of various macrophage-related functions is broadly classified into 7 major categories:

1. Phagocytosis
2. Release of reactive oxygen species that result in cellular killing specifically related towards bacterial lysis
3. Release of nitric oxide that is deadly to several otherwise antibody-resistant bacteria
4. Cytokine release of interleukins (IL1, IL2, IL4, and IL12)
5. Angiogenesis via VEGF that promotes capillary budding
6. Recruitment of other cells into the wound that continue the healing process
7. Different homeostatic roles of macrophages and Langerhans cells, including wound repair, follicle regeneration, salt balance, and cancer regression and progression in the skin

Interestingly, the inflammatory phase determines the difference between chronic and acute wounds. Uncomplicated wounds heal within 4 to 6 weeks. If they continue to remain nonhealing beyond this time, they are termed chronic. Several local and systemic factors affect the inflammatory phase of wound healing directly. These include pressure, tissue hypoxia, infection, tissue contamination, desiccation, and maceration. Systemic factors include age, stress, and comorbid conditions such as diabetes, vascular insufficiency, immunocompromise, malnourishment, obesity, and smoking. The common thread, however, in all nonhealing chronic wounds is *the persistence of proinflammatory conditions*. These specific tissue deficits result in a chronic cycle of chronically migrating inflammatory cells (PMNs, macrophages) that scavenge early healing tissue, degrade the newly formed matrix proteins, and then cyclically recover only to restart the inflammatory phase. This cycle leads to a chronically unstable wound that is unable to progress to the next phases of healing: cell proliferation, tissue remodeling, and resolution.

Biofilm One of the recent discoveries in the area of biofilm is an important microbial factor that impedes healing by affecting inflammatory processes in the wound-healing continuum. Biofilm comprises a colony of microorganisms enveloped with a matrix of extracellular polymers also known as extracellular polymeric substance (EPS) (Fig. 45-10). EPS affects chronic and acute dermal wounds. Its life cycle and effects on the bacterial colonies it protects are shown in Figs. 45-11 and 45-12. These include antibiotic resistance; latency (the ability to enter into latent states during inhospitable conditions); increasing species diversity; and quorum sensing (bacteria in the biofilm engage in a type of decision-making process in which behavior is coordinated through a “chemical” vocabulary).

Proliferation. This phase is arguably the first step towards restoration of tissue continuity. It is characterized by the production of extracellular matrix by the fibroblast, the most prominent cell type in the proliferative phase. Fibroblasts are

Figure 45-10. Slough that also comprises biofilm.

Figure 45-12. Biofilm is a barrier to wound healing.

the architects of wound healing and appear in the wound right at the end of the inflammatory phase. Collectively, fibroblasts support several major functions that lead to tissue repair, including the formation of collagen and the structural creation of the extracellular matrix. The formation of fibrin and fibronectin that is precipitated from the blood clot results in the formation of a provisional extracellular matrix that serves as a scaffold. Typically, this matrix can be compared to the framework of

a building without any walls or windows. The protein scaffold serves as a solid framework that subsequently hosts cells including human macrophages and fibroblasts. Simultaneous VEGF-derived angiogenesis promotes the formation of small vascular loops, known as capillary buds, that proliferate within the fibroblast matrix. Paradoxically, the major activating factor responsible for the formation of capillary buds is *low oxygen tension*. Poor oxygenation of the tissues increases

Figure 45-11. The lifecycle of biofilm.

the expression of hypoxia inducible factor (HIF) by endothelial cells. Specific DNA sequences of cells that regulate angiogenesis are turned on by HIF. This paradoxical negative loop is directly related to a low oxygen tension within the tissues. Subsequent release of the epidermal growth factor EGF and the transforming growth factor TGF- α by several cell types, including macrophages, platelets, and keratinocytes, strengthen the newly formed extracellular matrix. Once a robust scaffold is built, the epidermal cells from the edges of the wound on all sides migrate towards the center of the wound. This process is facilitated by several factors, including angiogenesis, neovascularization, and the release of fibroblast growth factor TGF- β and epidermal growth factor. The formation of the extracellular matrix is the key process that leads to subsequent reepithelialization. The extracellular matrix is primarily made of collagen. The different types of collagen that occur more predominantly in different types of tissues characterize the type of healing that occurs. Specifically, type I is present in scar tissues. After the formation of collagen, the fibers are now attached to form a provisional fibrin matrix. After a variety of complicated signaling that includes the transcription and processing of collagen messenger RNA, the collagen gets attached to hydroxylation of protein and lysine. The hydroxyproline in the collagen is responsible for the stable helical confirmation that is critical for the formation of a robust strong scar. It then transforms itself into a classical triple helical structure that is subsequently modified through glycosylation. It is important to realize that increased collagen stability is directly related to the degree of hydroxylation of the collagen and that fragile forms of collagen (which result in a fragile scar) are largely due to increases in nonhydroxylated collagen forms. Certain diseases including scurvy (vitamin C deficiency) or other diseases that are predominantly anaerobic in their nature can cause the formation of weak nonhydroxylated collagen, which is fragile and can easily undergo denaturation and lysis.

The next step is the cleavage of the procollagen N and C terminal peptides. A very important extracellular enzyme called *lysyl oxidase* is responsible for the strengthening of collagen by the formation of strong, stable cross-linkages. Microscopic examination of stable mature scars reveals that strong cross-linkages present in the intramolecular and the intermolecular compartments directly correlate with strength and stability. Epidermal cells migrate over the scaffold, and after the epithelial bridge is completed, enzymes are released to dissolve the attachment at the base of the overlying scab that falls off.

Contraction is one of the key end phases of proliferation. Typically, contraction starts approximately 7 days from tissue injury, when the fibroblasts differentiate into myofibroblasts. Myofibroblasts are similar to smooth muscle cells, have the same amount of actin (responsible for mobility), and are responsible for contraction it peaks at around 10 days post injury but can continue for several weeks. Myofibroblasts attach to the extracellular matrix (ECM) at the wound edges and to each other as well as to the wound edges via desmosomes and the fibronexus, through which actin in the myofibroblast is linked across the cell membrane to molecules in the extracellular matrix like fibronectin and collagen. This in turn facilitates the myofibroblasts to pull the ECM when they contract, thus reducing the wound size. Wounds contract at the rate of 0.75 mm to 1 mm daily. The formation of a strong, contracted, cross-linked collagen scar with reepithelialization heralds the end of the proliferative phase. Contraction usually does not occur symmetrically; instead, most

wounds have an “axis of contraction” that allows for greater organization and alignment of cells with collagen.

Remodeling/Maturation. The remodeling phase is also termed the *maturation phase*. It is primarily characterized by the remodeling of collagen through a balance between collagen formation and collagen lysis that results in the formation of a strong scar. Biochemically, the collagen is remodeled from type III to type I and is also accompanied by complete reepithelialization of the wound. The lysis of collagen is mediated by collagenases that are secreted by various cells—fibroblasts, neutrophils, and macrophages—each of which can cleave the collagen molecule at different but specific locations on all three chains and break it down to characteristic three-quarter and one-quarter pieces. These collagen fragments undergo further denaturation and digestion by other proteases. There is significant remodeling of the collagen during this process. It is aligned along tension lines, and significant reabsorption of water from the collagen fibers result in a denser alignment and stronger cross-linking. The remodeling phase establishes a new equilibrium with the formation of an organized scar. Several molecules, including TGF- β , which induces intracellular signaling of SMAD proteins, play an important role in the remodeling phase. Using SM 80 knockout mice and transgenic animals, a critical role of the SMAD pathway in the formation of scar has been delineated. This process is also facilitated by apoptosis and programmatic cell death, which helps to former a thinner scar that is stronger and more cosmetically appealing. This phase begins 3 weeks after the injury and continues for over 1 year. One must realize that despite the best cross-linking, scar tissue is weaker than injured skin and regains only 80% of its uninjured tensile strength. As it matures further, it becomes less red and less vascular because the reduced biologic activity within the scar renders the vascular capillaries redundant and they apoptose.

RECONSTRUCTIVE SURGERY

Reconstructive surgery restores normal anatomy and function using plastic surgery methods of tissue repair, rearrangement, and replacement. Tissues can be missing or damaged as a consequence of trauma, cancer, degeneration, congenital abnormalities, and aging. The primary adverse consequence of lost or impaired tissue is functional disability, which includes physical, psychologic, or social dysfunction. The clinical objective is to reestablish normal anatomy, function, and appearance in order to restore the patient as closely as possible to normal health. The most useful techniques transfer and modify tissues in the form of tissue grafts and surgical flaps.

RECONSTRUCTIVE STRATEGIES AND METHODS

The main aim of wound healing is to achieve a closed wound. Ordinarily, wounds heal via three main mechanisms:

1. **Primary intention:** This type of healing occurs in a clean wound without any apparent tissue loss. Mostly seen in surgical incisions that have been approximated (primary closure), healing by primary intention can only be implemented when the closure of the wound is precise and there is minimal disruption to the local tissue or the epithelial basement membrane. Typically, this wound seals off within 24 hours. Healing is faster than healing by secondary intention, and there is the least amount of scarring.

2. *Secondary intention*: Tissue loss following major trauma results in the formation of granulation tissue, which results in a broader scar (see earlier section, “Phases of Wound Healing”).
3. *Tertiary intention (delayed primary closure or secondary suture)*: The wound is initially cleaned, debrided, and observed, typically 4 or 5 days before closure. Examples of this type of healing include healing through the use of tissue grafts, including skin grafts and substitutes.

Skin Grafts and Skin Substitutes

Skin grafting methods date back millennia to ancient India, where they were used to resurface nasal defects. They were introduced in the modern era by Guisepppe Baronio, an Italian physician who studied skin grafting techniques in sheep and published his work entitled *Degli Innesti Animali (On Grafting in Animals)* in 1804.⁴

It is important to know the basic anatomic structure of skin in order to understand the principles of skin grafting. Skin is comprised of the epidermis, the dermis, specialized sensory nerve endings, and various skin appendages that lubricate and protect the skin as well as contribute to functions such as thermoregulation. The epidermis is a layer of cells that affords primary barrier function. It begins with a layer of cells called the basal layer. These are cuboidal-shaped cells that multiply and differentiate into flattened, keratinized squamous cells, which progressively migrate from the basal layers until they are finally released from the surface in a process known as *desquamation*. The junction between the dermis and the epidermis is composed of projections from the dermis into the epidermis, which are called *dermal papillae*. This feature secures the epidermis to the dermis by resisting sheer forces transmitted from the skin surface, helping to prevent separation of the epidermis from the dermis. The dermis contains sebaceous glands, whereas sweat glands and hair follicles are actually located below the dermis in the subcutaneous tissue and traverse the dermis and epithelium to reach the body surface. The dermal thickness and concentration of skin appendages vary widely from one location to another on the body. The blood supply to the skin occurs in a variety of patterns that form the basis for transferring tissue-containing skin, which will be discussed later in this chapter. Regardless of the pattern, there is a network of vessels just below the dermis called the *subdermal plexus* that supplies the skin immediately above and is important in thermoregulation. Finally, terminal vessels and capillaries fill the dermis and penetrate the dermal papillae to perfuse the cellular elements of the dermis and epidermis.

Skin grafting methods include split-thickness skin grafts (STSG), full-thickness skin grafts (FTSG), and composite tissue grafts. Each has its advantages and disadvantages, and selecting the best technique for a given circumstance depends on the reconstructive requirements, the quality of the recipient wound bed, and the availability of donor site tissue.

Split-Thickness Grafts. An STSG is the simplest method of tissue transfer. The name is derived from how these grafts are harvested by cutting through (i.e., splitting) the dermis at various levels. Thin STSGs are harvested through the superficial levels of the dermis. Thick grafts are harvested through deeper layers and include a larger amount of dermal tissue. The important characteristics of STSGs are determined by the thickness of dermis present in the graft. Thin grafts undergo less primary

contraction after harvest because they contain fewer elements of the dermal extracellular matrix such as elastic fibers. Thick grafts undergo greater amounts of primary contraction. This is important to remember when harvesting the graft because it is necessary to obtain sufficient tissue in order to restore the defect. On the other hand, thin grafts allow the wound to undergo a greater amount of contraction in a process traditionally referred to *secondary contraction* of the graft. This becomes important if the wound is adjacent to a mobile structure such as the oral commissure, which might be distorted as healing progresses. Thin grafts also have improved chances of complete engraftment, or “taking,” as they contain mostly epidermis, which has low metabolic demands, in contrast to thicker grafts that contain more dermis with greater metabolic needs.

A variety of techniques have been described to maximize the surface area that can be covered by harvested skin amount while minimizing the size of the donor site.⁵ One approach is to process the harvested skin into micrografts using devices specially designed for this purpose in the operating room. Another method is fractional skin harvesting, which involves harvesting a large number of full-thickness skin tissue columns that are then seeded onto the wound surface. The traditional method, however, is to mesh the graft. Meshed grafts usually also have enhanced reliability of engraftment because the fenestrations allow for egress of wound fluid and excellent contour matching of the wound bed by the graft. The fenestrations in meshed grafts must epithelialize by secondary intention from the surrounding graft skin. The major drawbacks of meshed grafts are poor cosmetic appearance and high rates of secondary contraction. Meshing ratios used usually range from 1:1.5 to 1:6, with higher ratios associated with magnified drawbacks related to meshing. For any case, a decision to mesh the graft must be balanced against the disadvantages. Other differences between thin and thick STSGs include final durability, pigmentation, and tendency to desiccation of the final result. The distinguishing characteristics of skin grafts types based on thickness are summarized in Fig. 45-13.

STSG donor sites heal by regeneration from dermal and epidermal elements remaining in the harvest site. Recesses between dermal papillae projecting into the dermis are lined by basal cells. These cells migrate across the wound surface and

Figure 45-13B. Characteristics of skin grafts.

reepithelialize it. During this process, the donor site must be kept moist and free of bacterial contamination. Depending on the thickness of the graft, uncomplicated donor site epithelialization typically is complete in 2 weeks. In most cases, it should be protected from mechanical shear and drying until the new skin matures with epidermal and dermal thickening and reactivation of sebaceous and sweat glands. Part of managing the donor site includes minimizing pain. Some recommended treatments include (a) subcutaneous anesthetic injection of adrenaline-lidocaine; (b) ice application; (c) topical agents such as lidocaine and bupivacaine; and (d) hydrocolloid- and polyurethane-based wound dressings accompanied with fibrin sealant.⁶ Maintaining air-tight coverage using transparent adhesive film dressing can protect the donor site during reepithelialization and minimize pain.

Full-Thickness Grafts. By definition, full-thickness skin grafts include the epidermis and the complete dermis. When harvesting and preparing this type of skin graft, the surgeon must carefully remove any retained subcutaneous tissue from the deep surface of the dermis in order to maximize the potential for engraftment. Full-thickness grafts are associated with the greatest amount of primary contraction, the least amount of secondary contraction, the highest durability, and ultimately the best cosmetic appearance. As a result, they are frequently used in reconstructing superficial wounds of the face and the hands. These grafts require clean, well-vascularized recipient beds free of bacterial colonization, previous irradiation, or fibrous wound tissue. They also work poorly in wounds associated with previous radiation treatments in cancer patients. The harvest site for an FTSG must be closed primarily because no skin elements remain in the area of harvest.

Skin Substitutes. Skin substitutes are typically types of extracellular matrices that are often acellular in nature and are either human-derived (allografts), animal-derived (xenografts), tissue engineered, or a combination of the three.⁷ These substitutes most often are employed to replace lost dermal and/or epidermal skin layers resulting from burns, trauma, and other superficial injuries to the outer skin layers. While a complete review of all of these commercially available materials is beyond the scope of this chapter, the benefits and applications of these useful adjuncts is growing, and they have shown to play an important role in current as well as future reconstructive, regenerative, and restorative measures for tissue and skin replacement. Essentially, they act similarly to grafts as they rely on

revascularization and autologous cell repopulation of the construct in order to “take” and become part of the lost anatomic structure they are acting to restore.

Graft Take. Skin graft healing, or “take,” occurs in three phases: imbibition, inosculation, and revascularization. Plas-matic imbibition takes place during the first 24 to 48 hours after placement of the graft onto the defect. During this time, the graft is held in place by a thin film of fibrin, and the cellular elements survive by diffusion of oxygen and substrate from plasma present in the open wound. After 48 hours, a fine vascular network forms from capillaries and small blood vessels in the wound bed and advances through the fibrin layer toward the graft. These new vascular buds encounter open, cut end vessels on the deep surface of the dermis of the graft and line up, forming loose anastomoses that begin to allow blood flow and the transfer of some nutrients and oxygen. This phase is called *inosculation* and is the period during which the graft is most at risk for failure. If the tenuous alignment of vessels between the wound bed and the graft are disrupted, then the final phase of healing will not occur. Events that can cause graft failure at this time include mechanical shear, formation of a seroma or hematoma, or bacterial contamination. The final phase of engraftment is called *revascularization*. During this phase, firmer vascular anastomoses are formed as the vessels heal, and the graft becomes perfused from the wound bed. Signs of perfusion, such as improved coloration and evidence of capillary refill, confirm engraftment and graft take. In most circumstances, these phases are complete by 4 to 5 days after graft placement. The dressing used after placing the skin graft is a critical part of success. It must prevent desiccation and shear stress from disrupting the graft, especially during the critical period of inosculation. Tie-over bolster dressings are a traditional method. Topical negative pressure wound dressings have been demonstrated to increase quantity and quality of split-thickness skin graft take compared to traditional bolster dressings. The benefits are particularly evident in wounds with irregular surface contours in areas that might be difficult to avoid motion.⁸

After skin graft take, the graft remains subject to late failure due to mechanical shear, desiccation, or bacterial infection. Depending on the location and clinical setting, the graft should continue to be protected using dressings, topical moisturizing creams, or antibacterial medications as indicated until stable healing obtains in up to 2 weeks.

Composite Grafts. Composite grafts contain other types of tissue besides skin. Additional elements must have low metabolic requirements in order to survive the time required for revascularization. Composite grafts might include subcutaneous fat, cartilage, perichondrium, and small amounts of muscle. Indications for composite grafts are limited to small areas with specialized tissue requirements such as nasal reconstruction. For example, excision of a skin cancer involving the nasal lobule may create a composite defect that involves internal nasal lining, supporting nasal cartilage, and external skin. The ear is a good donor site for a composite graft of tissue with a good color match for the face and small amounts of tissue configured naturally to simulate the contours of the nose. For example, harvest of tissue from the root of the helix of the ear causes a relatively inconspicuous donor site. The donor site for composite tissue grafts must be repaired with primary closure.

Surgical Flaps. A surgical flap is a unit of tissue harvested from a donor site and transferred to another location for

reconstructive purposes. The term “flap” is derived from techniques of adjacent skin tissue transfers fashioned as flaps of skin that were elevated and folded into the defect. The distinguishing feature of a surgical flap is having a blood supply independent of the injured area. A graft must go through the phases of healing described previously as it derives a new blood supply from the wound bed. A flap is brought to the wound with its own blood supply. This allows restoring tissue in areas of poor blood supply or with tissue requirements greater than what can be supported through a period of diffusion only.

There are a tremendous variety of surgical flaps that can be created depending on the individual patient’s reconstructive needs and available tissues. The challenge of reconstructive surgery is to design an appropriate flap to restore the defect with a minimal amount of morbidity related to the flap donor site. The different kinds of flaps can be broadly classified by three distinct characteristics: (a) the types of tissue contained, (b) the proximity to the defect, and (c) the pattern of blood supply.

The first way to classify different types of surgical flaps is by what tissue they contain. Nearly any type of vascularized tissue can be transferred as a surgical flap. One of the most common is a cutaneous flap, which contains skin and subcutaneous tissue. Another versatile type is a muscle flap, which contains only muscle. Musculocutaneous flaps contain a portion of muscle along with the overlying skin and all the intervening tissues. An osseous flap contains a segment of bone, and an osteocutaneous flap includes skin as well as the bone. Flaps can also be designed to include fascia and peripheral nerves. Visceral flaps contain segments of jejunum, stomach, colon, or the greater omentum. The choice of flap depends upon the reconstructive needs and availability of tissue.

The second way to classify surgical flaps is by their proximity to the defect. The location and distance between the flap donor site and the defect usually dictate the method required to transfer the tissue with preservation of the blood supply. Local flaps have a donor site located immediately adjacent to the defect.⁹ Regional flaps are harvested from the same anatomic region as the defect. Distant flaps are harvested and transferred from outside the anatomic region of the defect. During the transfer of all of these flaps, the blood supply remains attached to the source anatomic region. The tissue transmitting the blood supply is called the *flap pedicle*. When the blood supply is not divided during the transfer, it is referred to as a *pedicled flap*. If the distance between the donor site and the defect exceeds the length of the pedicle, the vessels can

be divided and then reattached to uninjured vessels within or adjacent to the defect after the tissue is placed there. This technique is called a *free tissue transfer*, and flaps transferred in this fashion are called *free flaps* because for some period of time during the procedure the tissue of the flap is completely separated, or free, of the patient. The diameter of the blood vessels that supply common surgical flaps is usually less than 5 mm. Repairing blood vessels of this caliber is considered microvascular surgery, and techniques for doing this are part of reconstructive microsurgery.

The third and perhaps most important way to classify different surgical flaps is by the pattern of their blood supply.¹⁰ Using this criterion, flaps are traditionally divided into random pattern flaps, axial pattern flaps, musculocutaneous flaps, fasciocutaneous flaps, direct cutaneous flaps, perforator flaps, and free flaps. These designations are based on how vessels reach from the deeper, usually named, arteries and veins to the superficial tissues and skin. These are described in greater detail in the following section.

Random Pattern Flaps. The simplest flap designs are random pattern flaps, so named because the blood supply is based on unnamed vessels in the attached base of the flap that perfuse through the subdermal plexus.¹¹ Random flaps are typically used to reconstruct relatively small, full-thickness defects, and they are designed following geometric principles of skin rearrangement with a traditional length-to-width ratio of 3:1. Exceptions to this principle regarding reliable dimensions abound, however, because of the variability in the patterns of perfusion and the density of the subdermal plexus in different regions of the body.

Random pattern flaps can be further subdivided based on the geometry of the transfer. Examples of this are transposition flaps, advancement flaps, and interpolated flaps. A transposition flap is fashioned adjacent to an area needing reconstruction and rotated into the defect. Large transposition flaps can require a skin graft to close the donor site. To avoid this problem, specialized types of transposition flaps have been devised. One that is particularly useful is called a Z-plasty. In this technique, two flaps are rotated, each into the donor site of the other, to rearrange the tissues in a way that redirects the lines of tension and lengthens the central limb. Another is the rhomboid (Limberg) flap (Fig. 45-14). In this technique, a skin flap is precisely designed with opposing 60° and 120° angles at the corners of a rhomboid designed immediately adjacent to the defect. This design can be modified to allow the flap to rotate into the defect

Figure 45-14. Limberg flap.

1978 with primary closure of the donor site with minimal distortion of the surrounding tissues as shown in the case of a gluteal repair (Fig. 45-15A–B, by complex closure; Fig. 45-15C–E, by modified Limberg flap). Modifications on the angle, including the Dufourmental modification, cause the parametric configuration to be optimized based on the defect¹² (Fig. 45-16). Rotational flaps are a type of transposition that is semicircular in design,

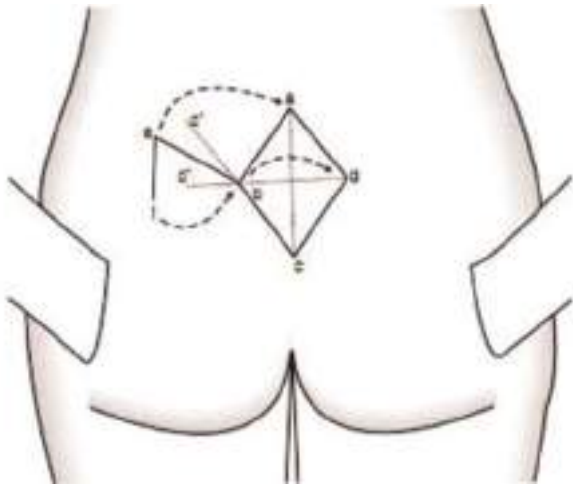

allowing the tissue to be rotated and permitting primary closure. Advancement flaps differ from transposition flaps because the tissue is moved forward from the donor site along the flap's long axis rather than being rotated about a point. Two common variants include the rectangular advancement flap (Fig. 45-17) and the V-Y advancement flap (Fig. 45-18). Finally, interpolation flaps rotate about a pivot point but are used to transfer tissue

into a nonadjacent area with an intervening portion of undamaged tissue between the donor site and the defect (Fig. 45-19).

Axial Pattern Flaps. Historically, surgeons made an increasing variety of surgical flaps to address a greater assortment of reconstructive problems. In the process, they noticed that some of these flaps routinely violated the strict limitations of accepted length-to-width ratio. Further investigation demonstrated that these flaps had significant arteries running parallel to the long axis of the flap. These flaps became known as *axial pattern flaps*.¹² The earliest example of this type of flap is the deltopectoral flap, originally described in 1971 by Bakamjian (Fig. 45-20A,B). This flap is based on cutaneous vessels perforating from inside the chest from the internal mammary artery and vein. After entering the subcutaneous tissues, they travel obliquely from the sternal border toward the deltoid area of the arm. Long flaps can be designed based on these vessels, which can reach into the head and neck to provide thin tissue from the upper chest to restore defects, especially after tumor ablation. Other important and useful axial pattern flaps are the groin flap and the posterior thigh flap.

Musculocutaneous Flaps. The vascular pattern of musculocutaneous flaps arises from major vessels that primarily supply a muscle and then secondarily supply the skin through multiple small vessels traversing between the superficial surface of the muscle and the subdermal plexus. The discovery of this pattern of cutaneous blood supply was a major breakthrough in reconstructive surgery because it made it possible to transfer units of tissue much larger than was possible with random or axial pattern flaps, enabling plastic surgeons to restore a greater range of deformities. Mathes and Nahai classified individual muscles into five types (I–V) according to the number and dominance of the vascular pedicles supplying each¹³ (Table 45-1).

Figure 45-17. Rectangular advancement flap.

Figure 45-18. V-Y flap closure.

There may be advantages to including muscle in a surgical flap besides ensuring adequate blood supply to the overlying skin. The classic example is breast reconstruction using a latissimus dorsi myocutaneous flap (Fig. 45-21A–C). Here, the latissimus muscle is harvested pedicled on the thoracodorsal vessels and transposed anteriorly onto the chest wall. Muscle is a highly vascularized tissue that is bulky and deformable. It can help to repair visible surface contour deformities by increasing the projection of tissue in the defect to reach the level of the surrounding undamaged tissues. It can also easily contour to fill spaces in a complicated wound surface, thus helping to prevent small fluid collections in recesses, which can be a harbor bacteria and become a nidus of infection. It is also possible to provide functional restoration using musculocutaneous flaps by coapting the motor nerve of the muscle in the flap to a corresponding motor nerve in the defect. This method can be used to restore motor function in patients with motor loss in the extremities or face.

Fasciocutaneous Flaps. Rather than having a blood supply primarily from underlying muscle, the skin and subcutaneous tissues of some anatomic regions are supplied from vessels communicating with the underlying superficial or deep fascia. Such flaps are referred to as *fasciocutaneous flaps*. The artery and vein of the flap pedicle passes between rather than through muscles, form a plexus of vessels within the fascia, and then send multiple small vessels to the subdermal plexus to perfuse the skin. There are clinical circumstances when a fasciocutaneous flap might have advantages over a musculocutaneous flap. Fasciocutaneous flaps are usually thinner compared to musculocutaneous flaps. They also do not create a functional loss of muscle in the donor site. Mathes and Nahai classified fasciocutaneous flaps into types A, B, and C (Table 45-2) based on how the vascular pedicle reaches the fascia from the major vessels deep to the fascia and muscles. Sural perforator fasciocutaneous flaps (Fig. 45-22A–D) are a modern example of reconstructing lower extremity defects that would be difficult to reconstruct without microvascular surgery.

Direct Cutaneous Flaps. Some surgical flaps have a vascular pedicle that reaches directly to the superficial tissues and subdermal plexus without passing through a muscle or fascia plexus. These are called *direct cutaneous flaps*.

Perforator Flaps. The final kind of surgical flap classified by the pattern of blood supply is the perforator propeller flap.^{14,15} The geometric measurements that are critical to its success are summarized in Fig. 45-23. Reconstructive procedures based

Figure 45-19. Forehead flap for nasal reconstruction.

on these flaps are the result of complementary advances in our understanding of cutaneous blood supply and improved surgical techniques.

Ian Taylor and a team of investigators from Melbourne, Australia, discovered that the blood supply to all portions of the skin was organized into discreet units, which they called *angiosomes*¹⁸. Analogous to dermatomes that describe the patterns of cutaneous sensation supplied by single sensory nerves, the cutaneous perfusion is organized into angiosomes supplied by a single arteries. These arteries arise from source blood vessels located deep to other structures like muscle and fascia and penetrate through as perforating vessels. Often the artery is accompanied by two venae comitantes, but in many regions an additional venous drainage system is present in the superficial planes. The territories of adjacent angiosomes overlap similarly to how dermatomes overlap. An angiosome is defined by the limits of an artery's terminal branching. At the

borders, these arterioles form anastomoses with the neighboring angiosome. The vessels that pass between these anatomic angiosomes are called *choke vessels*. In life, these may open or close in response to physiologic changes in order to increase or decrease, respectively, an artery's dynamic angiosome momentarily. Accordingly, at any given time point, the dynamic angiosome of an artery may be approximated by the volume of tissue stained by an intravascular administration of fluorescein into that artery (indicating the reach of blood flow from that artery into tissues). The potential angiosome of an artery is the volume of tissue that can be included in a flap that has undergone conditioning (see the following section). Both the dynamic and potential angiosomes extend beyond the anatomic angiosome of an artery. Although the angiosome concept provides some guidance to the size and volume limits of a flap harvest, there remains no quantifiable method to predict safe flap harvest limits with precision.

A

B

Figure 45-20A, B. Deltopectoral flap for cheek reconstruction.

Tissue Expansion. Tissue expansion is a technique that increases the amount of tissue in a surgical flap by first placing an inflatable device into the tissue beneath the planned flap and gradually expanding the tissue by regular inflation. Staged reconstruction using tissue expansion can significantly increase the amount of local, well-matched tissue for transfer while decreasing donor site morbidity. The most common method of skin expansion involves the placement of an inflatable silicon elastomer similar to a balloon with a filling port that is generally positioned in an easily accessible location beneath the skin. After wound healing, the device is gradually inflated by serial injections of sterile saline solution into the filling port. The

Table 45-1

Mathes-Nahai classification of muscular flaps

CLASSIFICATION	VASCULAR SUPPLY	EXAMPLE
Type I	One vascular pedicle	Gastrocnemius
Type II	Dominant and minor pedicles (the flap cannot survive based only on the minor pedicles)	Gracilis
Type III	Two dominant pedicles	Rectus abdominis
Type IV	Segmental pedicles	Sartorius
Type V	One dominant pedicle with secondary segmental pedicles (the flap can survive based only on the secondary pedicles)	Pectoralis major

process can require several weeks, depending on the amount of expansion and compliance of the tissues. When expansion is complete, the expander is removed, and the resulting expanded tissue is transferred into the defect.

The process of expanding flaps confers physiologic benefits that increase the reliability of the flap tissue. Histologically, expanded skin demonstrates thickened dermis with enhanced vasculature and diminished subcutaneous fat. Studies have shown that the increased amount of skin is the result of actual generation of new tissue. Also, the blood supply to an expanded flap is improved because of the period of delay associated with expansion process and the capsule formed around the device is highly vascular and contributes to the quality of blood supply.¹⁶

The disadvantages of tissue expansion have to do with possible complications, which include infection, hematoma, seroma, expander extrusion, implant failure, skin necrosis, pain, and peripheral nerve injury. Furthermore, an inflated expander is visible, and the temporary deformity may cause patients distress.

Tissue expansion has found particular usefulness in managing giant congenital nevi, secondary reconstruction of extensive burn scars, scalp reconstruction, and breast reconstruction. Expanders are available in a multitude of shapes and sizes, depending on the reconstructive needs. The technique permits reconstruction with tissue of similar color, texture, and thickness, with minimal donor site morbidity.

PEDIATRIC PLASTIC SURGERY

Congenital Craniofacial Anomalies

In 1981, Whitaker et al introduced a simple classification system to help conceptualize the vast array of congenital pathology involving the craniofacial region.¹⁷ Based on anatomy, etiology, and current treatment principles, most craniofacial anomalies can be classified into one of four categories: clefts, synostoses, atrophy-hypoplasia, or hypertrophy-hyperplasia-neoplasia (Table 45-3).

Clefts. Arguably, no operation in plastic surgery is more demanding of reconstructive principle and aesthetic intuition

B Preop, right mastectomy and left previous implant reconstruction

C Postoperative: bilateral latissimus flap with implant

Figure 45-21. Breast reconstruction (right side) with a latissimus flap.

than a cleft lip repair. Orofacial clefting is the most common birth defect in the world. Cleft lip, with or without cleft palate (CL/P), occurs spontaneously among Caucasian populations in approximately 1 out of every 1000 births. It is over twice as common (1 in 450) among Asians and Native Americans and

half as common (1 in 2000) in African Americans. There is a predilection among males, who are twice as likely to be affected as females. Left-sided cleft lip is twice as common as right and nine times as common as bilateral. Of patients born with CL/P, 29% have associated anomalies, which can range from minor physical differences to major organ involvement. While a family history of CL/P remains the strongest known predictive factor, other extrinsic risk factors include maternal smoking or early exposure to the anticonvulsant drug phenytoin.¹⁸

Epidemiologically, isolated cleft palate (CP) appears to be distinctly different from CL/P. CP occurs in 1 of every 2000 live births. It is twice as common in females, and it demonstrates no racial or ethnic preponderance. Nearly half of patients with isolated CP have a diagnosable syndrome and additional congenital anomalies. Evaluation by a geneticist is therefore indicated in all babies born with isolated CP. Like CL/P, isolated CP is multifactorial. Known environmental risk factors include maternal smoking or alcohol consumption, folate deficiency, use of steroids or anticonvulsant medications, or retinoid (vitamin A) excess.

Some familial patterns of orofacial clefting have been linked to specific genetic mutations. Van der Woude syndrome, an autosomal dominant form of CL/P associated with lower lip pits, is caused by an *IRF6* gene mutation (Fig. 45-24).²³ Stickler syndrome should be suspected in patients with isolated CP,

Table 45-2

Nahai-Mathes classification of fasciocutaneous flaps

CLASSIFICATION	VASCULAR SUPPLY	EXAMPLE
Type A	Direct cutaneous vessel that penetrates the fascia	Temporoparietal fascial flap
Type B	Septocutaneous vessel that penetrates the fascia	Radial artery forearm flap
Type C	Musculocutaneous vessel that penetrates the fascia	Transverse rectus abdominis myocutaneous flap

Figure 45-22. Reconstruction of a lateral malleolar defect using a reverse sural perforator flap.

with associated eye defects, sensorineural hearing loss, and joint abnormalities. This constellation of findings is due to an autosomal dominant mutation in a procollagen gene. Stickler is also the most common syndrome associated with Pierre Robin sequence (micrognathia, glossoptosis, and respiratory distress).¹⁹ These examples help emphasize the importance of early genetic workup for patients in whom a syndrome is suspected.

Embryology of the Lip and Palate The “primary palate,” which includes the nostril sill, upper lip, alveolus, and hard palate anterior to the incisive foramen, forms from fusion between the medial nasal and maxillary prominences during weeks 4 through 7 of gestation.^{20,24} Development of the hard palate posterior to the incisive foramen and the soft palate, which are collectively known as the “secondary palate,” occurs during weeks

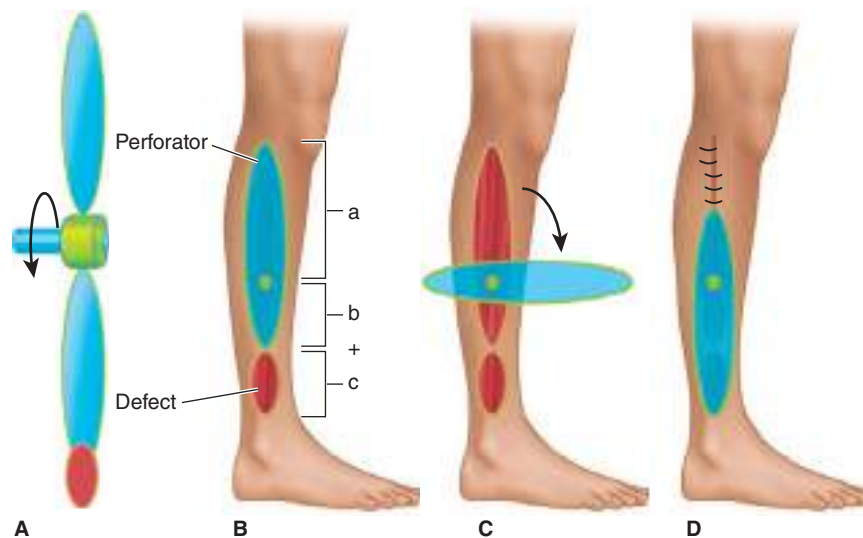

Figure 45-23. Geometric considerations for a propeller flap.

Table 45-3

Classification of craniofacial anomalies²¹

1. Clefts
2. Synostoses
3. Atrophy–hypoplasia
4. Hypertrophy–hyperplasia–neoplasia

6 through 12 of gestation. The lateral palatine processes initially hang vertically on either side of the developing tongue. Around week 8, these palatal shelves rotate into a horizontal orientation, bringing their free edges into close proximity with the nasal septum. Midline fusion then commences, proceeding posteriorly from the incisive foramen (Fig. 45-25).²³

Normal and Cleft Anatomy There are several key defining characteristics of the lip that make its surgical repair so challenging. On the surface, the philtrum of the upper lip is comprised of paired philtral columns and a central philtral dimple. The white roll passes along the vermilion-cutaneous junction, peaking at the base of the philtral columns and dipping centrally to form Cupid’s bow. Deep to the surface, the paired orbicularis oris muscles originate lateral to the oral commissures and encircle the mouth, decussating in the midline and sending off dermal insertions to the philtrum. This intrinsic muscle of the lip provides oral competence and assists with speech production and facial expression. Continuity of the orbicularis oris muscle is disrupted in babies born with a cleft lip. Aberrant muscle insertion into the piriform aperture laterally and the anterior nasal spine medially contributes to the hallmark appearance of cleft lip and nasal deformity (Fig. 45-26).^{20,25}

Clefts of the lip can be described as unilateral or bilateral and microform, incomplete, or complete. Microform cleft lip is the most minor variant and may manifest as subtly as a small notch in the vermilion. An incomplete cleft lip, by definition, requires an intact nasal sill. The term can otherwise be applied to a wide spectrum of anomaly, ranging from a partial cleft of the lip alone (Fig. 45-27A) to a near-complete cleft of the entire primary palate. A complete cleft lip involves all structures of the primary palate in their entirety, extending through the nasal sill and opening into the anterior nasal floor (Fig. 45-27B).^{20,26}

The normal palate functions primarily as a speech organ, but it is also intimately involved in feeding, swallowing, and breathing. The soft palate, or velum, together with lateral and posterior pharyngeal walls, can be conceptualized as a valve

Figure 45-24. Van der Woude syndrome.

that regulates the passage of air through the nasopharynx. The paired levator veli palatini muscles descend from the cranial base and decussate in the midline to form a sling within the soft palate. This sling acts to elevate the velum against the posterior pharyngeal wall, effectively closing the velopharyngeal port. In patients with cleft palate, the levator muscles are unable to cross the midline. Instead, they run parallel to the cleft margin and insert aberrantly into the posterior edge of the hard palate (Fig. 45-28A,B). Air is allowed to leak through the nose during attempts to suck or speak. This inability to build negative or positive intraoral pressure makes either task difficult, if not impossible. The tensor veli palatini muscles, which normally function to vent and drain the Eustachian tubes, are also disrupted in cleft anatomy. Eustachian tube dysfunction predisposes patients to frequent bouts of otitis media, which can lead to permanent hearing loss if left untreated.²⁰

The most clinically useful system to describe cleft palate morphology is the Veau classification. A Veau I cleft is midline and limited to the soft palate alone, whereas a Veau II cleft may extend further anteriorly to involve the midline of the posterior hard palate (the “secondary palate”). A Veau III cleft is a complete unilateral cleft of primary and secondary palates, in which the cleft extends through the lip, the alveolus, the entire length of the nasal floor on the cleft side, and the midline of the soft palate. Veau IV clefts are bilateral complete clefts of the primary palate that converge at the incisive foramen and continue posteriorly through the entire secondary palate (Fig. 45-29A,B). Not included in the Veau classification is the submucous cleft palate, which occurs when there is clefting of the soft palate musculature beneath intact mucosa. Submucous cleft palate classically presents as the triad of a bifid uvula, a midline translucency called the “zona Pellucida” and a palpable notch of the posterior hard palate.²¹

Presurgical Infant Orthopedics Current literature suggests aesthetic outcomes in patients with complete unilateral or bilateral clefts may be improved by reestablishing more normal skeletal, cartilaginous, and soft tissue relationships prior to definitive lip repair. Presurgical infant orthopedics (PSIO) can help to narrow wide clefts and align dental arches in preparation for surgery. Some methods of PSIO, such as nasoalveolar molding (NAM), provide the added benefits of elongating the columella and improving nasal tip asymmetry.²² The most common barrier to PSIO implementation is its imposition on families, who must be willing and able to keep frequent follow-up appointments for appliance adjustment. An excellent alternative to PSIO is a lip adhesion procedure, in which a complete cleft is surgically converted to an incomplete cleft. This preliminary stage of lip repair restores soft tissue continuity at the nasal sill, which helps to realign the underlying dental arches and reapproximate the soft tissues. In addition, the nasal deformity can be improved, both by repositioning of the cleft side alar base and placement of nasal conformers.²³

Cleft Lip Repair Although cleft lip surgery can be traced to antiquity, it was not until the first half of the 20th century that surgeons began to realize the inadequacy of a straight-line repair. In 1955, Ralph Millard pioneered his “rotation-advancement” technique, which was the first to address upper lip length deficiency while preserving intricate philtral anatomy (Fig. 45-29C).²⁴ The back-cut is designed high on the medial lip element just beneath the columella, enabling a downward *rotation* and leveling of Cupid’s bow, while the lateral lip element is *advanced* into the

Figure 45-25. Facial prominences and their contributions to facial development. Cleft lip results from failure of fusion between maxillary and medial nasal (a component of frontonasal) prominences.

rotation defect. Although other techniques exist, most lip repairs performed today are minor modifications of Millard's original rotation-advancement principle.²⁰

Bilateral cleft lip presents an even greater set of challenges to the reconstructive surgeon. With no overlying orbicularis oris muscle, an unrestrained premaxilla rotates anteriorly, completely displacing the incisor-bearing portion of the alveolus from the maxillary dental arch. Orbicularis continuity must be restored over an often protuberant premaxilla. The surgeon must carefully recreate the appearance of a symmetrical philtrum and median labial tubercle. Prototypical markings for bilateral cleft lip repair are demonstrated in Fig. 45-30A,B.²⁰

Any surgical approach to bilateral cleft lip repair would be incomplete without addressing the nasal stigmata, which include a short or absent columella, a poorly defined and underprojected nasal tip, and malpositioned lower lateral cartilages.²⁵ Primary

nasoplasty at the time of lip repair has become an increasingly common practice. Nasal skin and soft tissue are dissected free from the underlying cartilaginous framework, allowing for suture manipulation of lower lateral cartilages to improve tip symmetry, support, and projection.²⁰

Cleft Palate Repair The primary goal of palatoplasty is to enable normal speech development. A successful palate repair is one that results in a robust, layered reconstruction of the cleft and restoration of functional velar anatomy. The two most common techniques employed for soft palate repair are intravelar veloplasty (IVV) and Furlow double-opposing Z-plasty. Paramount to each technique is the complete release of aberrant levator muscle insertions from the posterior edge of the hard palate. This maneuver untethers the velum anteriorly, enabling maximal levator muscle excursion in the superior and posterior directions postoperatively.²¹

Figure 45-26. Hallmarks of unilateral cleft lip deformity include depression of the nasal tip and flaring of the alar base on the cleft side, deviation of the caudal septum and columella toward the non-cleft side, and deficient lip height (short philtral column) on the cleft side with cephalad rotation of the cleft side of cupid's bow.

Intravelar veloplasty requires meticulous dissection of the levator muscles with retropositioning and reconstruction of the sling mechanism in the posterior aspect of the soft palate. A Furlow double-opposing Z-plasty involves cleverly designed mirror image Z-plasties on the oral and nasal sides of the soft palate where the central limb of each Z-plasty is the cleft. The posteriorly based flap of mucosa on each surface of the palate incorporates the underlying levator muscle. Transposition of these flaps across the cleft lengthens the palate and, in a manner similar to IVV, corrects levator malposition. Lateral relaxing incisions can be utilized to relieve tension on the closure, if necessary (Fig. 45-31A–C).^{21,31} In experienced hands, both techniques have demonstrated excellent speech outcomes and

low fistula rates. However, direct comparison between the two methods has been difficult due to ongoing evolution of the IVV technique and wide variability in the extent of dissection between performing surgeons.²⁶

Clefts involving the hard palate (Veau II–IV) often require additional maneuvers for reconstruction. Wide undermining of the nasal floor mucosa in the subperiosteal plane facilitates the nasal-side repair. As palatal mucoperiosteum is thicker and less pliable, the oral-side closure generally requires the use of relaxing incisions along the lingual side of the alveolar ridge. Additional medialization of the palatal soft tissue can be obtained by increasing isolation of the greater palatine neurovascular pedicle, which emerges from its foramen near the posterolateral aspect of the hard palate. Narrow Veau II clefts may be closed on the oral side by medialization of bilateral bipediced mucoperiosteal flaps (von Langenbeck palatoplasty), while wider clefts may require detachment of one or both flaps anteriorly for additional medialization (Bardach two-flap palatoplasty). Lateral relaxing incisions are left open, and typically heal by secondary intention within two weeks (Fig. 45-32).^{21,27}

Complications of palate repair include oronasal fistula, velopharyngeal dysfunction, obstructive sleep apnea, and mid-face growth deficiency. Reported fistula rates vary widely in the literature, but increased incidence has been correlated with less experienced surgeons, wider clefts, and bilateral clefts.^{21,22} Few oronasal fistulae are amenable to closure with simple local tissue rearrangement. More commonly, a complete reelevation of palatal mucosa is required in order to obtain a tension-free layered closure. In the case of large or recurrent fistulae, there may be insufficient tissue available locally, and recruitment of regional healthy tissue from the buccal mucosa or tongue may be necessary.³²

Velopharyngeal dysfunction (VPD) is caused by incomplete closure of the velopharyngeal port, which results in air leaking through the nose during speech. Approximately 20% of patients develop VPD after primary palatoplasty. After insuring complete release and proper orientation of levator muscles, a posterior pharyngeal flap or a sphincter pharyngoplasty may be required to decrease the size of the velopharyngeal gap, allowing

Figure 45-28. Left unilateral complete cleft lip.

nasal air escape during speech.²¹ These operations carry a risk of obstructive sleep apnea, so preoperative polysomnography is indicated to rule out significant sleep-disordered breathing at baseline.

Timeline for Repair The longstanding debate regarding optimal timing for lip and palate repair is ongoing. Central to this controversy is the impact of early surgical intervention on speech outcomes and midface growth. Current evidence suggests earlier palate repair is better for speech but more detrimental to midface growth.²¹ Cleft care algorithms represent a compromise. Most experts perform lip repair between 3 and 6 months of age.^{33,34} Palate repair should be completed prior to the onset of speech development, usually around 10 to 12 months of age. The alveolar cleft is often repaired secondarily with a cancellous bone graft from the iliac crest. This operation provides bony support for the permanent teeth that will erupt adjacent to

Figure 45-29. **A.** Normal anatomy: the levator veli palatini muscle forms a muscular sling in the posterior aspect of the soft palate. **B.** Cleft anatomy: the levator veli palatini muscles turn anteriorly, run along the cleft margin, and insert aberrantly into the posterior edge of the hard palate. **C.** Rotation-advancement markings and repair for a unilateral complete cleft lip.

the cleft, and it is usually performed around 7 to 9 years of age. Orthognathic surgery and secondary rhinoplasty, if necessary, are delayed until skeletal maturity. The treatment timeline used at Nationwide Children's Hospital can be seen in Fig. 45-33.

The Importance of Team in Cleft Care Children born with CL/P require expertise of medical professionals from many different disciplines. In addition to experienced craniofacial surgeons, cleft teams typically consist of otolaryngologists, pediatricians, speech pathologists, feeding specialists, pediatric dentists, orthodontists, geneticists, psychologists, nurses, and social workers. Each member is an integral part of the team and absolutely essential for the delivery of comprehensive cleft care.²¹

Atypical Craniofacial Clefts Beyond the familiar scope of clefts confined to the lip and palate, there exist myriad forms of clefting that may affect the craniofacial skeleton. Sound epidemiologic studies of these atypical craniofacial clefts have been precluded by their extreme rarity, but rough estimates place them on the order of 100 times less common than CL/P. As a result, definitive causality has not been established. With the exception of some well-defined syndromes that include atypical craniofacial clefts, genetics does not appear to play a significant part in their pathogenesis. Some extrinsic factors that have been implicated include radiation, prenatal infections, early gestational exposure to teratogenic drugs or chemicals, and amniotic bands. Metabolic derangements and vascular disturbances have also been hypothesized to play a role.²⁷

While CL/P can be logically explained as an embryologic failure of fusion between facial processes, the location of the atypical craniofacial clefts is not well-accounted for by this theory. In the 1960s, Weston and Johnston used animal models to demonstrate the vast contributions of neural crest cells to mesenchymal development of the face. They postulated that failure of these cells to penetrate into the developing face could lead to breakdown of the surrounding epithelia and result in atypical craniofacial clefts. The last 30 years has seen continued refinement of this theory. Most recent evidence suggests that neural crest cells form developmental rests or ossification

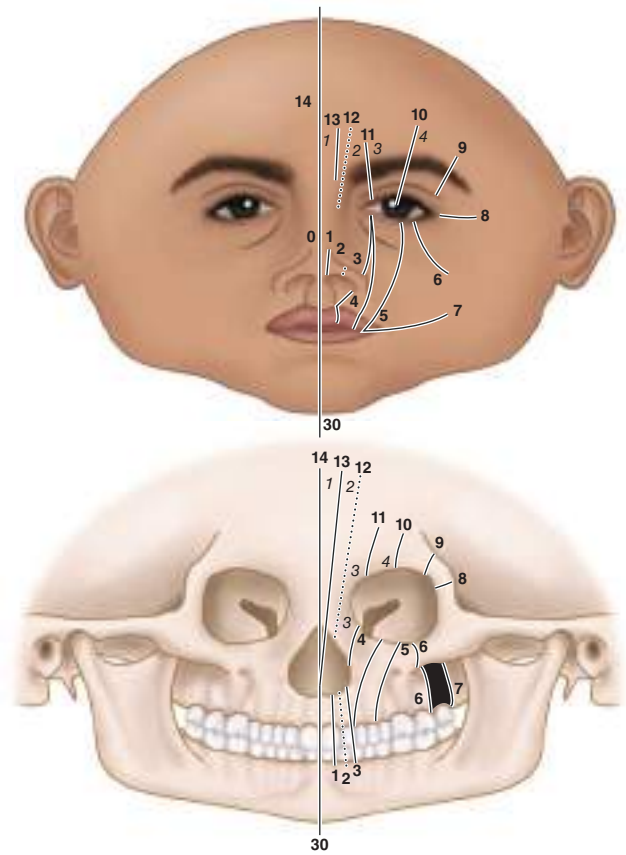

Figure 45-34. The Tessier classification of craniofacial clefts. Numbered lines designate soft tissue manifestations (*above*) of the underlying skeletal clefts (*below*).

centers within the well-known facial processes. An abnormal number or impaired differentiation of these ossification centers may better explain the locations of clefts that seem to follow no known embryologic fusion plane.³³

In 1974, Paul Tessier published detailed anatomic observations of a large series of children with atypical craniofacial clefts. He introduced a simple numbering system to classify these clefts based strictly on involved anatomy.²⁸ Clefts were assigned numbers 0 to 14 as they radiate around the orbit. Numbers 0 to 7 describe facial clefts, while 8 to 14 described cranial clefts. Fig. 45-34 illustrates the paths of soft tissue clefts (*above*) and their corresponding skeletal clefts (*below*).^{33,35}

A number 0 facial cleft and its number 14 cranial extension are midline clefts, which may be characterized by tissue deficiency or excess. Holoprosencephaly, a term used to describe a

Figure 45-33. The treatment timeline used at Nationwide Children’s Hospital.

failed cleavage of the prosencephalon into two separate cerebral hemispheres, presents as a midline tissue deficiency that causes variable degrees of hypotelorism and upper lip and nasal deformity. Mildly affected patients may have near-normal intelligence, while severely affected cases are incompatible with life. Representing the opposite end of the spectrum, patients with median cleft face dysmorphism typically present with a median cleft of the lip and/or premaxilla midline tissue excess, hypertelorism, bifid cranium, and a normal underlying CNS (Fig. 45-35A,B).³³

Tessier clefts 1, 2, and 3 originate at the cupid's bow. All proceed cephalad through the piriform aperture and affect the nose. While number 1 and 2 clefts spare the orbit, number 3 clefts create continuity between the orbit, maxillary sinus, nasal and oral cavities. Clefts 4, 5, and 6 begin lateral to cupid's bow, spare the nose, and pass cephalad to affect the orbit and lower eyelid. The number 7 cleft, otherwise known as *craniofacial microsomia*, extends transversely along a line from the oral commissure to the auricular tragus. Underlying skeletal clefts can involve the mandible, maxilla, orbit, and cranium. Tessier clefts 8 through 10 continue to radiate laterally and superiorly around the orbit. Cranial extensions are numbered such that the sum of the facial cleft and its corresponding cranial extension is always 14. For example, the number 1 facial cleft continues as the number 13 cranial cleft, and the number 5 facial cleft continues as the number 9 cranial cleft.^{33,35} Clefts can be unilateral or bilateral and

may occur in any combination. The constellation of bilateral Tessier clefts 6, 7, and 8 has been well-described within the context of Treacher Collins syndrome, in which patients exhibit malar hypoplasia, lower eyelid colobomas, and downward-slanting palpebral fissures (Fig. 45-36A–C).³³

Treatment of atypical craniofacial clefts varies widely with each unique patient. Classical approaches to surgical management involved excision of atrophic soft tissue along cleft margins with reconstruction by local tissue rearrangement, with or without underlying bone grafting. Unfortunately, this methodology gives little consideration to the aesthetic units of the face, and the resulting scars often cause postoperative deformities of their own. Ortiz-Monasterio and Taylor proposed a new treatment philosophy based on the following tenants:

1. Restoration of the craniofacial skeleton
2. Reconstruction with skin and soft tissue with like color and texture
3. Generous use of tissue expanders
4. Aesthetic unit and subunit reconstruction
5. Scar location at limits of aesthetic subunits
6. Symmetrical repositioning of key facial landmarks

Fig. 45-37 demonstrates the dramatic improvement in aesthetic outcome that is attainable when abiding by this treatment philosophy.²⁹

A

B

Figure 45-35. Tessier 0-14 clefts. **A.** Holoprosencephaly. Note the midline tissue deficiency, hypotelorism, and the rudimentary nose known as a “proboscis.” The degree of facial deformity in patients with holoprosencephaly typically reflects the degree to which the underlying CNS is affected. **B.** Median cleft face dysmorphism. Note the marked midline tissue excess and hypertelorism. Although this patient exhibits an obvious encephalocele, CNS function is usually normal.

C

Figure 45-36. A child with Treacher Collins syndrome and the hallmark combination of Tessier clefts 6, 7, and 8. Note the downward-slanting palpebral fissures and profound malar hypoplasia due to complete absence of zygomas.

Barring immediate danger to vital structures such as the eye, the timing of reconstruction can be determined on a case-by-case basis. Soft tissue clefts can be excised and closed by classical measures within the first year of life. However, bony reconstruction should be delayed until at least 5 to 6 years of age to minimize iatrogenic impairment of facial growth. Serial tissue expansion of the cheek prior to this time may be necessary to excise unfavorable scars and reorient them along aesthetic subunit boundaries. Preoperative imaging, such as computed

tomography (CT) or magnetic resonance imaging (MRI), is necessary to fully characterize the defects and plan the operation. Additional preoperative workup should include anesthesia evaluation and labs, as these operations can be lengthy and accompanied by significant blood loss. Preparedness for blood transfusion is imperative.^{33,34}

Craniofacial clefts are typically approached through a combination of bicoronal and oral vestibular incisions. Various osteotomies have been described to reposition components of

Figure 45-37. (left) Eight-year-old girl with significant deformity from local tissue rearrangement to reconstruct a right Tessier no. 4 cleft. the craniofacial skeleton, such as the orbits, maxilla, and mandible. These may be used in conjunction with bone grafts from the calvarium, ribs or iliac crest, and fixation can be achieved with standard techniques using bioresorbable plates or sutures.³³

Craniosynostosis. The term “craniosynostosis” refers to premature fusion of one or more calvarial sutures. It occurs in up to 1 out of every 2000 live births, and single-suture, nonsyndromic patients account for 85% of cases. Of these, isolated sagittal craniosynostosis is the most common form, while lamdoidal is the least common. Normal suture maintenance is driven by underlying brain growth and a complex biochemical interplay between the suture and the underlying dura mater.³⁰ Multiple genes have been implicated in the development of craniosynostosis, the most notable of which being *FGFR* and *TWIST*. Fifty percent of these present as de novo mutations, and most exhibit an autosomal dominant inheritance pattern. Environmental associations, such as maternal smoking, have been postulated, but definitive causality has not been proven.³¹

According to Virchow’s law, patients with craniosynostosis exhibit a predictable pattern of deformity that results from an arrest of cranial growth perpendicular to the prematurely fused suture, with a compensatory increase in growth parallel to the affected suture (Fig. 45-38). Isolated sagittal craniosynostosis,

Figure 45-38. (left) Patent sutures permit normal cranial growth in all directions. (right) Craniosynostosis results in restricted cranial growth across the synostotic suture with a compensatory increased growth parallel to the synostotic suture (Virchow’s law).

for example, results in restricted cranial growth in the transverse direction and a compensatory increase in the anterior-posterior diameter of the head with frontal and/or occipital bossing. This head shape is commonly referred to as “scaphocephaly.” Fig. 45-39 depicts various other isolated craniosynostoses and the patterns of deformity that ensue.³⁶

All patients with craniosynostosis should be screened for intracranial hypertension. It has been estimated that up to 17% of patients with single-suture involvement may develop elevated intracranial pressure (ICP). This risk approaches 50% in patients with multisuture craniosynostosis.³⁶ Signs and symptoms of increased ICP may include headache, inconsolability, nausea, vomiting, lethargy, sleep apnea, developmental delay, bulging fontanelles, hydrocephalus, papilledema, or loss of vision.^{36,38} Facial dysmorphism and a strong family history should raise suspicion for syndromic etiology, as seen in Apert, Crouzon, Pfeiffer, and Saethre-Chotzen syndromes, among others.

Diagnosis of craniosynostosis begins with physical exam. A recent prospective multicenter study suggests 98% accuracy of diagnosis based upon physical exam findings alone. Palpable ridges may be present on the cranium but are not pathognomonic for craniosynostosis. The much more reliable physical exam finding involves recognition of the distinct patterns of cranial growth that result from premature fusion of one or more sutures. Dysmorphic facies, suspicion for multisuture involvement, or any degree of uncertainty in the diagnosis can be clarified with adjunctive imaging. While skull plain films can provide useful information, 3D computed tomography has emerged as the new gold standard imaging modality for diagnosing craniosynostosis.³⁷

The goals of treatment for craniosynostosis are to achieve a more normalized head shape and to treat or prevent negative impacts on development that may result from increased ICP.³⁷ In general, two approaches exist: (a) strip craniectomy procedures and (b) remodeling procedures. Simply put, strip craniectomy procedures remove the synostotic suture in order to disinhibit cranial growth across the affected suture. Adjunctive techniques, such as cranial spring or distractor placement versus postoperative helmet therapy are frequently combined with strip craniectomies to improve aesthetic outcomes. Many surgeons who perform these procedures will do so as early as

Figure 45-39. Patterns of single-suture craniosynostosis. Scaphocephaly results from sagittal synostosis. Trigonocephaly results from metopic synostosis. Anterior plagiocephaly results from unilateral coronal synostosis. Brachycephaly results from bilateral coronal synostosis. Posterior plagiocephaly results from unilateral lambdoidal synostosis.

6 to 12 weeks of life to take advantage of early rapid brain growth, which helps drive cranial expansion after release of the synostotic suture. In addition, younger patients have a better capacity to heal the resulting cranial defects due to the high osteogeneticity of the underlying dura, which decreases substantially with age.³⁷ Remodeling procedures go further to normalize head shape by complete removal, rearrangement, and replacement of abnormal areas of the calvarium. Given the limited efficacy of the aforementioned strip craniectomy techniques in patients older than 6 months of age, cranial vault remodeling is generally accepted as the definitive treatment for craniosynostosis in this age group.³⁶

Advantages of strip craniectomy procedures include shorter operative times, less blood loss, and shorter hospital stays, while disadvantages include an inability to treat complex deformities from multisuture involvement, inability to treat areas of compensatory increased cranial growth, and the necessity for secondary hardware removal procedures. Remodeling procedures offer a more definitive correction of head shape in a single surgical procedure at the cost of increased operative times, higher rate of blood transfusions, and increased length of hospital stays.³⁷

The complexity of patients with syndromic craniosynostoses, such as Crouzon or Apert syndrome, mandates multidisciplinary care from an experienced team of subspecialists. These patients may present with urgent airway obstruction, dangerously elevated ICP, and/or vision-threatening globe protrusion (Fig. 45-40A–C).²³ Early surgical interventions, such as strip craniectomy or posterior cranial vault distraction, are designed to increase cranial volume and therefore decrease ICP. Although optimal timing of definitive reconstruction is debatable, results of cranial vault remodeling and midface advancement surgeries appear more stable and demonstrate less relapse when delayed.³² Hearing, speech, and feeding difficulties are common among patients with syndromic craniosynostoses. As always, the psychosocial implications of such profound facial differences make social workers and psychologists indispensable members of the team.²³

Atrophy and Hypoplasia. Two conditions that exemplify the atrophy and hypoplasia class of craniofacial anomalies are progressive hemifacial atrophy and Robin sequence. Progressive hemifacial atrophy, otherwise known as Parry-Romberg syndrome, is a rare, acquired, idiopathic atrophy of the skin,

subcutaneous tissue, muscle, and occasionally bone affecting one side of the face (Fig. 45-41). With a typical onset during the first or second decade of life, this self-limiting condition progresses with an indolent course for 2 to 10 years before stabilizing, or “burning out.” The pathogenesis of Parry-Romberg syndrome is not well understood. Autoimmune processes such as scleroderma, chronic neurotropic viral infections, trigeminal neuritis, intracerebral vascular malformations, and increased sympathetic nerve activity have all been postulated to play a role. After progression of atrophy ceases, the mainstay of treatment is volume and contour restoration with autologous fat grafting. More severe cases may require microvascular transfer of free tissue, such as the parascapular fasciocutaneous flap.³³

Robin sequence is defined as the triad of micrognathia, glossoptosis, and airway obstruction (Fig. 45-42).²³ Cleft palate is present in up to 90% of affected patients, though it is *not* an obligatory component of the diagnosis. The cause of this condition is not known, but many believe mandibular hypoplasia to be the inciting event. According to this theory, micrognathia (small jaw) prevents forward migration of the tongue during gestational development. Glossoptosis results, where the tongue remains flipped dorsally into an obstructive position within the oropharyngeal airway. The first step in management is prone positioning, which utilizes gravity to bring the mandible and tongue base forward and alleviate the upper airway obstruction. More severely affected babies may require emergent endotracheal intubation at the time of delivery in order to secure the airway.³⁴

A diagnosable syndrome can be expected in over 50% of patients born with Robin sequence. Stickler syndrome (congenital ocular, orofacial, auditory, and articular anomalies), which is the leading cause of childhood blindness due to retinal detachment, is the most commonly associated syndrome. For this reason, ophthalmology and genetics evaluations are indicated in all patients with Robin sequence. Additionally, a thorough airway evaluation by an otolaryngologist is necessary to confirm obstruction at the level of the tongue base and to rule out intrinsic airway anomalies or obstruction at lower levels of the respiratory tract.⁴¹

Babies who are mildly affected can often be managed nonsurgically with prone positioning alone. Close monitoring is required because obstructive symptoms do not always follow a linear course to resolution. High caloric expenditure on

Figure 45-41. Child with progressive hemifacial atrophy, otherwise known as Parry-Romberg syndrome.

increased work of breathing, in combination with reflux and feeding difficulties that are ubiquitous in this population, may manifest as poor weight gain over time. Persistent failure to thrive indicates a failure of conservative management.⁴¹

4▶ Robin sequence patients with single-level obstruction at the tongue base who have failed conservative measures should be considered for surgical airway management.⁴¹ Tongue-lip adhesion (TLA) is designed to bring the tongue base forward and out of the airway by temporarily sewing the under-surface of the tongue to the mucosal surface of the lower lip. Adhesions are typically reversed within the first year of life as significant mandibular growth and improved muscle tone of the tongue result in a stable airway.³⁵

Another option to treat upper airway obstruction in patients with Robin sequence is mandibular distraction osteogenesis (MDO). In this procedure, osteotomies are made in bilateral mandibular rami, and distractor devices are applied that enable a gradual (1–2 mm/day) lengthening of the mandible. As the mandible is brought forward, the tongue base follows, resulting in enlargement of the oropharyngeal airway. Specific risks include injury to tooth buds, inferior alveolar or marginal mandibular nerves, and disruption of mandibular growth potential.⁴¹

In Robin sequence, patients who fail or are not candidates for less invasive surgical maneuvers, tracheostomy remains the definitive option for airway control. Figure 45-43 represents an algorithm for management of children with Robin sequence proposed on the basis that TLA is less invasive and does not preclude subsequent MDO in the event of failure.⁴² However,

Figure 45-42. An infant with Robin sequence. Marked micrognathia and glossotoposis cause respiratory distress due to upper airway obstruction at the level of the tongue base. Note the presence of sternal retraction during inspiration.

one option has not been proven to be significantly better than the other, and many surgeons prefer MDO as a first-line intervention.

Hypertrophy, Hyperplasia, and Neoplasia. Numerous hypertrophic, hyperplastic, or neoplastic processes can affect the craniofacial region. The presence of certain vascular anomalies in the face can result in hypertrophy of surrounding bone or soft tissue.¹⁹ Patients with neurofibromatosis-1 may similarly present with hemifacial hypertrophy related to the presence of an underlying plexiform neurofibroma.³⁶ Fibrous dysplasia is a focal error in osteoblast differentiation that leads to replacement of normal bone with a disorganized mass of bony trabeculae and fibrous tissue. Seventy percent of lesions are monostotic, and

Figure 45-43. Algorithm for management of children with Robin sequence.

the remaining 30% are polyostotic. In the craniofacial region, fibrous dysplasia typically presents in childhood with pain and progressive asymmetry. Patients with McCune-Albright syndrome have polyostotic fibrous dysplasia, café au lait spots, and hyperfunctioning endocrinopathies, which classically manifest as precocious puberty. Lesions have a distinct “ground glass” appearance on CT scan. Small, monostotic fibrous dysplasia lesions can occasionally be resected completely and reconstructed with bone grafts. More commonly, surgical debulking and contouring is the treatment of choice.³⁷

Vascular Anomalies. Vascular anomalies affect approximately 5.5% of the population. They can be broadly categorized as either *tumors* or *malformations*.³⁸ Vascular tumors are characterized histologically by endothelial cell proliferation, with or without luminal structure. In contrast, vascular malformations are collections of abnormally developed vessels without significant endothelial cell turnover.³⁹

Hemangiomas Hemangiomas are the most common vascular tumor in children, presenting in up to 20% of premature infants. Females are four times as likely to be affected as males, and darker-skinned individuals are rarely affected. These benign tumors are believed to be collections of primitive blood vessels formed from angioblasts. Hemangiomas can occur anywhere throughout the body, with the liver being the most common extracutaneous site.⁴⁶

The natural history of hemangiomas is highly predictable depending on the timing of presentation and early clinical course. *Infantile* hemangiomas appear shortly after birth, usually between 2 weeks and 2 months of life. Cutaneous infantile hemangiomas may initially resemble a red scratch or bruise, while subcutaneous or visceral lesions go unnoticed. Rapid growth ensues over the next 9 to 12 months (“the proliferative phase”). During this time, cutaneous lesions become bright red and tense, while subcutaneous lesions may present as deep soft tissue masses with a bluish/purplish hue. After plateau of the proliferative phase, infantile hemangiomas reliably undergo a slow regression (“involution”), which is usually complete by 4 years of age. History alone can help differentiate a *congenital* hemangioma, which is fully formed at birth, from an *infantile* one. *Congenital* hemangiomas may exhibit rapidly involuting (RICH), noninvoluting (NICH), or partially involuting (PICH) clinical courses. History and physical is often sufficient to diagnose a hemangioma. Doppler ultrasound has become the imaging modality of choice, while MRI is typically reserved to confirm the diagnosis in cases of uncertainty.⁴⁰

Most hemangiomas can be observed and allowed to involute spontaneously. High-risk lesions that may require early intervention include ulcerated and bleeding hemangiomas; periocular hemangiomas, which can occlude the visual axis and lead to blindness; hemangiomas in the beard distribution, which place the patient at risk for upper airway obstruction (Fig. 45-44); and posterior midline lumbosacral hemangiomas, which may indicate underlying spinal dysraphism and cause cord compression. Patients with three or more hemangiomas should be screened by ultrasound for involvement of abdominal viscera, as large hepatic lesions may lead to high-output heart failure. Large segmental hemangiomas in the cranial nerve V distribution (Fig. 45-45) should raise suspicion for PHACES association (Posterior fossa malformations, Hemangiomas, Arterial anomalies, Cardiac defects, Eye anomalies, Sternal defects).⁴⁶ The LUMBAR association (Lower body

Figure 45-44. Hemangiomas in the beard distribution.

hemangiomas, Urogenital anomalies, Myelopathy, Bony deformities, Anorectal/Arterial malformations, Renal anomalies) should be considered in patients with large infantile hemangiomas of the lumbosacral region or lower extremities.⁴¹

▶ Oral propranolol therapy has emerged as the first-line treatment for complicated or high-risk infantile hemangiomas. When administered during the proliferative phase, this nonselective beta adrenergic receptor blocker causes rapid involution of the hemangioma. Several randomized, controlled trials have demonstrated oral propranolol to cause a greater decrease in lesion size compared to placebo and steroid therapy.⁴² In addition, many clinicians believe the side effect profile of propranolol (hypoglycemia, sleep disturbances, hypotension, bradycardia, bronchospasm) to be more favorable than that of systemic steroids.⁴³

While hemangioma involution may result in no visible sequelae, up to 50% of patients are left with a residual fibrofatty mass with atrophic, hypopigmented and/or telangiectatic overlying skin (Fig. 45-46A,B). If the residual deformity is troubling to the patient, surgical excision may be indicated.⁴⁶

Vascular Malformations Vascular malformations are collections of abnormally formed vessels that demonstrate minimal endothelial cell turnover. They are present at birth and grow slowly in proportion with the patient. Vascular malformations are classified on the basis of anatomic origin of the abnormal vessels: capillary malformations (CM), venous malformations (VM), lymphatic malformations (LM), and arteriovenous malformations (AVM). These classes can be further categorized into “slow-flow” or “fast-flow” lesions (Table 45-4).⁴⁶

Capillary malformations, formerly known as “port wine stains,” present at birth as flat, pink patches of skin. They typically darken with age and may develop a thickened or “cobblestoned” appearance. CMs may be found anywhere on the body, and overgrowth of underlying soft tissue or bone can occur. History and physical is sufficient to diagnose isolated CMs, but syndromic associations do exist that would warrant

Figure 45-45. Large segmental hemangiomas in the cranial nerve V distribution.

further work-up.⁴⁶ Sturge-Weber syndrome often presents with CMs in the V1/V2 nerve distributions of the face and may be accompanied by vascular malformations of the underlying leptomeninges or globe. Patients are at high risk for seizure, stroke, and glaucoma, for which pharmacologic prophylaxis may be

indicated.⁴⁴ The mainstay of treatment of CMs is pulsed-dye laser therapy (Fig. 45-47A, pre procedure; Fig. 45-47B post procedure). Other surgical interventions, if necessary, are aimed at addressing soft tissue or bony overgrowth.⁴⁶

Venous malformations are lobulated collections of dilated veins that typically involve skin, mucosa, or subcutaneous tissue, although 50% demonstrate deeper involvement. Lesions may or may not be noted at the time of birth. VMs generally grow in proportion to the patient but may undergo accelerated growth during puberty or pregnancy. Swelling of the mass may occur with dependent positioning or Valsalva maneuvers, such as crying. On exam, superficial VMs are soft, compressible masses with a bluish hue. Firm, tender nodules may be present, which represent calcifications known as *phleboliths*. Deeper, intramuscular VMs may present with pain or increased extremity circumference, while lesions of the GI tract may simply present with bleeding. MRI with contrast is the imaging modality of choice, although ultrasound can be used in infants and young children to avoid sedation. Observation is indicated for asymptomatic lesions. Compression of involved extremities helps alleviate pain and swelling and prevent thrombosis and phlebolith formation. Due to the high risk of recurrence after surgical excision, the first line of treatment for symptomatic VMs is sclerotherapy. Surgery is reserved for small, well-localized lesions amenable to complete resection; extremity lesions near major peripheral nerves; or residual deformities after sclerotherapy (Fig. 45-48A, before laser; Fig. 45-48B, after laser; and Fig. 45-48C, after limited resection).⁴⁶

Lymphatic malformations, previously referred to as “cystic hygromas,” are collections of abnormal lymph channels that may cross multiple tissue planes and cause swelling, pain, bleeding, or bony overgrowth. LMs are classified as macrocystic, microcystic or combined. Large, macrocystic lesions can alter form and impair function locally through mass effect. Cutaneous components of LMs present as vesicles that may bleed or become infected. While superficial lesions can be diagnosed by history and physical exam alone, deeper lesions require MRI

to confirm the diagnosis and assess the extent of the disease. Asymptomatic LMs can be observed. Sclerotherapy is the treatment of choice for all macrocysts. Symptomatic microcystic LMs have been treated with oral sirolimus, and draining cutaneous vesicles have been successfully ablated with CO₂ laser therapy. Recurrence after surgery is common; therefore, excision is reserved for severely symptomatic lesions no longer amenable to sclerotherapy or small, well-localized lesions where excision can be curative (Fig. 45-49A–C).⁴⁶

A

B

C

Figure 45-49. A. Lymphatic malformation of the neck. B. After sclerotherapy with significant skin excess. C. Seven months after resection of excess skin.

Arteriovenous malformations are abnormal vascular connections between arteries and veins without intervening capillary beds. AVMs involving the skin appear pink and are warm to the touch. A palpable pulse or thrill may be present from the fast-flow shunting of blood from arterial to venous circulation. Lack of local capillaries can cause a painful, ischemic ulceration of the skin. Patients with large AVMs are at risk for development of congestive heart failure. Doppler ultrasound is the imaging modality of choice, but MRI is often obtained to provide additional information on the extent of the lesion. Observation is appropriate for asymptomatic AVMs. For symptomatic AVMs, embolization is frequently employed 24 to 72 hours prior to excision to minimize operative blood loss. Excision or embolization alone is rarely curative and highly likely to recur. Indications for surgery include small, well-localized AVMs; focal deformities that result from an AVM; or symptomatic AVMs not amenable to embolization.⁴⁶

When multiple types of vascular malformations cohabit, they are collectively referred to as combined malformations. Patients with Klippel-Trenaunay syndrome demonstrate a combined capillary, venous, and lymphatic malformation of an extremity resulting in bony and/or soft tissue overgrowth (Fig. 45-50).⁴⁵

Figure 45-50. A patient with Klippel-Trenaunay syndrome involving the right lower extremity. The combined capillary, venous, and lymphatic malformations result in generalized overgrowth of the extremity.

Table 45-5

Classification of CMN's

PROJECTED ADULT DIAMETER	CMN CLASSIFICATION
<1.5 cm	Small
≥1.5 cm and <11 cm	Medium
≥11 cm and ≤20 cm	Large
>20 cm	Giant

Congenital Melanocytic Nevi. Congenital melanocytic nevi (CMN) are hyperpigmented lesions present at birth that result from ectopic rests of melanocytes within the skin. They can be distinguished histologically from acquired nevi by their extension into the deep dermis, subcutaneous tissue, or muscle.⁴⁶ Depending on their size and location, CMNs may cause severe disfigurement and accompanying psychologic distress. Classification is based on projected diameter of the largest dimension on the fully-grown adult (Table 45-5).⁴⁷ While CMNs are generally common (1% incidence), only 1 in 20,000 children are born with a giant lesion. At birth, CMNs often appear flat, brown and hairless. They grow in proportion with the patient and may develop color variegation, verrucous thickening, hypertrichosis, erosions, or ulcerations over time. CMNs carry an estimated 0.7% to 2.9% lifetime risk of melanoma, with the majority of cases presenting before puberty. Patients with giant CMNs, multiple satellite lesions, or trunk lesions appear to be at higher risk for malignancy. Melanomas can develop within the CMN itself, but they may also present as primary cancers at distant, extra-cutaneous sites, such as the GI tract or the central nervous system. Patients with CMNs require regular skin surveillance by a dermatologist. A biopsy is indicated for concerning changes in color or shape, nodularity, or ulceration. If melanoma is diagnosed, management should proceed in accordance with standard melanoma treatment guidelines.⁵⁵

CMNs with multiple (>20) satellite lesions or midline CMNs over the trunk or calvaria should raise suspicion for neurocutaneous melanosis, a condition resulting from melanoblast proliferation in the central nervous system (CNS). In addition to the risk of CNS melanoma, patients with neurocutaneous melanosis may suffer from developmental delay, seizures, intracranial hemorrhages, hydrocephalus, cranial nerve palsies, or tethered spinal cord. High-risk patients should be evaluated by MRI between 4 and 6 months of age. While asymptomatic patients may be followed with serial MRI, patients with symptomatic neurocutaneous melanosis often succumb to their disease within 2 to 3 years of diagnosis.⁵⁴

The goals in surgical management of CMN are (a) to decrease cancer risk, (b) to reduce symptoms, (c) to improve appearance, (d) to improve psychosocial health, and (e) to maintain function.⁵⁴ It is important to note that the risk of melanoma is not eliminated even with complete excision of a CMN. Indeed, a definitive cancer risk reduction from surgical excision of CMNs has yet to be proven. Management paradigms have therefore shifted from complete excision and reconstruction to maximal excision and reconstruction without compromising function or aesthetic outcome.⁵⁵ From serial excisions or skin grafting, to tissue expansion or free tissue transfer, plastic surgeons have drawn from the entire armamentarium in meeting the substantial reconstructive challenges posed by giant CMNs. Treatment plans must be grounded in principle: “tissue

losses should be replaced in kind,” and “reconstruct by units.”⁴⁸ Figure 45-51A–C shows an infant with a giant CMN of the posterior trunk and right flank preoperatively; at end of the first round of tissue expansion; and at the culmination of three rounds of tissue expansion, excision, and closure by local tissue rearrangement.⁴⁹

RECONSTRUCTIVE SURGERY IN ADULTS

2001

Reconstructive surgery applies techniques that modify tissues in order to restore a normal function and appearance in a patient with congenital or acquired deformities. The most common causes of acquired deformities are traumatic injuries and cancer.

A

B

C

Figure 45-51. A. An infant with a giant CMN of the posterior trunk and right flank. B. Tissues expanders were placed under adjacent normal skin in preparation for first-stage excision. C. The same patient at 11 years of age after three rounds of tissue expansion and excision.

We will focus first on trauma. Although any anatomic region can be subjected to injuries that might require reconstructive surgery, traumatic fractures, and soft tissue damage in the head and neck and extremities are most common. The manner in which these reconstructive steps are conducted is critical. Reconstructive surgery involves the coordination of many specialties and must occur according to a particular timeline, involving complex system-based practice.

Maxillofacial Injuries and Fractures

Management of maxillofacial injuries typically occurs in the context of multiple trauma. Concomitant injuries beyond the face are the rule rather than the exception. The first phase of care is activation of the advanced trauma life support protocols. The most common life-threatening considerations in the facial trauma patient are airway maintenance, control of bleeding, identification and treatment of aspiration, assessment for closed head injuries, and identification of other injuries. Once the patient's condition has been stabilized and life-threatening injuries managed, attention is directed to diagnosis and management of craniofacial injuries.

Physical examination of the face focuses first on assessment of soft tissue injuries as manifested by surface contusions and lacerations. Part of this process is intranasal and intraoral examination. Associated injuries to the underlying facial skeleton are determined by observation, palpation, and digital bone examination through open lacerations. Signs of a facial fracture include contour abnormalities, irregularities of normally smooth contours such as the orbital rims or inferior border of the mandible, instability, tenderness, ecchymosis, facial asymmetry, or displacement of facial landmarks. Traditional plain radiographs have largely been replaced by high-resolution CT, which is widely available at emergency centers that typically receive these patients. Reformatting raw scans into coronal, sagittal, and 3D views is a valuable method to elucidate and plan treatment for complex injuries.

The facial skeleton can be divided into the upper third, middle third, and lower third. The upper third is comprised bounded inferiorly by the superior orbital rim and is formed by the frontal bone. The middle third is the most complex and is formed primarily by the maxilla, nasal bones, and zygoma. The lower third is inferior to the oral cavity and is formed by the mandible. The functional structure of the midface may be understood as a system of buttresses formed by the frontal, maxillary, zygomatic, and sphenoid bones. These buttresses are oriented vertically and horizontally and distribute forces applied to the bones in order to maintain their shape and position without fracturing. There are three paired vertical buttresses called the nasomaxillary, zygomaticomaxillary, and pterygomaxillary buttresses. The horizontal buttresses of the midface pass through the superior and inferior orbital rims and hard palate. A guiding principle of facial fracture management is to restore the integrity of these buttresses.

Mandible Fractures

Mandibular fractures are common injuries that may lead to permanent disability if not diagnosed and properly treated. The mandibular angle, ramus, coronoid process, and condyle are points of attachment for the muscles of mastication, including the masseter, temporalis, lateral pterygoid, and medial pterygoid muscles (Fig. 45-52). Fractures are frequently multiple. Alterations in dental occlusion usually accompany mandible fractures. Malocclusion is caused by forces exerted on the mandible of the

Figure 45-52. Mandibular anatomy.

many muscles of mastication on the fracture segments. Dental occlusion is perhaps the most important basic relationship to understand about fracture of the midface and mandible. The Angle classification system describes the relationship of the maxillary teeth to the mandibular teeth. Class I is normal occlusion, with the mesial buccal cusp of the first maxillary molar fitting into the intercuspal groove of the mandibular first molar. Class II malocclusion is characterized by anterior (mesial) positioning, and class III malocclusion is posterior (distal) positioning of the maxillary teeth with respect to the mandibular teeth (Fig. 45-53). These occlusal relationships guide clinical management.

The goals of surgical treatment include restoration of dental occlusion, fracture reduction and stable fixation, and soft

Figure 45-53. Angle classification. Class I: The mesial buccal cusp of the maxillary first molar fits into the intercuspal groove of the mandibular first molar. Class II: The mesial buccal cusp of the maxillary first molar is mesial to the intercuspal groove of the mandibular first molar. Class III: The mesial buccal cusp of the maxillary first molar is distal to the intercuspal groove of the mandibular first molar.

tissue repair. Nonsurgical treatment may be used in situations in which there is minimal displacement, preservation of the pretraumatic occlusive relationship, normal range of motion, and no significant soft tissue injury. Operative repair involves first establishing and stabilizing dental occlusion and holding in place with maxillomandibular fixation to stabilize the relationships between the mandible and maxilla. The simplest method for this is to apply arch bars to the maxillary and mandibular teeth then use secure them together using interdental wires. Alternatives are sometimes indicated (e.g., screws placed into the bone of the maxilla and mandible that serve as posts for spanning the maxilla and mandible with wires), especially for patients with poor dentition. Once the dental relationships are established, then the fractures can then be reduced and fixed using wire or plates and screws that are specially designed for this purpose. The fracture is surgically exposed using multiple incisions, depending on the location of the fracture and condition of the soft tissues. The fracture is visualized and manually reduced. Fixation may be accomplished using traditional interfragment wires, but plating systems are generally superior. The mandibular plating approach follows two schools of thought: rigid fixation as espoused by the Association for Osteosynthesis/Association for the Study of Internal Fixation and less rigid but functionally stable fixation (Champy technique). Regardless of the approach, it is important to release maxillomandibular fixation and begin range of motion as soon as possible to prevent temporomandibular joint ankylosis. Fractures immediately inferior to the mandibular condyles, called subcondylar fractures, are unique in that there is ordinarily minimal displacement because the fragments are less subject to displacement from muscle forces and there is little bone available across the

fracture line to permit fixation. These are most often treated with maxillomandibular fixation alone.

Important considerations in postoperative management are release from maxillary-mandibular fixation and resumption of range of motion as soon as possible to minimize the risk of temporomandibular joint ankylosis. Complications to be avoided include infection, nonunion, malunion, malocclusion, facial nerve injury, mental nerve injury, and dental fractures.

Frontal Sinus Fractures

The frontal sinus is located in the upper third of the face. It is actually a paired structure ordinarily fused in the midline immediately superior to the orbital rims. It has an anterior bony table that defines the contour of the forehead and a posterior table that separates the sinus cavity from the underlying dura of the intracranial frontal fossa. The anterior table is a relatively weak and subject to fracture when it sustains a direct forceful blow, making frontal sinus fractures relatively common in facial trauma. Each sinus drains through the medial floor into its frontonasal duct, which empties into the middle meatus within the nose.

Treatment of a frontal sinus fracture depends on the fracture characteristics as shown in the algorithm (Fig. 45-54). The diagnosis is established by physical examination and confirmed by CT scan. Closed fractures that are not depressed and causing a visible deformity may be observed. Depressed or open fractures must be explored. Fractures that involve only the anterior table are reduced and fixed using interosseous wires or miniature plates and screws. Fractures of the posterior table without disruption of the dura evidenced by leaking cerebrospinal fluid can be treated in similar fashion. When the dura is disrupted, excising the bone and mucosa or the posterior table

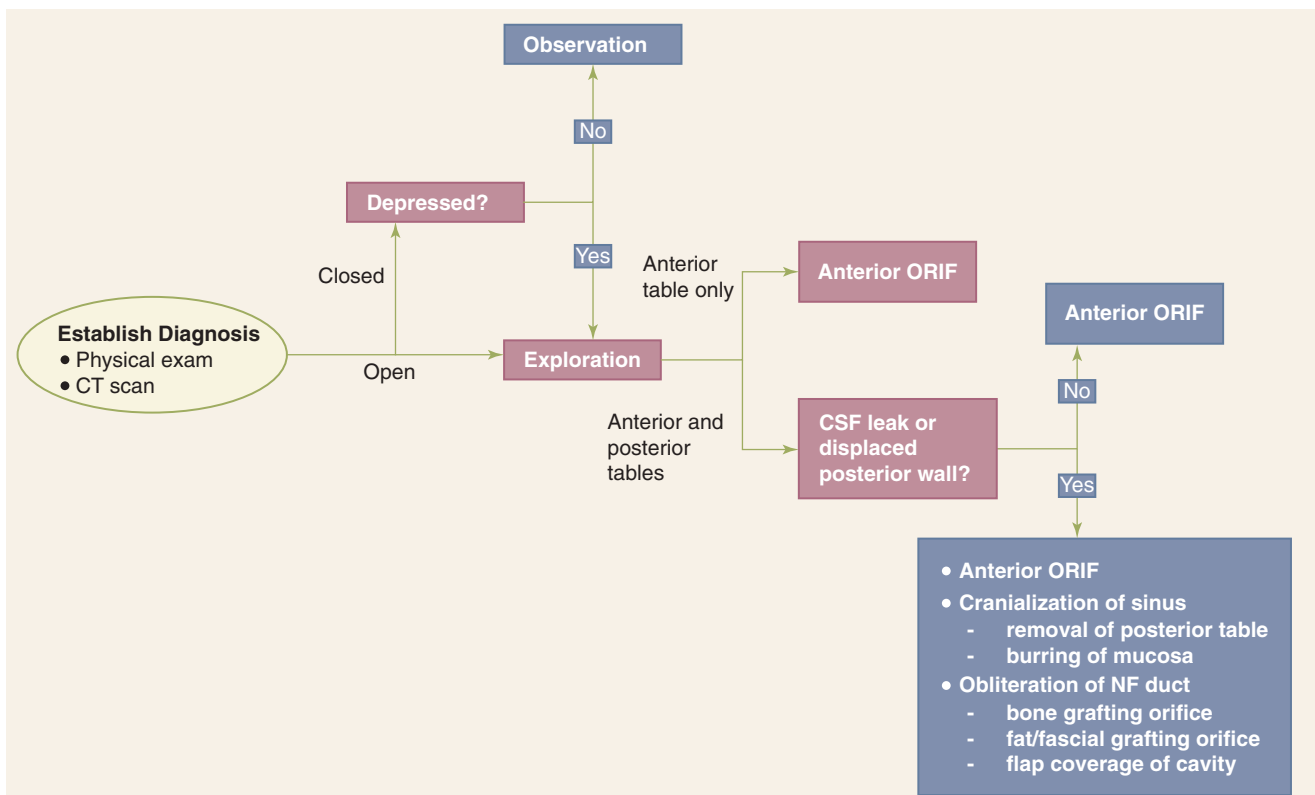

Figure 45-54. Algorithm for the treatment of frontal sinus fracture. CSF = cerebrospinal fluid; CT = computed tomography; NF = nasofrontal; ORIF = open reduction, internal fixation.

and obliterating the nasofrontal duct with a local graft or flap converts with frontal sinus into the anterior frontal fossa of the cranial vault, “cranializing” it.

Orbital Fractures

Treatment of all orbital injuries begins with a careful examination of the globe, which often is best completed by a specialist to assess visual acuity and ocular mobility and to rule out globe injury. Fractures may involve the orbital roof, the orbital floor, or the lateral or medial walls (Fig. 45-55). The most common fracture involves the floor because this is the weakest bone. This type of fracture is referred to as an orbital a “blow-out” fracture because the cause is usually direct impact to the globe that results in a sudden increase in intraorbital pressure with failure of the orbital floor. The typical history is either a direct blow

during an altercation or a sports-related event with a small ball directly striking the orbit. Because the medial floor and inferior medial wall are made of the thinnest bone, fractures occur most frequently at these locations. These injuries may be treated with observation only if they are isolated and small without signs of displacement or limitation of mobility of the globe. However, surgical treatment is generally indicated for large fractures or ones associated with enophthalmos (retrusion of the globe), which suggests increased intraorbital volume and restriction of upward gaze on the injured side, with entrapment of inferior orbital tissues or double vision (diplopia) persisting greater than 2 weeks.²⁸ There are a variety of options for surgical exposure of the orbital floor, including the transconjunctival, subciliary, and lower blepharoplasty incisions. All provide good access for accurate diagnosis and treatment, which involves reducing orbital contents and repairing the floor with either autologous bone or synthetic materials. Late complications include persistent diplopia, enophthalmos, or displacement of the lower eyelid ciliary margin inferiorly (ectropion) or rolling inward (entropion). Entropion causes the eyelashes to brush constantly against the cornea and is very uncomfortable. Each of these sequelae has procedures for repair should they occur.

Orbital floor fractures can be associated with fractures of the lateral or inferior orbital rim. These are typically a component of facial fractures that extend beyond the orbit involving the zygomatic and maxillary bones and are discussed in more detail in the next section.

It is important to be aware of two adverse associated conditions seen at times in patients with orbital fractures. The first is superior *orbital fissure syndrome*. Cranial nerves III (oculomotor nerve), IV (trochlear nerve), and VI (abducens nerve), and the first division of cranial nerve V (VI, trigeminal nerve) pass into the orbit from the base of the skull and into the orbit through the superior orbital fissure. Direct fractures of the posterior orbit or localized swelling caused by a fracture nearby can cause compression of these nerves. Symptoms include eyelid ptosis, protrusion of the globe (proptosis), paralysis of the extraocular muscles, and anesthesia supraorbital and trochlear nerve distributions. The second condition to remember is *orbital apex syndrome*. This is the most severe circumstance in which superior orbital fissure syndrome is combined with signs of optic nerve (cranial nerve II) compression manifested visual changes ranging up to complete blindness. This is a medical emergency that requires immediate treatment to prevent permanent loss of function.

Zygomaxillary Complex Fractures

The zygoma defines the lateral contour of the middle third of the face and forms the lateral and inferior borders of the orbit. It articulates with the sphenoid bone in the lateral orbit, the maxilla medially and inferiorly, the frontal bone superiorly, and the temporal bone laterally. It forms the anterior portion of the zygomatic arch, articulating with the zygomatic projection of the temporal bone. The temporalis muscle, a major muscle of mastication, passes beneath the zygomatic arch and inserts on the coronoid process of the mandible.

Fractures of the zygomatic bone may involve the zygomatic arch alone or any of its other portions and bony relationships. Isolated arch fractures manifest as a flattened, wide facial appearance with edema and ecchymosis. Typically, they are also associated with pain or limited mobility of the mandible. Nondisplaced fractures may be treated without surgery, but

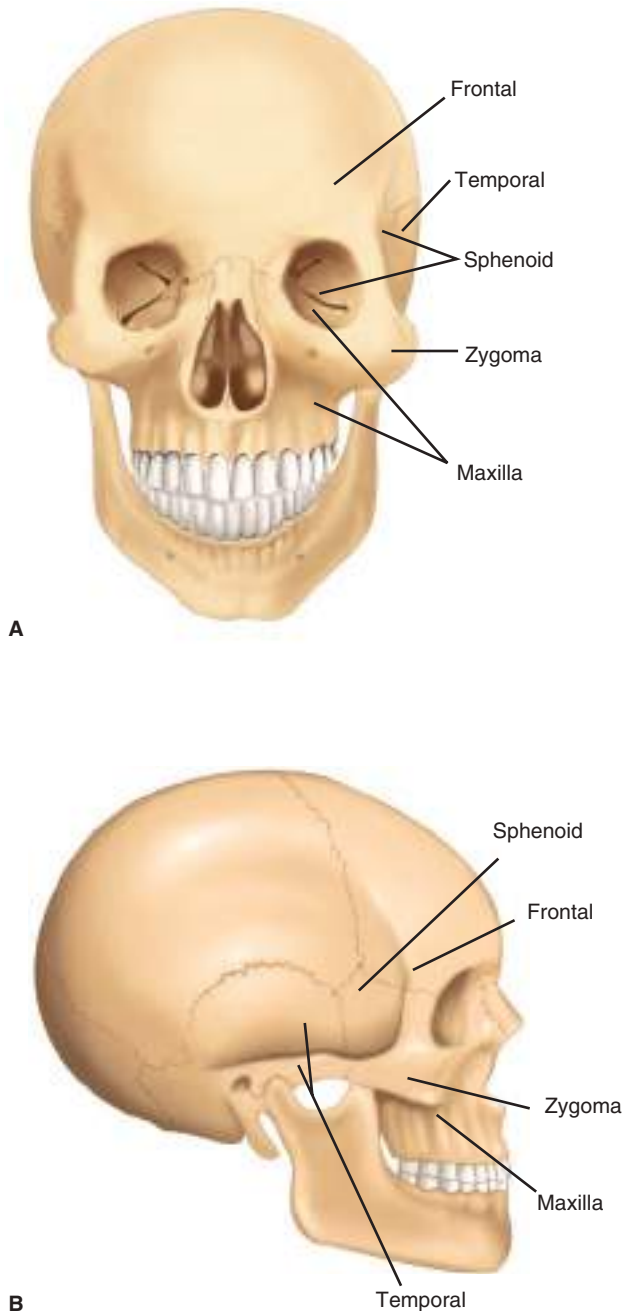

Figure 45-55. Facial bone anatomy.

displaced or comminuted fractures should be reduced and stabilized. This can be accomplished using an indirect approach from above the hairline in the temporal scalp, the so-called “Gilles approach,” or directly through a coronal incision in severe fractures.

A common fracture pattern is called the zygomaticomaxillary complex (ZMC) fracture. This involves the zygomatic arch, the inferior orbital rim, the zygomaticomaxillary buttress, the lateral orbital wall, and the zygomaticofrontal buttress. Muscle forces acting on the fracture segment tend to rotate it laterally and inferiorly, thereby expanding the orbital volume, limiting mandibular excursion, creating an inferior cant to the palpebral fissure, and flattening the malar eminence. ZMC fractures are almost always accompanied on physical examination by altered sensation in the infraorbital nerve distribution and a subconjunctival hematoma.

Treatment of displaced ZMC fractures is surgical. Each fracture site is exposed through incisions strategically placed to gain access but minimize disfiguring facial scars afterwards. These include an incision in the upper eyelid, exposing the zygomaticofrontal buttress and lateral orbital wall; a subtarsal or transconjunctival incision in the lower eyelid, exposing the orbital floor and infraorbital rim; and a maxillary gingivobuccal sulcus incision, exposing the zygomaticomaxillary buttress. Severe fractures involving the arch require wide exposure through a coronal incision.

Nasoorbitalethmoid and Panfacial Fractures

Nasoorbitalethmoid (NOE) fractures are defined anatomically by a combination of injuries that involve the medial orbits, the nasal bones, the nasal processes of the frontal bone, and the frontal processes of the maxilla. If improperly treated, these injuries cause severe disfigurement and functional deficits from nasal airway collapse, medial orbital disruption, displacement of medial canthus of the eyelids, and nasolacrimal apparatus dysfunction. Telecanthus is abnormally wide separation of the medial canthus of the eyelids and is produced by a splaying apart of the nasomaxillary buttresses to which the medial canthal ligaments are attached. NOE fractures require surgical management with open reduction and internal fixation. At times, the thin bones are so comminuted that they are not salvageable and must be replaced or augmented using autologous bone grafts or synthetic materials. Each fragment is carefully identified, returned to a normal anatomic position, and fixed in place using plates and screws or interosseous wiring all bone fragments meticulously, potentially with primary bone grafting, to restore their normal configuration. The key to the successful repair of NOE fractures is to carefully reestablish the nasomaxillary buttress and to restore the normal points of attachment of the medial canthal ligaments.

NOE fractures are typically caused by such extreme forces that they are frequently associated with intracranial injuries and multiple other facial bone fractures in a presentation referred to as a panfacial fracture. These may involve any combination of the fractures described previously. The challenge of these injuries is to reestablish normal relationships of key anatomic landmarks. A combination of salvable bone fragments, autologous bone grafting, and synthetic materials accomplishes this.

Posttraumatic Extremity Reconstruction

The primary goal in posttraumatic extremity reconstruction is to maximize function. When structural integrity, motor function,

and sensation can be reasonably preserved, then extremity salvage may be attempted. Otherwise, severe injuries require amputation best performed following reconstructive surgery principals that set the stage for maximizing function with prosthetics and minimizing chronic pain and risk of tissue breakdown. Microvascular surgical techniques are an essential part of extremity trauma surgery, allowing replantation of amputated parts or transfer of vascularized bone and soft tissue when tissue in zone of injury cannot be salvaged. Soft tissue techniques combined with advances in bone fixation and regeneration with distraction have proven tremendous benefit for patients with severe limb-threatening extremity trauma. Current state-of-the-art techniques require multidisciplinary cooperation between orthopedic, vascular, and plastic surgeons as presented in the algorithm (Fig. 45-56). Reconstructive techniques include the use of vascularized bone, bone distraction techniques, external fixation, nerve grafts and transfers, composite tissue flaps, and functioning muscle transfers tailored to the given defect. The future promises further advances with routine application of vascularized composite allografts, engineered tissue replacements, and computer animated prosthetics controlled intuitively by patients via sensors that are placed on the amputation stump and able to detect impulses transmitted through undamaged peripheral nerves remaining in the extremity.

Common causes of high-energy lower extremity trauma include road traffic accidents, falls from a height, direct blows, sports injuries, and gunshots. As with maxillofacial trauma, the first phase of care is activation of the advanced trauma life support protocols. The most common life-threatening considerations are airway maintenance, control of bleeding, and identification of other injuries. Once the patient's condition has been stabilized and life-threatening injuries managed, attention is directed to diagnosis and management of the extremity. Tetanus vaccine and antibiotics should be provided as soon as possible for open wounds.

Systematic evaluation of the traumatized extremity helps to ensure no important findings are missed. Physical examination to assess the neurovascular status, soft tissue condition, and location of bone fractures forms the foundation of ordering imaging studies to provide details of bone and vascular injuries. Evidence of absent pulses is an indication to consider Doppler ultrasound examination followed by angiography to detail the exact nature of the injury. The blood supply must be immediately restored to devascularized extremities. Crush injuries might be associated with compartment syndrome, in which tissue pressure due to swelling in the constricted facial compartments exceeds capillary perfusion pressure and causes nerve and muscle ischemia. In the early stages of compartment syndrome, findings include pain on passive stretch of the compartment's musculature in a pale, pulseless extremity without evidence of direct vascular injury. Neurologic changes consisting of paresthesias followed by motor paralysis are late signs. Once recognized, decompressive fasciotomies must be performed as soon as possible to prevent permanent tissue loss. Compartment syndrome can be a late event after fracture reduction and fixation (either internal or external), so the extremity must be reevaluated regularly in the early postoperative period. This is especially true in situations where there has been a period of ischemia prior to successful revascularization.

Several scoring systems for extremity trauma severity have been suggested to aid in treatment planning. Open fractures can be classified according to a system devised by Gustilo and

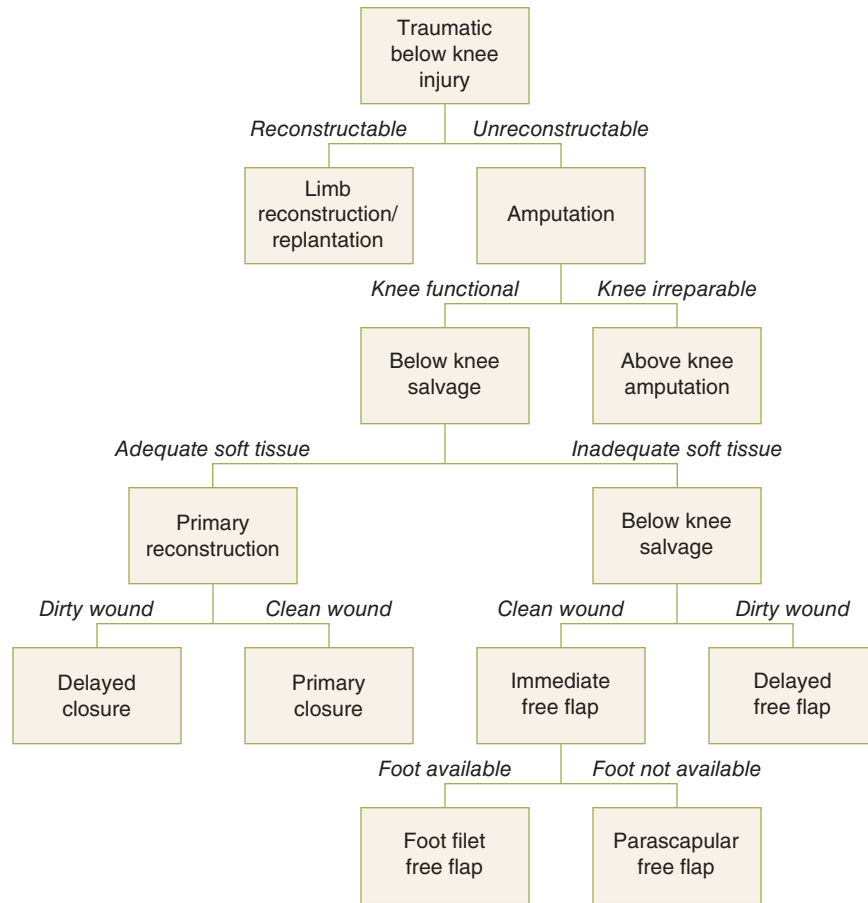

Figure 45-56. Algorithm of posttraumatic extremity reconstruction.

colleagues. Grades I and II are open fractures with minimal soft tissue disruption. Grade III injuries most often require consideration of soft tissue reconstruction. Grade IIIA are open fractures with severe soft tissue injury but adequate soft tissues to repair. Grade IIIB involves a loss of soft tissue that will require some technique for tissue replacement. Grade IIIC involves a vascular injury requiring reconstruction. For the most severe injuries, the most important decision is whether to attempt extremity salvage or proceed with amputation. Patients with extensive fracture comminution, bone or soft tissue loss, wound contamination, and devascularization have a poor prognosis. Extremity salvage requires multiple operations and a prolonged period of rehabilitation and physical therapy. The loss of plantar sensation historically favored below-knee amputation, but this is no longer an absolute recommendation. A final decision to attempt salvage must be made within the context of comorbidities, socioeconomic considerations, patient motivation, and overall rehabilitative potential.

The first step in surgical management is complete debridement of all devitalized tissue. Early one-stage wound coverage and bony reconstruction is generally advocated and should be performed jointly by extremity trauma orthopedic and plastic surgical teams.⁵⁰ It is acceptable for reconstruction to be deferred briefly if the adequacy of debridement is certain. Negative pressure wound therapy is useful between debridement and definitive reconstruction to control the wound drainage and prevent bacterial contamination. When there is segmental bone loss, it is advisable to achieve soft tissue closure prior to performing osseous reconstruction. Preparation for later restoration of the bone

requires steps to prevent the soft tissue from collapsing into the space where bone is needed. A common technique for this is to fill the space with antibiotic-impregnated beads or an antibiotic spacer at the time of soft tissue restoration until definitive bony reconstruction is possible. An external fixation may be needed, if there is segmental bone loss (Fig. 45-57A,B).

The sequence for reconstruction is meticulous debridement of nonviable tissue, fracture reduction and stabilization, vascular repair if necessary, and finally restoration of the soft tissue coverage. A multidisciplinary team of specialists works together to perform these procedures in order to obtain the best outcomes. Orthopedic and plastic surgeons perform wound debridement. Orthopedic surgeons then reduce and stabilize the fractures. Vascular surgeons reconstruct damage major vessels. Finally, plastic and reconstructive surgeons perform soft tissue coverage. Ideally, each operating team completes their part of the procedure sequentially during the same anesthetic.

Choices for soft tissue coverage of open fractures include split-thickness skin grafts, temporary skin substitutes followed later by skin grafting, local rotation flaps, or free tissue transfers. Selecting the most appropriate option depends on the quality of the local tissues and location of the soft tissue defect relative to the underlying fracture and fixation hardware. The guiding principle is to be certain that the source of tissue transferred into the defect is outside of the zone of injury. When flaps are selected, either fasciocutaneous or muscular flaps may be indicated depending on tissue availability, wound bed contours, and surgeon preferences. Uneven wound surface contours are more reliably obliterated with a

A

B

Figure 45-57A, B. An external fixation for segmental bone loss.

pliable muscle flap. Fasciocutaneous flaps may provide more durable coverage in areas subject to abrasion or pressure from footwear, for example, on the foot or around the ankle. Some defects can be covered with flaps containing both skin and muscle if indicated. Ideal coverage for weight-bearing areas should be able to resist pressure and shear and provide sensation. Split-thickness skin grafts are reasonable for coverage of exposed healthy muscle or soft tissue. Local flaps may be used to cover smaller defects as long as uninjured tissue is located nearby. These may be designed as traditional random or axial

flaps, but the most advanced techniques are based on underlying perforators that allow extremely versatile flap designs customized to the defect. These flaps are designed with a perforating vessel at the base near to the defect and a long axis extending an equal distance opposite. The flap is elevated and rotated into the defect in a motion reminiscent of an airplane propeller, which gives rise to the designation “propeller flap” for this kind of reconstruction (Fig. 45-58A, defect ulnar side of the forearm, with an external fixator; Fig. 45-58B, propeller flap; Fig. 45-58C, flap is inset; Fig. 45-58D, 6 weeks after

A

B

C

D

Figure 45-58. A. Defect ulnar side of the forearm, with an external fixator. B. Propeller flap. C. Flap is inset. D. Six weeks post operation.

the operation). The advantages of this technique are that it does not impair muscle function and it can often complete a complex reconstruction without the need for microvascular surgery.

When requirements exceed the potential for skin grafts or local flaps, tissue must be transferred from distant sites. The reconstructive choices differ based on the anatomic location of the defect and the extent of damage. This is often the case for major injuries in the middle or lower third of the leg where bones are covered with thin soft tissue and less donor tissue is available. A traditional method is to obtain tissue by creating a pedicled flap from the opposite, uninjured extremity. Cross-leg flaps remain effective, but indications are limited to circumstances where microsurgery is not possible or in young children who are less prone to risks associated with prolonged immobilization necessary for these flaps, such as joint stiffness or deep vein thrombosis. Free tissue transfer is the preferred alternative. The general principles of reconstructive microsurgery in lower extremity trauma are to select recipient vessels outside of the zone of injury, select donor tissue suitable for the defect with minimal risk of donor site morbidity, and ensure there is bone stability before reconstruction using either internal or external fixation. For example, a latissimus dorsi muscle flap provides a large amount of tissue for reconstruction, but loss of the latissimus function can make it more difficult for the patient to use crutches for ambulation during rehabilitation. Muscle or fasciocutaneous flaps each have a role in selected circumstances.⁵¹ Bone can also be added to help fracture repair.⁵² Free flaps can also be designed as “flow-through” flaps, which reconstruct missing segments of major vessels and provide soft tissue or bone coverage.⁵³

After wound healing, proper physical and/or occupational therapy and rehabilitation is essential for the best long-term outcomes. This often requires many months of consistent retraining and conditioning in order to return to the functional status enjoyed by the patient before injury. Properly fitted orthotic appliances and footwear provide essential protection against pressure-related complications and can improve function. Late complications such as osteomyelitis may appear, evidenced by signs of infection months or even years after reconstruction. Very often this is caused by inadequate debridement at the time of initial surgery.

When limb salvage either is not possible or is not in the best interest of the patient, amputation is indicated. Maximizing limb length, providing durable soft tissue coverage, and managing peripheral nerves to avoid chronic pain help to ensure good functional recovery using extremity prosthetics. Ideally, local tissues are used; however, when they are unavailable or inadequate, the amputated part can be a useful source of skin grafts or tissues for microvascular free transfers to the stump, which preserves length and avoids a more proximal amputation. Transected nerves from amputation procedures can be managed using a technique called targeted muscle reinnervation (TMR). TMR surgery takes the transected peripheral nerves resulting from the amputation procedure, and a nerve transfer is then performed to freshly deinnervated motor nerves within the residual limb or stump. By performing these nerve transfers, the sensory and mixed-motor sensory nerves typically transected during amputation are given fresh motor nerves to rapidly reinnervate, which can directly aid in bioprosthetic function and improve pain control. The improvement in pain is a result of reducing phantom limb pain and symptomatic neuroma formation. This technique has shown to be a major advance over traditional traction neurectomy techniques, which often contribute to increased phantom and residual limb pain rates and a much higher chance of symptomatic neuroma formation compared to TMR.⁵⁴

Oncologic Reconstructive Surgery

Oncology-related reconstructive surgery has broad applications in specialty of plastic and reconstructive surgery. Solid tumors necessarily destroy normal tissues, and surgical treatment involves excising the tumor with a margin of uninvolved normal tissue, which adds to the extent of tissue loss. As is illustrated in the case of a lower extremity sarcoma, reconstructive strategies are meticulously designed as an algorithm for effective functional and cosmetic restoration (Fig. 45-59).

8► Chemotherapy and radiation have side effects and complications that can cause tissue loss, leading to functional and cosmetic deformities that can be improved with reconstructive surgery. The goal of comprehensive cancer treatment is to restore the patient to full health, which includes normal function and appearance.

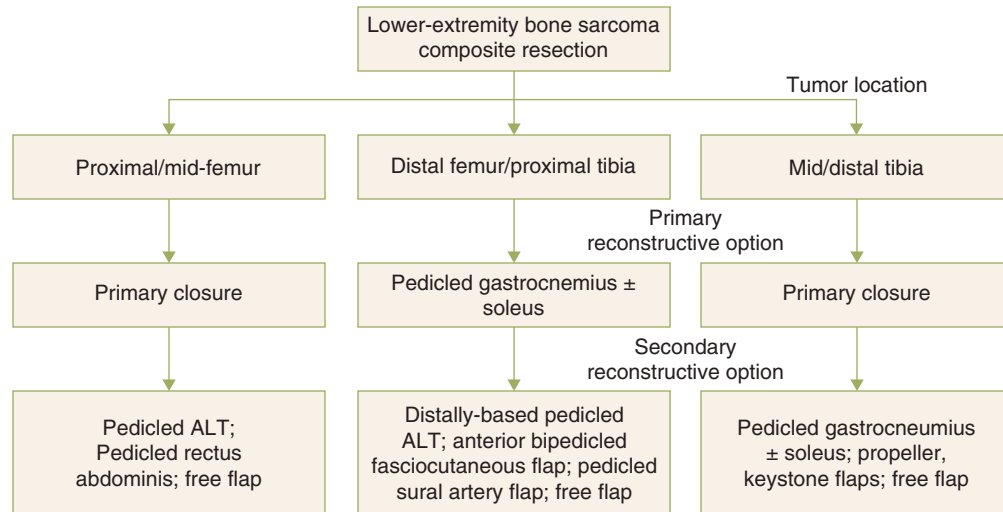

Figure 45-59. Algorithm for effective functional and cosmetic restoration after resection of a lower extremity sarcoma.

Reconstructive surgery in the context of oncology has several distinctive aspects compared to the larger field of reconstructive surgery in general. The procedure must be highly reliable in order to avoid surgical complications that might interfere with adjuvant therapies.

Breast Reconstruction

Breast cancer is the most common malignancy besides skin cancer in women and the second leading cause of cancer-related death for women in the United States. Breast reconstruction is an important part of comprehensive cancer treatment. A number of studies have shown that breast reconstruction, both immediate and delayed, does not impede standard oncologic treatment, does not delay detection of recurrent cancer, and does not change the overall mortality associated with the disease.⁴⁶⁻⁴⁸

Preoperative counseling of the breast cancer patient regarding reconstruction options should include discussion of the timing and technique of reconstruction. It is important to ensure that the patient has realistic expectations of outcome and an understanding of the number of procedures that might be necessary to perform in order to obtain the best outcome. The plastic surgeon and surgical oncologist must maintain close communication to achieve optimal results.

Delayed breast reconstruction occurs any time after the mastectomy is performed, usually 3 to 6 months after the operation, depending on the patient's circumstances and reasons for not electing immediate reconstruction. Although good outcomes can be obtained, it is more difficult to achieve a result that is similar to the preoperative breast shape and size because of established scarring of the chest wall. Nevertheless, it is a good option for patients who are undecided or not candidates for immediate reconstruction because of advanced disease or comorbidities.

Immediate reconstruction is defined as initiation of the breast reconstructive process at the time of the ablative surgery. Patients are considered candidates for immediate reconstruction who are in general good health and have stage I or stage II disease determined primarily by the size and location of the tumor. There are selected exceptions, such as when an extensive resection requires chest wall coverage. Breast reconstruction might be performed in these cases, but it is really incidental to achieving chest wall coverage. Disadvantages of immediate reconstruction include the potential delay of adjuvant therapy in the event of postoperative complications. Also, if there is uncertainty regarding the need to adjuvant radiation therapy, decision-making regarding immediate reconstruction is a challenge. Breast reconstructions by all techniques are adversely affected by radiation therapy, and many surgeons feel reconstruction should be delayed until at least 6 months after treatment.

Once the patient chooses to have immediate reconstruction, she must select a reconstructive technique. In patients selected for breast conservation, oncoplastic tissue rearrangement can be performed to minimize adverse effects of lumpectomy on breast appearance. For patients electing total mastectomy there are essentially three options: (a) tissue expansion followed by breast implant placement, (b) combined tissue flaps with breast implants, and (c) autologous tissue flaps only. After examining the patient, the surgeon then should describe those methods for which the patient is a satisfactory candidate. The patient should then be encouraged to choose based on her goals and an understanding of the advantages and disadvantages of each technique.

Oncoplastic Breast Reconstruction

Breast conservation therapy (BCT) consists of excision of the breast tumor with a surrounding margin of normal tissue combined with postoperative whole-breast irradiation. Although the overall survival for properly selected patients is shown to be comparable to total mastectomy and reconstruction, the breast can often be distorted and unnatural appearing after treatment. The area of the lumpectomy may create a depression with contour deformity, and contraction of the lumpectomy space over time can distort the nipple out of alignment and create an asymmetry with the contralateral breast. This is especially true for women with small breasts in whom a high percentage of breast volume is removed with the lumpectomy.

Oncoplastic surgery refers to the set of techniques developed to lessen breast deformity from a partial mastectomy. One of the most common methods of minimizing adverse effects on breast appearance is to rearrange the skin, parenchyma, and nipple location of the breast at the time of tumor extirpation using surgical techniques developed for breast aesthetic surgery. This procedure involves elevating the skin from the underlying glandular tissue, mobilizing the nipple on a vascular pedicle, and preserving as much of the vascularized glandular tissue as possible. After lumpectomy, the tissue is rearranged to shift glandular tissue into the defect and redrape the skin and nipple onto the new breast mound. After healing and completion of radiotherapy, a contralateral conventional mastopexy or breast reduction can be performed on the contralateral side to achieve symmetry.

Implant-Based Reconstruction

Immediate breast reconstruction based entirely on the use of implanted devices is initially the most expedient technique. Sometimes it is possible to place a full-size implant at the time of mastectomy when the breasts are small (volume <400 cc) and the patient is a young nonsmoker with good chest wall musculature. In most patients, however, a period of tissue expansion is required. The tissue expander is inserted beneath the pectoralis major and serratus anterior muscles at the time of the mastectomy and partially inflated. Alternatively, the tissue expander can be placed only under the pectoralis major muscle or even completely on top of the chest wall muscles then covered with acellular dermal matrix directly beneath the mastectomy skin flaps. Total muscle coverage is the traditional approach, but these alternatives may be suitable only for well-selected patients. Expansion usually requires 6 to 8 weeks to complete, and an implant exchange is performed typically 3 months later. The advantages of this technique are that it involves minimum additional surgery at the time of the mastectomy, has a recovery period essentially the same of that of the mastectomy alone, and creates no additional scarring. The disadvantages of this technique are the length of time necessary to complete the entire reconstruction (up to 1 year), the requirement for a minimum of two operative procedures, and a less predictable cosmetic result due to complete reliance on devices. Also, the patient awakens from surgery without a full-size breast and during the time of expansion must accept a breast of abnormal size and shape. Although the final shape of the breast may be satisfactory, it may lack a natural consistency due to the superficial placement of the device, especially when saline-filled implants are used. Finally, breast implants may develop late complications such as capsular contracture, infection, or extrusion. This method is ideal for a slender, small-breasted woman with minimal ptosis.

who wish to avoid additional scarring and time for convalescence. It may also be suitable for women undergoing bilateral reconstruction because symmetry is more easily achieved if both breasts are restored using the same technique. Women who elect this type of immediate reconstruction must understand that breast implants do not have an unlimited service life and that additional surgery will be likely be required to replace the breast implant at some time in the future.

Tissue Flaps and Breast Implants

The latissimus dorsi musculocutaneous flap is the most common transfer used in combination with breast implants. Other flaps may also be used, depending on patient preference and tissue availability. The principal advantage in using a tissue flap is immediate replacement of missing skin and soft tissue. In cases where there is already adequate breast skin, then a muscle only may be transferred to provide suitable implant coverage. The implant allows the final breast volume to be accurately reproduced to match the contralateral breast or, in bilateral reconstruction, adjust the breast size according to the patient's desires. The advantages of this technique are that the implant is protected by abundant tissue, a period of tissue expansion is avoided, and the full benefit of preserving the breast skin is realized to achieve a natural-appearing breast. The disadvantage of this technique compared to implants alone is that it results in additional scarring and requires a longer period of recovery. For many patients, this approach represents an acceptable compromise between implant-only reconstruction and autologous tissue reconstruction, incorporating some of the advantages and disadvantages of each.

Autologous Tissue Reconstruction

Immediate reconstruction using only autologous tissue is the most elaborate method of breast reconstruction but consistently yields the most durable, natural-appearing results. Breast implants cannot match the ability of the autologous tissue to conform to the breast skin and envelop and simulate natural breast parenchyma. The most useful flap is the transverse rectus abdominis musculocutaneous (TRAM) flap, although other

donor areas are also possibilities in selected cases. Autologous reconstruction is usually the best option in patients who require adjuvant radiation therapy.⁵⁵

The TRAM flap may be transferred to the chest using a variety of methods, depending on the circumstances of the individual patient. As a pedicled flap, it is transferred based on the superior epigastric vessels and tunneled beneath the skin to reach the mastectomy defect. As a free flap, it is based on the inferior epigastric vessels that are revascularized by microvascular anastomosis to vessels on the chest wall nearby the mastectomy defect. Often the microvascular technique using the deep inferior epigastric perforator (DIEP) flap is preferred because there is less risk of partial flap loss or localized areas of fat necrosis due to a more reliable blood supply (Fig. 45-60A, before operation on right breast; Fig. 45-60B, after mastectomy and immediate reconstruction with a DIEP flap). In immediate reconstruction with an axillary dissection, the axillary vessels are completely exposed and free of scar following the lymph node dissection in patients without previous surgery and radiation. In women being treated for recurrence with previous axillary surgery, the axillary vessels are less reliable, and plans should be made for the possibility of using the internal mammary vessels. The internal mammary vessels have become the most common recipient vessels for free tissue transfer in breast reconstruction in the contemporary era of sentinel lymph node biopsy that is used as a technique to perform axillary lymph node dissection in a more limited number of patients. Regardless of the technique used to transfer the tissue, the donor site is closed in a similar manner as an abdominoplasty, by repairing the abdominal wall and advancing the upper abdominal skin downward. The umbilicus is preserved on its vascular stalk brought to the surface through a small incision immediately above its location on the abdominal wall (Fig. 45-61A,B). Other donor sites including the buttock may be used in transferring the skin and fat supplied by the inferior gluteal artery perforator (IGAP) or the superior gluteal perforator as the main blood supply.

The advantages of using this technique are complete restoration of the breast mound in a single stage, avoidance of

Immediate right DIEP Flap

Preoperative

potential problems associated with breast implants, and consistently superior cosmetic results. The disadvantages are the magnitude of the operation, additional scarring, risks of development of abdominal bulges, and a longer period of convalescence. Although the initial cost is greater, over the long term the total cost appears to be less because of less need for secondary procedures to exchange implants, achieve suitable cosmetic appearance, or care for implant-related problems. This is the best operation for patients who want the most natural breast restoration possible and who are less concerned about the amount of surgery, scarring, and recovery period.

Accessory Procedures

After complete healing of the breast mound from the initial stages of reconstruction, refinements and accessory procedures may be performed at a later time to optimize the natural appearance of the reconstructed breast. These may include soft tissue

modifications of the breast mound revision, repositioning or the breast implant, scar revisions, autologous fat grafting, and nipple-areola complex reconstruction. A variety of methods have been described for nipple reconstruction. They are all based on local tissue rearrangements or skin grafts to create a projecting piece of skin and subcutaneous tissue that simulates the natural nipple (Fig. 45-62A,B). The pigmentation of the areola may be simulated with tattooing of colored pigments selected to match the normal coloration of the patient's original anatomy.

Trunk and Abdominal Reconstruction

In the torso, as in most areas of the body, the location and size of the defect and the properties of the deficient tissue determine choice of reconstructive method. A distinction is made between

9► partial-thickness and full-thickness defects when deciding between grafts, flaps, synthetic materials, or a combination of techniques. Unlike the head and the lower leg, the trunk

Bilateral IGAP Flap

Figure 45-62A, B. Pre- and postoperative images following IGAP flap, nipple reconstruction, and tattooing.

harbors a relative wealth of regional transposable axial pattern flaps that allow sturdy reconstruction, only rarely requiring distant free tissue transfer. Indeed, the trunk serves as the body's arsenal, providing its most robust flaps to rebuild its largest defects.

The chest wall is a rigid framework designed to resist both the negative pressure associated with respiration and the positive pressure from coughing and from transmitted intra-abdominal forces. Furthermore, it protects the heart, lungs, and great vessels from external trauma. Reconstructions of chest wall defects must restore these functions. When a full-thickness defect of the chest wall involves more than four, this is usually an indication for the need for rigid chest wall reconstruction usually using synthetic meshes made of polypropylene, polyethylene, or polytetrafluoroethylene, which may be reinforced with polymethylmethacrylate acrylic. In contaminated wounds, biologic materials are preferred, such as acellular dermal matrix allografts. For soft tissue restoration, the pectoralis major muscle is commonly used as a pedicled flap for coverage of the sternum, upper chest, and neck. It may be mobilized and transferred on a vascular pedicle based on the pectoral branch of the thoracoacromial artery or a vascular supply based on perforators from the internal mammary vessels. Either flap design is useful in covering the sternum after dehiscence or infection occurring as a complication of median sternotomy or with sternal resection for tumor extirpation. For the lower third of the sternum, a rectus abdominis muscle flap based on the superior epigastric vessels or the deep inferior epigastric vessels is useful. If based on the inferior blood supply, it must be transferred as a free flap with recipient vessels outside of the zone in injury. The latissimus dorsi musculocutaneous flap is useful for chest wall reconstructions in places other than the anterior midline. Similar to the pectoralis major muscle, it may be transferred on either a single blood supply that is based on the thoracodorsal vessels from the subscapular system or on vessels perforating from deeper source vessels near to the posterior midline. The serratus anterior muscle can be included on the same vascular pedicle to further increase its surface area. Finally, the trapezius muscle flap, based on the transverse cervical vessels, is generally used as a pedicled flap to cover the upper midback, base of neck, and shoulder. The superior portion of the muscle along with the acromial attachment and spinal accessory nerve must be preserved to maintain normal shoulder elevation function.

The abdominal wall also protects the internal vital organs from trauma, but with layers of strong torso-supporting muscles and fascia rather than with osseous structures. The goals of reconstruction are restoration of structural integrity, prevention of visceral herniation, and provision of dynamic muscular support. Although abdominal wall defects may occur in association with oncologic tumor resections, the most common etiology is fascial dehiscence after laparotomy. When a reconstruction plan is being formulated, careful physical examination and review of the medical history will help prevent selection of an otherwise sound strategy that, because of previous incisions and trauma, is destined for failure.

Superficial defects of the abdominal skin and subcutaneous tissue are usually easily controlled with skin grafts, local advancement flaps, or tissue expansion. Defects of the underlying musculofascial structures are more difficult to manage. The abdominal wall fascia requires a minimal-tension closure to avoid dehiscence, recurrent incisional hernia formation, or

abdominal compartment syndrome. Prosthetic meshes are frequently used to replace the fascia in clean wounds and in operations that create myofascial defects. When the wound is contaminated, as in infected mesh reconstructions, enterocutaneous fistulas, or viscus perforations, prosthetic mesh is avoided because of the risk of infection. The technique of component separation procedure has proven beneficial for closing large midline defects with autologous tissue and avoiding prosthetic materials. This procedure involves advancement of bilateral flaps composed of the anterior rectus fascia rectus and oblique muscles after lateral release. Midline defects measuring up to 10 cm superiorly, 18 cm centrally, and 8 cm inferiorly can be closed using this method.

Techniques based on rearranging and reinforcing abdominal wall elements might be inadequate for extremely large or full-thickness abdominal wall defects. For these defects, regional flaps or free flaps are required. Pedicled flaps from the thigh are useful, such as the tensor fasciae latae pedicled flap, based on the ascending branch of the lateral circumflex femoral vessels, or the anterolateral thigh flap, based on the descending branch of the lateral circumflex vessels. Bilateral flaps might be required.

Pelvic Reconstruction

Another important area for consideration of reconstructive surgical procedures is in the perineum.⁵⁶ The perineal region is part of the specialized part of the trunk that supports the pelvic outlet lying between the pubic symphysis, the coccyx, the inferior rami of the pubis, and the ischial tuberosities. Support is provided by the urogenital diaphragm, the deep and superficial fasciae, and the skin. Specialized anatomic structures pass through the perineum. Posteriorly is the anus, and anteriorly are the genitalia and urethra. Treatment of tumors involving this area often require a combination of surgery and radiation. The resulting loss of tissue and healing impairment coupled with the nonyielding nature of the bony pelvic outlet can result in unique reconstructive requirements that often are best addressed with tissue transfer. The reconstruction must achieve wound healing and restore support to the pelvic contents, accommodate urinary and bowel function, and finally restore the penis in men and the vagina and vulva in women. Local flaps, regional flaps, or free tissue transfer all have possible application depending on the extent of the resection and local tissue compromise.

Other Clinical Circumstances

Besides trauma and cancer, other etiologies can cause functional and cosmetic deformities due to tissue impairment for which reconstructive surgery has value. These include pressure sores, diabetic foot ulcers, and lymphedema.

Pressure Sores. A pressure ulcer is defined as tissue injury caused by physical pressure applied to the tissues from an external source at a magnitude that exceeds capillary perfusion pressure. Prolonged tissue ischemia leads to local tissue necrosis. Pressure ulcers tend to occur in people debilitated by advanced age, chronic illness, poor nutrition, prolonged immobilization, motor paralysis, or inadequate sensation. Spinal cord injury patients are especially prone to developing pressure sores. Pressure sores can also occur in healthy individuals who undergo prolonged surgical operations and parts of the body supporting the weight of the patient on the operating table (e.g., the occiput, the sacral prominence, the heels of the feet) are improperly padded.⁵⁷

Pressure sores are an important contributor to morbidity in patients suffering from limited mobility. Most can be prevented by diligent nursing care in an attentive, cooperative patient. Preventing pressure ulcers requires recognition of susceptible and utilizing appropriate measures to reduce pressure on areas of the body at risk. This involves frequent position changes while sitting or supine and the use of pressure-reducing medical equipment such as low-air-loss mattresses and seat cushions and heel protectors. Malnourishment, poor glucose control in diabetics, poor skin hygiene, urinary or bowel incontinence, muscle spasms, and joint contractures all increase the risk of pressure sore formation. Mitigating these factors is essential before embarking on a complex reconstructive treatment plan. Successful reconstruction also requires a cooperative and motivated patient with good social support.

Surgical treatment of pressure ulcers is based on wound depth. The staging system is summarized in Fig. 45-63.⁵⁸ Stage I and II ulcers are treated nonsurgically with local wound care and interventions to relieve pressure on the affected area. Patients with stage III or IV ulcers should be evaluated for surgery. Important features for preoperative assessment include the extent of soft tissue infection, the presence of contaminated fluid collection or abscess, osteomyelitis, and communication with deep spaces (e.g., joint space, urethra, colon, or spinal canal). Laboratory blood tests and imaging studies help establish whether soft tissue or bone infection is present. Plain radiographs are usually adequate to rule out osteomyelitis; CT and MRI are helpful when plain films are equivocal. Necrotic tissue and abscesses should be surgically debrided without delay to prevent or treat systemic sepsis. Bone must also be excised if it appears involved, as evidenced by poor bleeding, softness, or frank purulence. Patients with high spinal cord injuries at or above the level of the fifth thoracic vertebra may experience sudden extreme elevation of blood pressure, an

autonomic-mediated event called *hyperreflexia*. This condition must be immediately recognized and treated to prevent intracranial and retinal hemorrhage, seizures, cardiac irregularities, and death.

After adequate debridement, the pressure ulcer can be treated nonsurgically in patients who have shallow wounds with healthy surrounding tissues capable of healing secondarily with offloading pressure. Nonsurgical treatment is also best in patients for whom surgery is contraindicated because of previous surgery or comorbidities. For surgical candidates, primary closure is rarely performed because an inadequate amount of quality surrounding tissue prevents closure without tension, making the repair predisposed to failure. Split-thickness skin grafting can be useful for shallow ulcers with well-vascularized wound beds on which shear forces and pressure can be avoided after repair, a rare circumstance in most patients with pressure ulcers.

The mainstay of surgical treatment is tissue transfer following several guiding principles. Local muscle or musculocutaneous flaps are suitable for areas of heavy contamination and complex wound surface contours. Durability requires the ability to consistently off-load of the area of reconstruction postoperatively. Fasciocutaneous flaps afford more durable reconstruction when off-loading is not possible. The anatomic location is an important determinant of flap choice. Once a donor site is selected, a flap of adequate size is designed and transferred in a way that avoids suture lines in the area under pressure. Large flaps also permit readvancement if the patient experiences a recurrent ulcer in the same area. Sacral pressure sores may be managed with fasciocutaneous or musculocutaneous flaps based on the gluteal vessels. Ischial pressure sores may be managed with gluteal flaps or flaps transferred from the posterior thigh, such as the posterior thigh flap based on the descending branch of the inferior gluteal artery. Trochanteric ulcers

Stage 1

Observable pressure related alteration of intact skin whose indicators as compared to the adjacent or opposite area of the body may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), and/or sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones the ulcer may appear with persistent red, blue or purple hues.

A

Stage 2

Partial thickness skin loss involving epidermis and/or dermis. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

B

Stage 3

Full thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

C

Stage 4

Full thickness skin loss with extensive destruction, tissue necrosis or damage to muscle, bone, or supporting structures (for example, tendon or joint capsule). Undermining and sinus tracts may also be associated with Stage 4 pressure ulcers.

D

Figure 45-63. The staging system for pressure sores.

Figure 45-64. Flap reconstruction of pressure ulcers. *Top row:* Preoperative and 1-month postoperative photos of a stage IV sacral decubitus ulcer treated with a myocutaneous gluteus maximus flap. *Bottom row:* Preoperative and 1-month postoperative photos of a stage IV trochanteric ulcer treated with a myocutaneous V-Y tensor fasciae latae flap.

may be managed with musculocutaneous flaps based on the tensor fasciae latae, rectus femoris, or vastus lateralis muscles (Fig. 45-64). The obligatory loss of motor function associated with using these flaps adds no additional functional impairment in patients already paralyzed as a result of strokes or spinal cord injuries.

Proper postoperative care after flap reconstruction of pressure ulcers is critical for success. Low-pressure, air fluidized beds help to off-load the affected area and prevent new areas of involvement during the first 7 to 10 days of healing. Other important measures are adequate nutritional support and medications to prevent muscle spasms. Careful coordination with patient care providers is planned preoperatively in order to avoid gaps in care that can lead to early recurrent ulceration. Care of the pressure ulcer patient is a labor-intensive process that requires attention to detail by the surgeon, nurses, therapists, caseworkers, and family.

Diabetic Foot Ulceration. The pathophysiology of primary diabetic lower limb complications has three main components: (a) peripheral neuropathy (motor, sensory, and autonomic), (b) peripheral vascular disease, and (c) immunodeficiency. Altered foot biomechanics and gait caused by painless collapse of ligamentous support, foot joints, and foot arches

change weight-bearing patterns. Blunted pain allows cutaneous ulceration to begin. With breakdown of the skin barrier function, polymicrobial infections become established. Bacterial invasion is often fostered by poor blood supply due to peripheral vascular disease coupled with microangiopathy. Finally, local host defenses may be less effective in resisting bacteria because of poor blood supply and impaired cellular function. Cutaneous ulcerations may progress painlessly to involve deeper soft tissues and bone. The ultimate endpoint of this process is such severe tissue damage that extremity amputation is the only treatment remaining. More than 60% of nontraumatic lower extremity amputations occur in diabetics. The age-adjusted lower extremity amputation rate in diabetics (5.0 per 1000 diabetics) was approximately 28 times that of people without diabetes (0.2 per 1000 people).⁵⁹ Improved patient education and medical management, early detection of foot problems, and prompt intervention play important roles in improving the chances of limb preservation.⁶⁰

The best approach to managing diabetic patients with lower extremity wounds is to involve a multidisciplinary team composed of a plastic and reconstructive surgeon, a vascular surgeon, an orthopedic surgeon, a podiatrist, an endocrinologist specializing in diabetes, a nutritionist, and a physical or

occupational therapist. This brings together the greatest level of expertise to manage bone and soft tissue issues as well as the underlying disease and medical comorbidities. Treatment begins with rigorous control of blood glucose levels and a thorough assessment of comorbidities. In addition to careful detailing of the extent of the wound and the tissues involved, physical examination documents sensory deficits and vascular status. Plain radiographs, MRI, bone scintigraphy, and angiography or duplex Doppler ultrasound imaging may be indicated. A patient with significant vascular disease may be a candidate for lower extremity endovascular revascularization or open bypass.⁶¹ Nerve conduction studies may diagnose surgically reversible neuropathies at compressive sites and aid in decisions about whether to perform sensory nerve transfers to restore plantar sensibility.⁶⁰ Antibiotic and fungal therapies should be guided by tissue culture results.

Surgical management starts with debridement of devitalized tissues. Methods of wound closure are dictated by the extent and location of the remaining defect. Negative pressure wound dressings may be appropriate for superficial defects in an effort to allow secondary healing or as a temporizing measure until definitive wound closure can be achieved. Skin grafts might be indicated at times but cannot be expected to provide durable coverage in weight-bearing or high-shear areas. Local and regional flaps can be considered if the extremity is free of significant occlusive peripheral vascular or combined with vascular bypass. Microvascular free tissue transfers are appropriate when defects are large or when local flaps are not available. Combination lower extremity bypass and free flap coverage has proved beneficial for the treatment of the diabetic foot in terms of healing and reduction of disease progression (Table 45-6). Consultation with a podiatrist or an orthopedic surgeon who specializes in foot and

ankle problems can be considered to improve foot biomechanics and manage bony prominences that act as pressure points on the soft tissue to reduce the risk of recurrent ulceration. Proper footwear (including orthotic devices and off-loading shoe inserts), hygiene, and toenail and skin care are essential.⁶⁰

Lymphedema. Lymphedema is the abnormal accumulation of protein-rich fluid in the interstitial spaces of the tissues. It is a complex disorder with both congenital and acquired causes. No universally effective remedy has been devised, but a variety of treatment methods including reconstructive surgery have been effective in carefully selected patients.

It is important to be familiar with the fundamentals of lymph physiology in order to understand the rationale for the various forms of lymphedema treatment. Lymph fluid is formed at the capillary level where there is a net outflow of fluid and serum proteins from the intravascular space into the interstitium. In the average adult, this amounts to approximately 3 liters of fluid daily. Open-ended lymph capillaries collect this fluid where the lymphatic endothelial cells form loose intercellular connections that freely allow fluid to enter. From here, the network of specialized vascular structures gathers the extravasated fluid and transports it back into central circulation. The system is a high-volume transport mechanism that clears proteins and lipids from the interstitial space primarily by means of differential pressure gradients. Lymph fluid enters the lymph vessels driven by colloid and solute concentration gradients at the capillary level. Flow is sustained in the larger vessels through direct contractility of the lymph vessel walls and by indirect compression from surrounding skeletal muscle activity. Throughout the system, one-way valves prevent reverse flow. The lymphatic vessels course throughout the body alongside the venous system, into which they eventually drain via the major thoracic and cervical ducts at the base of the neck.

Under normal conditions, there is a balance between fluid formation and lymph transport capacity. With congenital hypoplasia or acquired obstruction, there is a reduction in transport capacity resulting in accumulation of fluid and protein in the interstitium. Localized fluid stagnation, hypertension, and valvular incompetence further degrade transport capacity and accelerate lymph fluid accumulation edema. Dissolved and suspended serum proteins, cellular debris, and waste products of metabolism elicit an inflammatory response with associated with fibrovascular proliferation and collagen deposition leading to firm, non-pitting swelling characteristic of chronic, long-standing edema. Lymphoscintigraphy can help detail the lymphatic anatomy and quantify lymphatic flow. MRI can provide additional information about the larger caliber lymphatic vessels, possibly helping to identify specific points of obstruction.

Primary lymphedema is caused by congenital hypoplasia and is classified clinically based on the age of the affected individual when swelling first appears. Lymphedema present at birth is an autosomal dominant disorder sometimes referred to as Milroy's disease. Lymphedema praecox occurs near the time of puberty but can appear up to age 35. This form tends to occur in females and usually affects the lower extremity. It accounts for more than 90% of cases. Finally, lymphedema tarda appears after the age of 35 years and is relatively rare.

Secondary lymphedema is the acquired form of the disorder and is more common than congenital causes. Worldwide the most common etiology is parasitic infestation with filarial, a highly specialized nematode transmitted by blood-eating insects

Table 45-6

Some reconstructive options for the diabetic foot

AREA OF DEFECT	RECONSTRUCTIVE OPTIONS
Forefoot	V-Y advancement Toe island flap Single toe amputation Lisfranc's amputation
Midfoot	V-Y advancement Toe island flap Medial plantar artery flap Free tissue transfer Transmetatarsal amputation
Hindfoot	Lateral calcaneal artery flap Reversed sural artery flap Medial plantar artery flap ± flexor digitorum brevis Abductor hallucis muscle flap Abductor digiti minimi muscle flap Free tissue transfer Syme's amputation
Foot dorsum	Supramalleolar flap Reversed sural artery flap Thinner free flaps (e.g., temporoparietal fascia, radial forearm, groin, thinned anterolateral thigh flaps)

found mostly in developing countries. In nonaffected areas of the world, the most common cause of secondary lymphedema is regional lymphatic vessel destruction associated with cancer treatment. It often occurs in the upper extremity of women treated with surgery and radiation therapy for breast cancer. In the lower extremities, it is associated with neoplasms treated with inguinal or retroperitoneal lymph node dissection.

The goal of lymphedema treatment is to minimize functional and cosmetic disability caused by chronic enlargement and to prevent infection of the involved extremity. The foundations of management are patient education and nonsurgical interventions, which include limb elevation, external compressive garments and devices, and manual lymphatic massage, sometimes referred to as complex decongestive physiotherapy. The patient must use protective gloves or garments when engaged in activities that might cause minor skin injury, such as gardening, smoking cigarettes, and cooking. Interstitial lymph fluid is prone to infection. When signs of infection appear, prompt treatment that often includes hospitalization with intravenous antibiotics is essential to prevent severe infection and further destruction of remaining lymphatic system and worsening of lymphedema.

When nonsurgical methods fail, surgery can be considered as a treatment option. Surgical operations for lymphedema are either ablative, designed to remove excess lymphedematous tissues, or reconstructive, intended to restore lymph function and improve transport capacity. These choices are presented in Fig. 45-65. Ablative procedures range from minimally invasive

measures such as suction lipectomy to complete excision of skin and subcutaneous tissue down to muscle fascia with split-thickness skin grafting. Contemporary reconstructive procedures establish new connections between the venous and lymphatic systems somewhere proximal to the point of obstruction. A variety of methods have been described, including lympholymphatic, lymphovenous, lymph node venous anastomoses, and vascularized lymph node transfer. Each of these procedures can yield success, and it has become clear that patient selection is perhaps the most important aspect of surgical care because the patient must be matched to the procedure most likely to yield improved control of swelling and prevent infection. Reconstructive surgery is not generally a cure for the condition, but rather it is intended to ease management challenges and reduce the risks of infection. After surgery, continued use of nonsurgical techniques is still required for optimal results.

AESTHETIC SURGERY AND MEDICINE

Aesthetic, or cosmetic, surgery is an important part of the specialty of plastic surgery. The American Medical Association defines cosmetic surgery as “surgery performed to reshape normal structures of the body to improve the patient’s appearance and self-esteem.” It is a natural extension of surgical techniques for tissue modification traditionally developed for other reasons. Because aesthetic surgery primarily relates to personal appearance and attractiveness and not a particular disease process, there has been a tendency to dismiss the health value of

Figure 45-65. Algorithm for lymphedema management.

aesthetic surgery. Nevertheless, personal appearance plays an important role in psychosocial health. Physical attractiveness plays a role in the marketplace with well-documented influence on employment opportunities, advancement, and earnings.⁶² The multibillion industry of products and services designed to optimize appearance, which spans a wide spectrum between simple cosmetics to elaborate surgical procedures, bears testament to the perceived value by the general population.

Important work demonstrates a link between aesthetic surgery and psychosocial health. Surgery performed on the face,⁶³ nose,⁶⁴ ears,⁶⁵ breast,⁶⁶ and body⁶⁷ can positively affect quality of life on multiple scales. There is a clear association between one's personal appearance and success in the marketplace. As the primary benefits of aesthetic surgery are related to the psychosocial outcomes, it is important to assess the state of psychological health prior to offering aesthetic surgery. A variety of preoperative psychological comorbidities can adversely affect outcomes, most notably a syndrome known as *body dysmorphic disorder*,⁶⁸ present in individuals who manifest a preoccupation with one or more perceived defects or flaws in physical appearance that are not observable or appear slight to others.⁶⁹ Performing a surgical procedure to modify personal appearance in such an individual is associated with a high risk of a poor outcome.

It is important for all surgeons to have an appreciation of the methods of patient evaluation, surgical techniques, and typical outcomes that might be anticipated in aesthetic surgery. Patients seek aesthetic surgery when they are unable to achieve a personal standard of physical appearance without surgical modification of various body parts that most affect their appearance. This is especially true for features that are visible in public and strong determinants of appearance, such as the face, breasts, abdomen, and buttocks. The etiology of undesirable characteristics of form or skin quality can be familial or acquired through natural processes of aging, injury, cancer, or degeneration. Unwanted changes in appearance that result from these processes may still fall within the range of normal appearance yet fall short of the patient's personal aesthetic ideal. Patient assessment requires an understanding of personal and cultural ideals of appearance. The surgeon must be knowledgeable about the various surgical and nonsurgical techniques that might be considered to address the patient's concerns.

In practical terms, there are both reconstructive and cosmetic elements to almost every plastic surgery case, and the definition of "normal" structure is sometimes very subjective and difficult to quantify. Nevertheless, there are patients for whom it is a priority to make surgical changes to their bodies in the clear absence of a functional deformity. Aesthetic surgery patients present a unique challenge to the plastic surgeon because the most important outcome parameter is not truly appearance, but patient satisfaction. Optimally, a good cosmetic outcome will be associated with a high level of patient satisfaction. For this to be the case, the plastic surgeon must do a careful analysis of the patient's motivations for wanting surgery, along with the patient's goals and expectations. The surgeon must make a reasonable assessment that the improvements that can be achieved through surgery will meet the patient's expectations. The surgeon must appropriately counsel the patient about the magnitude of the recovery process, the exact location of scars, and potential complications. If complications do occur, the surgeon must manage these in a manner that preserves a positive doctor-patient relationship.

Aesthetic Surgery of the Face

A thorough evaluation of the patient who presents for facial aesthetic surgery begins with acquiring a clear understanding of the patient's primary concern regarding appearance. Examination focuses on that region but takes into consideration overall facial appearance that might be contributing to the patient's concerns but of which the patient is unaware. The skin quality is carefully assessed as well as the location, symmetry, and position of each critical feature of facial appearance such as scalp hairline, forehead length, eyebrow shape and position, eyelid configuration, nasal proportions, and shape of the lips. Overall facial proportions are assessed, such as the prominence of the orbital rims and malar areas, the chin projection, and contours along the margin of the mandible. An appropriately performed facelift can yield an aesthetically pleasing result (Fig. 45-66).

A variety of procedures have been described for modifying facial appearance. Nonsurgical interventions topical treatments of the skin surface include chemical and laser facial peels. Injections of biocompatible materials made of processed biologic proteins (e.g., collagen, hyaluronic acid) or synthetic materials such as polymethylmethacrylate can modify the depth of facial wrinkles and fullness of facial structures such as the lips. Appearance can also be modified using neuromodulators to block facial muscle function to reduce undesirable movements of facial landmarks or deepening of facial wrinkles. Surgical interventions may be employed when the structure and position of facial features require modifications greater than what may be achieved with nonsurgical procedures. Browlift operations raise the position of the eyebrows (Fig. 45-67). Blepharoplasty is a set of procedures that modify the shape and position of the upper and lower eyelids. Facelift modifies the configuration and amount of facial skin and subcutaneous

B

Figure 45-67. Facelift. **A.** Preoperative appearance. **B.** Postoperative appearance.

structures to correct features such as deep nasolabial folds, skin redundancy along the inferior border of the mandible, and loss of definition of neck contours. Rhinoplasty involves a complex set of procedures to modify the size, shape, and airway function of the nose (Fig. 45-68).

Aesthetic Surgery of the Breast

Surgery to modify the shape, volume, and nipple position of the breast are among the most common aesthetic procedures.

Breast reduction surgery reduces the amount of both skin and breast tissue volume and modifies the position of the nipple on the breast mound (Fig. 45-69). The most common indication is to treat symptoms of large breasts known as macromastia, which is associated with a symptomatic triad of upper back pain, bra strap grooving, and skin rashes under the fold of the breasts. Unilateral breast reduction is often performed to achieve breast symmetry after contralateral postmastectomy breast reconstruction. As with all breast surgery, achieving a natural and cosmetically acceptable appearance is essential to a satisfactory outcome. Mastopexy techniques share many aspects with breast reduction except that breast volume is preserved and only the amount of skin and location of the nipple are modified. Fundamental to the success of the procedure is the establishment of symmetric and proper nipple position. Nipple ptosis is graded by the nipple position relative to the inframammary fold.

Many patients seek surgical intervention to increase breast size in a procedure known as augmentation mammoplasty (Fig. 45-70). Breast volume is increased by insertion of a synthetic implant specifically designed for this purpose. Modern breast implants are manufactured from various formulations of silicone polymers. The implant shell, which is in contact with the tissues, is always made from silicone elastomer. The filling material can be either silicone or saline, depending on the patient and surgeon preference. As with any surgical procedure that involves implanting synthetic materials, the surgeon must fully understand the nature of the materials and be able to inform the patient of all known risks and benefits.

The pervasive risk of breast cancer among women mandates careful consideration of the impact of any breast surgery on cancer screening, diagnosis, and treatment. Preoperative breast cancer screening consistent with current American Cancer Society guidelines should be performed for all patients undergoing elective breast reshaping surgery. After breast augmentation surgery, routine screening mammograms are no longer considered adequate. Patients with breast implants must have diagnostic mammograms where a radiologist studies the images at the time of the study to ensure they completely visualize the breast tissue.

Gynecomastia is a condition of excess breast tissue in males. It can be caused by a wide range of medical disorders, including liver dysfunction, endocrine abnormalities, genetic syndromes (e.g., Klinefelter's syndrome), renal disease, testicular tumors, adrenal or pituitary adenomas, secreting lung carcinomas, and male breast cancer. Pharmacologic agents associated with the potential side effect of breast enlargement include marijuana use, digoxin, spironolactone, cimetidine, theophylline, diazepam, and reserpine. Although all of these possible causes must be considered in any patient presenting with gynecomastia, the majority of patients have idiopathic enlargement of the breast parenchyma, often occurring in teenagers. Surgical correction of this condition is often indicated.

Aesthetic Surgery of the Body

Aesthetic surgery may be applied to the torso and extremities. The most common circumstance is following massive weight loss, typically as a result of bariatric surgery. Morbid obesity stretches the skin and supporting ligaments that tether it to the underlying fascial framework. Decreasing the amount of subcutaneous fat often results in significant skin laxity that creates body contour deformities. Improvement can be achieved only through skin excision. Therefore, all body-contouring surgery

A

B

C

Figure 45-68. A. Rhinoplasty anatomy. B. Preoperative appearance. C. Postoperative appearance.

represents a trade of excess skin for scar, and this must be emphasized during patient consultation. The patient willing to accept scars in exchange for improved contour is likely to be satisfied with the procedures. With the increased number of bariatric surgery procedures over the past decade, body-contouring surgery has become very popular and is emerging as a new subspecialty of plastic surgery.

Excess skin and subcutaneous tissue on the anterior abdominal wall creates a redundancy that can hang over the pubic area called an *abdominal wall pannus*. It can cause difficulty dressing and maintaining proper personal hygiene. A panniculectomy is a procedure that removes the redundant skin and subcutaneous tissue of the pannus. If additional contouring

of the abdominal wall is performed, the procedure is known as *abdominoplasty*. During this procedure, not only is the pannus excised but the maximum amount of skin is excised to tighten the abdominal wall. Optimum contouring typically requires tightening of the underlying abdominal wall by suturing the midline and transposing the umbilicus as the upper abdominal skin is advanced inferiorly. At times additional skin must be excised transversely, requiring a concurrent vertical incision to remove skin in two vectors (Fig. 45-71). Possible complications include skin necrosis, persistent paresthesias of the abdominal wall, seroma, and wound separation. Necrosis of the umbilicus may complicate preservation of that structure if the stalk is excessively long or an umbilical hernia is repaired. Adding a

Figure 45-69. Inferior pedicle reduction mammoplasty.

Figure 45-69. (Continued)

vertical resection increases the incidence of skin necrosis, especially at the confluence of scars in the lower abdomen.

Brachioplasty, or arm lift, excises excess skin and subcutaneous tissue from the arms. It results in improved contour but

leaves a visible longitudinal scar on the medial aspect of the arm. Therefore, it is reserved for patients with excessive skin in that region. The patient willing to accept the scar can be happy with the results. Complications include distal seroma and wound separation. Paresthesias in the upper arm and forearm may occur secondary to injury of sensory nerves passing through the resection area, though this rarely affects function. Incisions that cross the axilla must be designed to avoid axillary contractures that limit shoulder mobility.

Thigh and buttock lifts treat loose skin on the thighs and buttocks. A variety of methods have been described, and application requires proper patient selection in order to obtain the best outcome. The lateral thighs can be lifted simultaneously during abdominoplasty with one scar along the belt line. If the lift is continued on the posterior torso, a buttocks lift can be performed as well. This procedure is referred to as a *circumferential lower body lift*. Contouring the medial thighs typically requires an incision in the groin crease. Firmly anchoring the deep thigh fascia to Colles' fascia is essential to help prevent spreading of the labia. In cases of severe excess skin on the inner thighs, a long vertical incision is necessary. Complications of thigh and buttock lift include seroma, wound separation, skin necrosis, and change in the shape of the genital region (with possible sexual dysfunction).

Suction Lipectomy

Liposuction is a technique that involves the removal of adipose tissue through minimal incisions using a hollow suction cannula system. The key consideration in determining acceptable candidates for this body contouring technique directly relies on the patient's inherent skin elasticity, which provides the sought-after retraction of skin over the lipos aspirated adipose depot to improve area contour. Thus, assessment of skin tone is a vital part of the preoperative patient evaluation. If there is excessive skin laxity in the body area to be treated, it may worsen after liposuction and contribute to contour irregularities, voids, and abnormal appearance.

This technique can be highly effective in the correctly chosen patient as the access port sites provide minimally visible scars and can remove significant amounts of fatty tissue to improve contour. However, it is worth mentioning that liposuction is not considered a weight-loss treatment; rather, it is a tool for addressing unwanted and troublesome adipose depots. Typically, the best candidates for liposuction are individuals who are close to their goal weight and have focal adipose deposits that are resistant to diet and exercise (Fig. 45-72). The suction cannula system removes adipose tissue by avulsing fat into the small holes located within the cannula tip. As the cannula is repeatedly passed throughout the adipose planes to remove the fat, one can often visualize and feel the reduction in the fat depot area treated. In general, larger-diameter cannulas remove adipose tissue at a faster rate yet carry a higher risk of causing contour irregularities such as grooving and/or uneven removal of fat. Newer liposuction technologies employing ultrasonic or

laser probes to heat and emulsify fat via cavitation before suction are gaining increasing application because they also aid in better tightening of the overlying skin envelope. However, use of these technologies also increases the chance and incidence of tissue damage and injury from the heat of the cannula and can cause burn injury to skin and underlying structures.

A major advance in the field of liposuction involves application of tumescent local anesthesia. This method involves the infiltration of very dilute lidocaine and epinephrine (lidocaine 0.05% and epinephrine 1:1,000,000) in large volumes throughout the subcutaneous tissues prior to suction removal of fatty tissue. Tumescent volumes can range from one to three times the anticipated aspirate volume. The dilute lidocaine provides sufficient anesthesia to allow the liposuction to be performed without additional agents in some instances. However, in cases where large volumes of fat are to be removed or in cases where multiple sites are to be addressed, then sedation and/or general anesthesia is often preferred. With tumescent anesthesia, the absorption of the dilute lidocaine from the subcutaneous tissue is very slow, with peak plasma concentrations occurring approximately 10 hours after the procedure. Therefore, the standard lidocaine dosing limit of 7 mg/kg may be safely exceeded. Current recommendations suggest a limit of 35 mg/kg of lidocaine with tumescent anesthesia. A very important component of the tumescent anesthetic solution is diluted epinephrine, which has proved to limit blood loss during the procedure.

Safety issues are paramount for liposuction because of potential fluid shifts postoperatively and hypothermia. If ≥ 5000 mL of aspirate is to be removed, the procedure should be

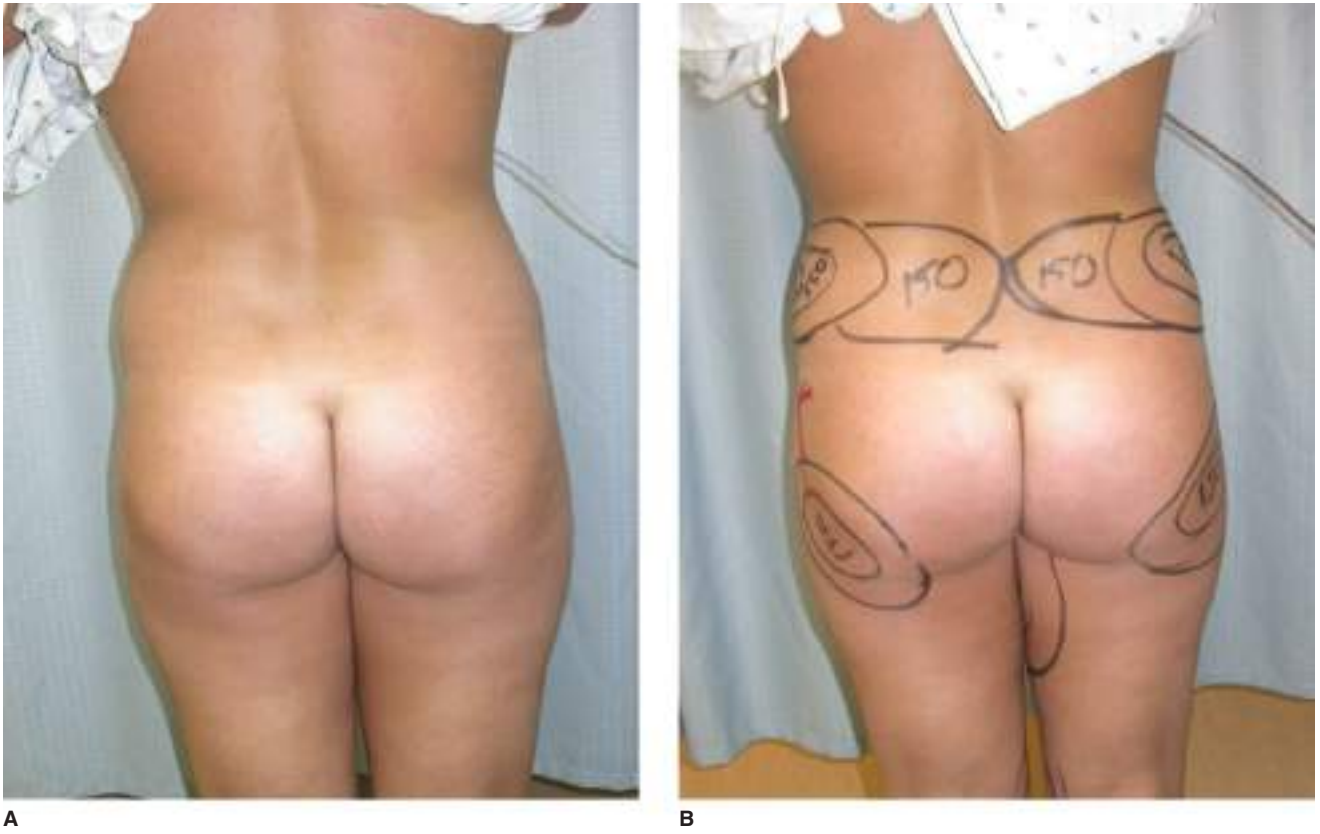

Figure 45-72. A and B. Preoperative photos of a 22-year-old woman with focal adipose deposits on the trunk and extremities. C. Patient 3 months after surgery.

performed in an accredited acute care hospital facility. After the procedure, vital signs and urinary output should be monitored overnight in an appropriate facility by qualified and competent staff familiar with perioperative care of the liposuction patient.

Autologous Fat Grafting

The concept of reinjecting fat tissue harvested by liposuction has been put into practice for decades. Key to the technique is a processing step in which the sterilely collected fat is separated from the aqueous (primarily tumescent fluid) and free lipid fractions. This can be done by centrifugation and/or filtering. Ideally, the prepared adipose grafts are then injected into the tissues using specially designed blunt-tipped cannulas that provide for micro-graft injection. Small aliquots of fat grafts are injected with each cannula pass to deposit the grafts within the vascularized tissues of the recipient bed. Autologous fat grafting has gained increased interest and has been applied to various areas of aesthetic and reconstructive surgery. Specific applications include fat grafting to augment areas where fat atrophy is commonplace (aging of the face or hands), to enhance breast aesthetics and/or other breast reconstruction techniques, gluteal augmentation, or to address contour deformities or irregularities caused by iatrogenic, traumatic, oncologic, or congenital processes.

BRIEF HISTORY OF ANESTHESIA

The discovery of anesthesia is one of the seminal American contributions to the world. Along with infection control and blood transfusion, anesthesia has enabled surgery to occupy its fundamental place in medicine. Before the advent of anesthesia in the 1840s, many substances and methods had been tried in the search for pain relief and better operating conditions. Patients were typically restrained by several attendants, and only the most stoic could tolerate the screams heard in the operating theater.

Beginnings

Horace Wells (1815–1848), a dentist, first pursued using nitrous oxide for the relief of pain in surgical procedures in 1844.¹ After experimenting on himself, Wells attempted to demonstrate the analgesic effects of nitrous oxide for a dental procedure at Harvard Medical School in 1845. The public demonstration was a failure, at least partially, due to improper administration of the gas. Wells never recovered from his humiliating experience and eventually committed suicide. However, he does hold a place in history as the first person to recognize and use the only anesthetic from the 1800s that is still in use today—nitrous oxide.

Ether Day

William Morton (1819–1868) was a dentist and partner of Horace Wells. After taking a course in anesthesia from Wells, Morton left the partnership in Hartford, Connecticut, and established himself in Boston. He continued his interest in anesthesia, but using diethyl ether instead of nitrous oxide. Ether proved a good choice. He practiced the administration of ether on a

dog and then used it when extracting teeth from patients in his office. On October 16, 1846, Morton gave the first public demonstration of ether as an anesthetic for Johns Collins Warren, a distinguished surgeon and one of the founders of Massachusetts General Hospital. In attendance in the surgical amphitheater were several surgeons, medical students, and a newspaper reporter. After induction of anesthesia, Warren successfully removed a vascular mass from the patient's neck with no ill effects (Fig. 46-1). The description of this public demonstration of ether was published in the *Boston Medical and Surgical Journal* (now *The New England Journal of Medicine*).² The stature of Warren lent considerable credence to the advent of surgical anesthesia. The news spread rapidly, and surgeons around the world were quick to adopt this new invention. Massachusetts General Hospital has restored and preserved the original amphitheater where the demonstration took place, now called the Ether Dome. The description of the public demonstration of ether was voted as the most important article published in the history of *The New England Journal of Medicine* in its first 200 years.³

The Modern Era

Anesthesia has developed rapidly over the past century. Inhaled anesthetics, initially discovered fortuitously by observation, have been synthetically produced and remain the mainstay of anesthetic maintenance. The advent of the hollow syringe and needle and discovery of rapidly acting intravenous anesthetics allowed for rapid induction of anesthesia. Development of endotracheal intubation and mechanical ventilation revolutionized the delivery of inhaled anesthetics. The discovery of local anesthetics led to the development of peripheral nerve blocks

Key Points

- 1▶ The discovery of anesthesia was one of the most important advances and has enabled surgery to occupy its fundamental place in medicine.
- 2▶ Advances in anesthetic monitoring have made the administration of anesthesia safer than ever. Types of cardiovascular monitors include arterial catheters, central venous and pulmonary artery catheters, and transesophageal echocardiography.
- 3▶ A detailed preoperative evaluation should be performed on each patient when circumstances allow, with special attention devoted to functional status. The American College of Cardiology/American Heart Association guidelines for preoperative evaluation can guide workup.
- 4▶ The American Society of Anesthesiologists has developed specific guidelines for preoperative fasting to mitigate the risk of aspiration of gastric contents; individual patients may need more stringent preoperative fasting periods and/or rapid sequence inductions.
- 5▶ The American Society of Anesthesiologists has developed an algorithm for management of the difficult airway. Notably, in patients in whom both intubation and ventilation are impossible, the algorithm calls for placement of a laryngeal mask airway as the next step.

and spinal anesthesia. Concurrently, physiologic monitoring techniques have advanced to make the administration of anesthesia safer than ever.

Initially, anesthesia was given by medical students, nurses, and dentists, but eventually became a physician specialty of medicine of its own. The American Board of Anesthesiology was formed in 1938. Over the past 50 years, anesthesiology has increasingly specialized and also spread outside the operating

room into critical care, pain management, and perioperative medicine.

BASIC PHARMACOLOGY

Pharmacokinetics and Pharmacodynamics

Pharmacodynamics is the study of what a drug does to the body; pharmacokinetics is the study of what the body does to a drug.

Figure 46-1. Robert Cutler Hinckley, *The First Operation with Ether*. (Reproduced with permission from Boston Medical Library in the Francis A. Countway Library of Medicine, Boston, Massachusetts.)

The conduct of anesthesia is predicated upon the pharmacodynamics and pharmacokinetics of the drugs used.⁴

Administration, Distribution, Metabolism, and Elimination

Administration of a drug affects its pharmacokinetics, as there will be different rates of drug entry into the circulation. For example, medications administered via the oral route are subject to first-pass effect of the portal circulation; this can be bypassed with the IV, nasal, or sublingual route. Other routes of drug administration include transdermal, intramuscular, subcutaneous, or inhalation.

Distribution is the delivery of a drug from the systemic circulation to the tissues. Once a drug has entered the systemic circulation, the rate at which it will enter the tissues depends on the blood flow into that tissue, as well as the molecular size of the drug, lipid solubility, capillary permeability, polarity, plasma protein and tissue binding, and volume of distribution, the fluid volume in which the drug distributes. The distribution or redistribution of drugs can play a critical role in shaping their clinical use. For instance, clinically, the effect of propofol is terminated by its redistribution into fatty tissues and not metabolism of the drug.

Metabolism is the permanent breakdown of original compounds into smaller metabolites. Drug *elimination* varies widely; some drugs are excreted unchanged by the body, some decompose via plasma enzymes, and some are degraded in the liver. Many drugs rely on multiple pathways for metabolism and elimination (i.e., metabolized by liver enzymes and then excreted by the kidney).

Context-sensitive half time is the time required for blood concentrations of a drug to decrease by 50% after its discontinuation, which is determined by the interaction of the duration of administration, distribution and accumulation, and metabolism and excretion. Fig. 46-2 illustrates the context sensitive half-time for commonly used anesthetics and opioids.⁴

Pharmacodynamics

Pharmacodynamics, or how the plasma concentration of a drug translates into its effect on the body, depends on biologic variability, receptor physiology, and clinical evaluations of the actual drug. An agonist is a drug that causes a response (activates a receptor). A full agonist produces the full receptor/tissue response, and a partial agonist elicits less than the maximum response induced by a full agonist. An antagonist is a drug that blocks agonist mediated responses. An additive effect means that a second drug acts with the first drug and will produce an effect that is equal to the algebraic summation of both drugs. A synergistic effect means that two drugs interact to produce an effect that is greater than expected from the two drugs' algebraic summation. Tolerance, desensitization, or tachyphylaxis occurs when a larger than expected dose is required to produce a response. Tolerance usually results from chronic drug exposure, either through enzyme induction (e.g., alcohol) or depletion of neurotransmitters (e.g., cocaine).⁴

Potency, Efficacy, Lethal Dose, and Therapeutic Index

The *potency* of a drug is the dose required to produce a given effect, such as pain relief or a change in heart rate. The average sensitivity to a particular drug can be expressed through the calculation of the effective dose; ED50 would have the desired effect in 50% of the general population. The *efficacy* of any therapeutic agent is its power to produce a desired effect. Two drugs may have the same efficacy but different potencies.

Figure 46-2. Context-sensitive half time for commonly used anesthetics (A) and opioids (B). The vertical axis represents the half-time, or the time required for plasma concentrations of the drug to drop by 50%. The horizontal axis represents the duration of a continuous infusion. (Reproduced with permission from Longnecker DE, Mackey SC, Newman MF, et al: *Anesthesiology*, 3rd ed. New York, NY: McGraw-Hill Education; 2018.)

Dose-response curves show the relationship between the dose of a drug administered (or the resulting plasma concentration) and the pharmacologic effect of the drug. The lethal dose (LD50) of a drug produces death in 50% of animals to which it is given, and the toxic dose (TD50) is the dose that elicits a toxicity in 50% of humans to which it is given. The ratio of the toxic dose and effective dose, TD50/ED50, is the therapeutic index. A drug with a high therapeutic index is safer than a drug with a low or narrow therapeutic index.⁴

ANESTHETIC AGENTS

Inhaled Anesthetics

Inhaled anesthetics have greatly advanced since the original demonstration with ether. Modern agents provide faster induction and emergence and provide all of the major characteristics of general anesthesia: unconsciousness, analgesia, and muscle relaxation.

Minimum alveolar concentration (MAC) is a measure of anesthetic potency. It is the ED50 of an inhaled agent (i.e., the dose required to prevent movement in response to skin incision in 50% of patients). The higher the MAC, the less potent an agent is. Advantages and disadvantages of inhaled anesthetics are shown in Table 46-1.⁵

Nitrous Oxide. Nitrous oxide has a low solubility and is a weak anesthetic agent, but it has the most rapid onset and offset. Because

Table 46-1

Advantages and disadvantages of inhaled anesthetics

ANESTHETIC	ADVANTAGES	DISADVANTAGES
Nitrous Oxide	No odor, taste, or pungency Rapid uptake and elimination Analgesic effect Minimal cardiovascular depression Minimal biotransformation Inexpensive	Airspace expansion Increased nausea and vomiting Inhibits methionine synthase Environmental pollutant Supports combustion
Isoflurane	Good muscle relaxation Bronchodilation Stable heart rate Inexpensive	Slow uptake and elimination
Sevoflurane	Rapid uptake and elimination Not pungent	Breakdown to compound A in circuit More expensive than isoflurane
Desflurane	Rapid uptake and elimination Very low biotransformation	Airway irritant Requires electric/heated vaporizer Expensive

Data from Longnecker DE, Brown DL, Newman MF, et al: *Anesthesiology*, 2nd ed. New York, NY: McGraw-Hill Education; 2012.

its MAC is 104%, it must be combined with other agents to provide general anesthesia. A recent randomized controlled trial demonstrated that use of 70% nitrous oxide, given as part of a general anesthetic, did not increase the risk of death or major adverse cardiovascular events.⁶ Nitrous oxide has been shown to increase the rate of postoperative nausea and vomiting (PONV).

Volatile Agents. The volatile inhaled anesthetics are generally more soluble in blood than nitrous oxide, are more potent, and thus require lower inspired concentrations. Currently, isoflurane, sevoflurane, and desflurane are the agents that are most commonly used. Older agents, including halothane, which was associated with hepatotoxicity, are no longer widely used.

Isoflurane is the most inexpensive and widely available of the agents currently used. Sevoflurane has relatively rapid uptake and elimination. It is also not pungent and is therefore commonly used for inhalational induction. Desflurane has the most rapid uptake and elimination of the three most commonly used volatile agents. It is also the most expensive, requires a heated-electric vaporizer, and is an airway irritant. All of the volatile inhalational agents as well as the depolarizing neuromuscular blocker succinylcholine are triggering agents for malignant hyperthermia.⁵

Intravenous Agents. Intravenous agents are used to produce unconsciousness, analgesia, muscle relaxation, and/or amnesia. They include barbiturates, propofol, benzodiazepines, ketamine, etomidate, opioids, and nonopioid analgesics.⁷

Barbiturates Barbiturates used in anesthesia include thiopental and methohexital. These drugs act as agonists at the γ -aminobutyric acid (GABA) receptor, which inhibit excitatory synaptic transmission. Clinically, they produce a rapid, smooth induction of general anesthesia and wear off quickly. They cause hypotension and myocardial depression in a dose-dependent manner. Barbiturates are seldom used in modern anesthesia, with the exception of methohexital, which is still commonly used during electroconvulsive therapy.

Propofol Propofol is an alkylated phenol that inhibits synaptic transmission through its effects at the GABA receptor. It has a short duration, rapid recovery, and low incidence of nausea and vomiting. Consequently, it is the induction agent of choice. Propofol causes hypotension in a dose-dependent manner, and it should be used cautiously in patients with cardiac disease or hypovolemia. Continuous infusion of propofol is commonly used for sedation in the intensive care unit setting. Continuous infusions of propofol are also used for moderate-to-deep sedation for many procedures and are also commonly incorporated into total intravenous anesthetics (TIVA), most commonly for neurosurgical procedures. Propofol is an irritant and frequently causes pain on injection. Propofol also has anticonvulsant properties.

Benzodiazepines Benzodiazepines are most commonly used to reduce anxiety and produce amnesia. Midazolam, which has a rapid onset and relatively short duration of action, is by far the most commonly used benzodiazepine in anesthesia. Lorazepam and diazepam are still sometimes used as anxiolytics or amnestics. Benzodiazepines act as agonists at the GABA_A receptor. They produce sedation, vasodilation, and respiratory depression in a dose-dependent manner. They should be used with caution when given with opioids because a synergistic reaction causing respiratory depression is common. Oral midazolam is commonly used for anxiolysis in children. Benzodiazepines are excellent anticonvulsants and only rarely cause allergic reactions. Benzodiazepines should be administered cautiously in older adult patients due to the heightened risk of delayed awakening and postoperative delirium.

Etomidate Etomidate is an imidazole derivative used for IV induction. Its rapid and almost complete hydrolysis to inactive metabolites results in rapid offset. Like the IV agents mentioned earlier, etomidate acts on the GABA receptor. Etomidate has little direct effect on cardiac output and heart rate; induction doses thus cause less reduction in blood pressure than seen with propofol. Etomidate is associated with pain on injection. Notably, etomidate causes adrenal suppression,^{8,9} although whether a single dose of etomidate given at induction causes clinically relevant adrenal suppression remains controversial.¹⁰⁻¹³

Dexmedetomidine Dexmedetomidine is an IV α_2 -adrenergic agonist, administered as a continuous infusion, and has both sedative and analgesic properties. It is useful for sedation in an intensive care unit setting and as an adjunct to general anesthesia, especially as part of a total intravenous anesthetic. Side effects include hypotension and bradycardia in a dose-dependent manner. It does not cause respiratory depression at commonly used doses and is thus particularly useful for procedural sedation for patients at high risk of respiratory complications. It is synergistic with opiates and thus can be used to facilitate an opiate-sparing anesthetic.^{14,15}

Ketamine Ketamine differs from the aforementioned IV agents in that it produces analgesia as well as amnesia. Its principal

action is on the *N*-methyl-d-aspartate (NMDA) receptor. It is a dissociative anesthetic, producing a cataleptic gaze with nystagmus. Patients may experience delirium and hallucinations while regaining consciousness. The addition of benzodiazepines has been shown to reduce the incidence of these side effects. Ketamine typically increases heart rate and blood pressure, which may cause myocardial ischemia in patients with coronary disease. Ketamine is often used in acutely hypovolemic patients to maintain blood pressure via sympathetic stimulation. Importantly, ketamine is a direct myocardial depressant in patients who are catecholamine depleted, and it can produce profound hypotension and low cardiac output in such patients. Ketamine is a bronchodilator and is sometimes used as an induction agent in asthmatic patients. It can increase intracranial pressure and intraocular pressure, and thus its use in patients with trauma to the head and neck is controversial. Ketamine can be administered intramuscularly to induce anesthesia in patients who would not tolerate an inhalational induction or IV placement, such as patients with developmental delay.

Opioid Analgesics The commonly used opioids—morphine, codeine, hydromorphone, meperidine, and the fentanyl-based compounds—act on μ -receptors in the brain and spinal cord. The main side effects of opioids are euphoria, sedation, constipation, and respiratory depression, which also are mediated by μ -receptors in a dose-dependent fashion. Although opioids have differing potencies required for effective analgesia, equianalgesic doses of opioids result in equal degrees of respiratory depression. Thus, there is no completely safe opioid analgesic, and no reason to suppose that one opioid is safer than another. The synthetic opioid fentanyl and its analogues sufentanil, alfentanil, and remifentanil are used in the operating room. They differ pharmacokinetically in their lipid solubility, tissue binding, and elimination profiles and thus have differing potencies and durations of action. Fentanyl, which is highly lipid-soluble, accumulates in tissues and exhibits a steep increase in its context-sensitive half-time with infusions. Remifentanil is remarkable in that it undergoes rapid hydrolysis that is unaffected by sex, age, weight, or renal or hepatic function, even after prolonged infusion. Alfentanil and sufentanil are seldom used, having largely been replaced by remifentanil in the modern era. Morphine and meperidine have active metabolites that are renally excreted and thus should be used with caution or avoided in patients with renal insufficiency.

Naloxone, an opioid antagonist, can be used to rapidly reverse the effects of opioids, and is commonly used to rescue patients from opioid-associated respiratory depression. Naloxone is poorly absorbed orally and is also often combined with oral opioids to prevent abuse by injection use of the combined drug. Methylnaltrexone and alvimopan are both peripheral opioid antagonists and can reverse the opioid side effect of constipation without affecting analgesia.^{16,17}

Nonopioid Analgesics *Ketorolac* is a parenteral nonsteroidal anti-inflammatory drug (NSAID) that produces analgesia by reducing prostaglandin formation via inhibition of the enzyme cyclooxygenase (COX). Intraoperative use of ketorolac reduces postoperative need for opioids. Ketorolac along with other NSAIDs can cause major side effects, including bleeding, platelet dysfunction, and acute kidney injury and should be used cautiously in elderly patients or patients with renal insufficiency.

Acetaminophen is an analgesic drug and antipyretic; its site of action is in the central nervous system. Use of acetaminophen

has been shown to reduce opioid requirements postoperatively. Long available in an orally administered form as well as a rectal suppository, an intravenous formulation of acetaminophen is now available which has become widely used in the postoperative setting.¹⁸

Lidocaine is a local anesthetic commonly used for local infiltration, nerve blocks, or epidural infusions. Recently, intravenous infusions of lidocaine have been shown to be beneficial in the perioperative period. A large meta-analysis of 42 trials with 2800 patients showed that intravenous lidocaine infusions modestly reduced postoperative pain, reduced opioid requirements, and shortened time to recovery of bowel function for patients undergoing abdominal surgery.¹⁹

Local Anesthetics

Local anesthetics act on sodium channels to block transmission of neural impulses. They are divided into two groups based on their chemical structure: the amides and the esters. In general, the amides are metabolized in the liver, and the esters are metabolized by plasma cholinesterases, which yield metabolites with slightly higher allergic potential than the amides. Amides include lidocaine, bupivacaine, mepivacaine, prilocaine, and ropivacaine. Lidocaine has a fairly rapid onset and is shorter acting. Ropivacaine and bupivacaine have a slower onset and are longer lasting. All three are commonly used for local infiltration and regional nerve blocks. Amides are 95% metabolized in the liver, with a minority excreted unchanged in the kidneys. Prilocaine and mepivacaine are seldom used in anesthesia at present. Esters include cocaine, procaine, chlorprocaine, tetracaine, and benzocaine. Esters are hydrolyzed in the blood by plasma esterases.

When used in large quantities over a short period of time, local anesthetic levels can rise in the blood and cause central nervous system (CNS) toxicity and cardiovascular toxicity. Symptoms of CNS toxicity include restlessness, tinnitus, and slurred speech and can progress to seizures and coma. Cardiovascular toxicity may manifest as hypotension, conduction abnormalities leading to heart block, and ventricular arrhythmias, and it may lead to cardiac arrest. The type of local anesthetic used affects the risk of developing toxicity; bupivacaine is most often associated with cardiovascular toxicity. Other risk factors for local anesthetic systemic toxicity include cumulative dose, site of injection, and preexisting renal, hepatic, or cardiac disease in the patient.²⁰ In addition to treating symptomatology, local anesthetic systemic toxicity can be treated with intravenous administration of lipid emulsion.²¹

Neuromuscular Blockers

While general anesthetics provide muscle relaxation, they usually do so at a much deeper anesthetic depth than required for amnesia and hypnosis. For this reason, neuromuscular blockers are commonly administered to attain adequate relaxation at levels of anesthesia sufficient to produce hypnosis, amnesia, and analgesia. Neuromuscular blockers block conduction at the neuromuscular junction of skeletal muscle.²²

The two categories of neuromuscular blockers in use are depolarizing and nondepolarizing blockers. Characteristics of neuromuscular blockers currently used are summarized in Table 46-2. Succinylcholine is the only depolarizing agent used currently. It binds to acetylcholine receptors on the postjunctional membrane in the neuromuscular junction and causes depolarization of muscle fibers. The rapid onset (less than 60 seconds) and rapid offset (5–8 minutes) of succinylcholine make it ideal for management of the airway in certain

Table 46-2

Commonly used neuromuscular blockers

AGENT	TYPE	INTUBATING DOSE	CONSIDERATIONS
Succinylcholine	Depolarizer	1 mg/kg	Can cause severe hyperkalemia Contraindicated in burns, denervating conditions Excessive or prolonged use can lead to phase II block
Rocuronium	Nondepolarizer	0.6 mg/kg 1.2 mg/kg for RSI	Primarily hepatic metabolism Can be reversed with suggamadex or acetylcholinesterase inhibitor
Vecuronium	Nondepolarizer	0.1 mg/kg	Primarily hepatic metabolism Can be reversed with suggamadex or acetylcholinesterase inhibitor
Cisatracurium	Nondepolarizer	0.1 mg/kg	Hoffman degradation Can be reversed with an acetylcholinesterase inhibitor

RSI = rapid sequence induction

situations.²³ Succinylcholine has several adverse effects including transient hyperkalemia, which can be severe or even fatal for patients with burns and denervating injuries. Succinylcholine can cause bradycardia, which can be severe in children. It is also associated with transient increases in intracranial and intraocular pressure. The depolarization caused by succinylcholine causes skeletal muscles to fasciculate, which in turn, can result in post-operative myalgias. Succinylcholine is a known trigger of malignant hyperthermia in susceptible individuals. Succinylcholine is broken down by pseudocholinesterase; patients who are homozygous for pseudocholinesterase deficiency will have prolonged neuromuscular blockade, typically lasting for several hours.

There are several nondepolarizing neuromuscular blocking agents in clinical use. Long-acting agents including pancuronium are no longer widely used. Intermediate-duration neuromuscular blockers include the steroid-based drugs vecuronium and rocuronium, which are metabolized by the liver as well as by the kidney, and the benzylisoquinolone drugs atracurium and cisatracurium, which undergo breakdown in plasma known as Hofmann elimination. All nondepolarizers reversibly bind to the postsynaptic terminal in the neuromuscular junction and prevent acetylcholine from depolarizing the muscle. Muscle blockade occurs without fasciculation and without the subsequent side effects seen with succinylcholine. Neuromuscular blockade with nondepolarizing drugs is typically reversed. Failure to adequately reverse neuromuscular blockade is associated with an increased risk of perioperative respiratory failure and death. Reversal agents include acetylcholinesterase inhibitors including neostigmine, edrophonium, or pyridostigmine that are given concurrently with muscarinic-anticholinergics, almost always atropine or glycopyrrolate. Recently, suggamadex, a chelating agent, has been approved for use as a reversal agent for reversal of neuromuscular blockade by the steroid paralytics rocuronium and vecuronium. When given at a very high dose, suggamadex can even rapidly reverse the effect of an intubating dose of a steroid neuromuscular blocker.

ANESTHETIC MONITORING

Over the past several decades, advancement in anesthetic monitoring has made administration of anesthesia safer than ever.

▶ The goal of anesthetic monitoring is to continuously monitor the patients' cardiovascular status, pulmonary status, respiratory physiology, anesthetic depth, concentration of

gases administered, and temperature. The American Society of Anesthesiology (ASA) has established standards for basic intraoperative monitoring that are listed in Table 46-3. Types of anesthetic monitoring are listed in Table 46-4.

Cardiovascular monitoring includes continuous ECG monitoring as well as blood pressure monitoring, which is to be measured and recorded at least every 5 minutes. Blood pressure monitoring can be done using noninvasive blood pressure cuff measurements or invasively using an arterial catheter. Other cardiovascular monitors include monitoring of central venous pressure, pulmonary artery pressure, and cardiac output. In high-risk

Table 46-3

American Society of Anesthesiologists standards for basic intraoperative monitoring

Standards

Standard 1: Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics and regional and monitored anesthesia care.

Standard 2: Oxygenation, ventilation, circulation, and temperature shall be continually evaluated

Oxygenation

Inspired gas oxygen analyzer

Pulse oximetry

Monitoring of patient clinical status

Ventilation

Auscultation

Observation of the patient

Observation of reservoir bag

End-tidal carbon dioxide analysis

Circulation

Continuous electrocardiogram display

Heart rate and blood pressure recorded at least every 5 minutes

Evaluation of circulation: auscultation of heart sounds, palpation of pulse, pulse oximetry, blood pressure monitoring with noninvasive means or intra-arterial catheter pressure measurement

Temperature

Core and/or skin temperature

Reproduced with permission from Longnecker DE, Mackey SC, Newman MF, et al: *Anesthesiology*, 3rd ed. New York, NY: McGraw-Hill Education; 2018.

Table 46-4

Types of anesthesia monitors and their properties

TYPE OF MONITOR	WHAT IS MEASURED	INVASIVENESS	POTENTIAL FOR COMPLICATIONS
Physical examination	Heart sounds, breath sounds, pulse, color, mental status, etc	Noninvasive	–
Pulse oximetry	Arterial oxygen saturation	Noninvasive	–
Arterial catheter	Blood pressure, acid/base status	Invasive	++
Noninvasive blood pressure measurement	Blood pressure	Noninvasive	+/-
Electrocardiography	Cardiac rhythm, rate, ST segments	Noninvasive	–
Capnography	Ventilatory, circulatory status	Noninvasive	–
Electroencephalogram, bispectral index, etc	Brain function, depth of anesthesia	Noninvasive	+/-
Temperature probe	Body temperature	Noninvasive to invasive	+/-
Central venous pressure, pulmonary artery pressure	Cardiac function, volume status	Invasive	+++
Transesophageal echocardiogram	Cardiac function, volume status	Invasive	+++

anesthetics such as liver transplantation and cardiac surgery, transesophageal echocardiography (TEE) is employed to monitor myocardial function and volume status. Intraoperative TEE can also be used to guide surgeons when performing complex cardiac surgeries, including cardiac valve replacements.

Monitoring of oxygenation and ventilation includes use of continuous pulse oximetry, monitoring of exhaled end-tidal carbon dioxide (ETCO₂), and monitoring of fraction of inspired oxygen. End tidal CO₂ monitoring also provides important information about systemic perfusion. During cardiac arrest, there is no delivery of CO₂ to the lungs, and the end-tidal CO₂ is thus very low or zero; a sudden spike in end tidal CO₂ during cardiopulmonary resuscitation correlates with return of spontaneous circulation.²⁴ Modern ventilators also measure peak and plateau inspiratory airway pressure and minute ventilation. Adequacy of oxygenation and ventilation can also be confirmed by arterial blood gas analysis.

Temperature monitoring is performed using a temperature probe, usually inserted in the esophagus or nasopharynx. Core body temperature can be measured with temperature sensing Foley catheters. Temperature can also be measured at the skin.

Several monitors exist that measure *depth of anesthesia*, including the bispectral index (BIS) monitor and the SedLine monitor. While these monitors were designed to prevent awareness under anesthesia, a multicenter trial of over 6000 patients showed that titrating anesthetic concentration to the BIS monitor was not superior to titrating anesthetic depth to end-tidal anesthetic concentration with goal MAC greater than 0.7.²⁵

Peripheral nerve stimulators can be used to *monitor depth of neuromuscular blockade*. A train-of-four monitor delivers four successive stimuli over 2 seconds. Presence of four twitches without fade with a ratio of the height of the first twitch to the height of the fourth twitch at least 0.9 suggests adequate reversal of neuromuscular blockade.²⁶ The presence of one or two twitches (absence of the last two or three) is generally sufficient for the relaxation required for almost any kind of abdominal or thoracic operation.

PERIOPERATIVE EVALUATION AND PREPARATION

The ASA has adopted basic standards for the evaluation of patients before surgery. These standards require the anesthesiologist to evaluate the medical status of the patient, develop a plan of anesthetic care, and discuss this plan with the patient and/or the patient's legal guardian.

A preoperative evaluation includes an appropriately detailed medical history, current drug therapy, appropriate physical examination, and review of laboratory and specific testing results. Based on these findings, the anesthesiologist may conclude that a patient is not in optimal medical condition to undergo elective surgery. These findings and opinions are then discussed with the patient's primary physician or surgeon, and the surgery may be delayed (or cancelled) until the patient's medical condition is further evaluated and optimized.

The medical history obtained at the preoperative visit should include the patient's previous exposure and experience with anesthesia, as well as any family history of problems with anesthesia. History of atopy is an important aspect of this evaluation in that it may predispose patients to form antibodies against antigens that may be represented by agents administered during the perioperative period. Concurrent medications should be fully evaluated when circumstances allow, and adverse interactions with agents administered during the perioperative period need to be considered. A review of the function of major organ systems should also be performed. The physical examination is targeted primarily at the central nervous system, cardiovascular system, lungs, and airway.

Laboratory testing should be based on the patient's condition and the proposed procedure. Otherwise healthy patients usually do not need laboratory testing for minor procedures. Preoperative testing may be necessitated by findings on physical examination; for example, an electrocardiogram should be obtained if an irregular heart rhythm is noted, and an echocardiogram may be indicated if a new murmur is observed on

Table 46-5

American Society of Anesthesiologists physical status classification

ASA PHYSICAL STATUS	DESCRIPTION
I	A healthy patient without systemic disease
II	A patient with mild systemic disease
III	A patient with severe systemic disease
IV	A patient with severe systemic disease that is a constant threat to life
V	A moribund patient not expected to survive without the operation
VI	A declared brain-dead patient whose organs are being removed for donation

Data from American Society of Anesthesiologists: ASA Physical Status Classification System Developed. ASA House of Delegates/Executive Committee. Amended: October 15, 2014.

auscultation. Chest imaging or pulmonary function testing may be indicated if abnormalities are noted on pulmonary examination and may be pertinent to the administration of the anesthetic or the recovery from anesthesia and surgery. Urine pregnancy testing is typically performed on the day of surgery in women of childbearing age.

ASA Physical Status Assessment

The ASA classification system is a scale used to risk-stratify patients for anesthesia and surgery. The scale, ranging from physical status I to VI, is shown in Table 46-5. Patients undergoing emergent surgery are denoted by an “E”; for example, an otherwise healthy patient undergoing an appendectomy for appendicitis would be classified as ASA IE. Mortality has shown to increase with increasing ASA physical status, and it has been shown to be higher for patients undergoing emergency surgery.²⁷

Airway Evaluation

Airway examination can identify most patients in whom management of the airway and conventional endotracheal

intubation may be difficult. It is vitally important to recognize such patients before administering medications that induce apnea. The Mallampati classification (Fig. 46-3) is based on the structures visualized with maximal mouth opening and tongue protrusion in the sitting position.²⁸ Patients with higher Mallampati classification, in combination with other airway abnormalities, can be difficult to intubate. Other predictors of difficult intubation include short neck, immobility of the neck,²⁹ a large overbite, a small mandible, or the inability to shift the lower incisors in front of the upper incisors. The thyromental distance, the distance from the thyroid cartilage to the tip of the chin should be greater than 6 cm; thyromental distance of less than 6 cm has been associated with difficult intubation.³⁰ Obesity is also a risk factor for difficult intubation, and neck circumference has been identified as a risk factor for both difficult intubation as well as difficult mask ventilation.³¹

Cardiovascular Disease

Cardiac risk is widely regarded as the most important risk associated with anesthesia and surgery, and it has been the focus of an enormous amount of scholarship over the past four decades. The revised cardiac risk index incorporates six patient and surgical factors to assess a patient’s risk of major adverse cardiac events in the perioperative period: history of ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes requiring insulin, chronic kidney disease with baseline creatinine greater than 2, and whether the surgery is in a high-risk area, namely major vascular, intraperitoneal, or intrathoracic. In 2014, the American College of Cardiology and the American Heart Association published guidelines for perioperative workup and management of patients with cardiovascular disease; a simplified version is seen in Fig. 46-4 .

3▶ Notably, this guideline stresses the importance of functional status in determining need for further evaluation; patients with good functional status can typically proceed to surgery without additional evaluation. Functional capacity is measured in metabolic equivalents (METs), with patients unable to attain 4 METs considered to have poor functional status. Activities representing 4 METs including walking up a flight of stairs, climbing a hill, or walking on level ground at 3 to 4 miles per hour.³²

MALLAMPATI CLASSIFICATION

CLASS 1: Soft palate, fauces, uvula, pillars

CLASS 2: Soft palate, fauces, portion of uvula

CLASS 3: Soft palate, base of uvula

CLASS 4: Hard palate only

Figure 46-3. The Mallampati classification.

Figure 46-4. Simplified cardiac evaluation for noncardiac surgery. (Data from Eagle KA, Berger PB, Calkins H, et al: ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery), *J Am Coll Cardiol.* 2002 Feb 6;39(3):542-553.)

These recent guidelines have minimized the role of routine screening. Preoperative electrocardiograms and stress testing are unnecessary for asymptomatic patients undergoing low-risk surgery.

Special attention is required for patients with coronary stents. Elective surgery should be delayed a stent has been inserted, which allows time for it to stabilize and the risk of in-stent thrombosis to decrease. The ACC/AHA guidelines recommend delaying elective surgery for 30 days after bare metal stent placement and for 1 year after drug eluting stent placement. Dual antiplatelet therapy should be continued for urgent or emergent procedures that take place before the minimum recommended waiting period.³² For semi-elective surgeries in patients with drug-eluting stents, where the risk of delaying surgery is greater than the risk of in-stent thrombosis, ACC/AHA guidelines recommend surgery be delayed for 180 days.

Current recommendation is that β -blockers and statins should be continued in patients who are on them chronically. β -Blockers may be started in the perioperative period for patients with multiple RCRI risk factors or who are at intermediate or high risk for myocardial ischemia. If started in the perioperative period, β -blockers should be started long enough before surgery to ascertain their safety, and not on the day of surgery.^{32,33} Recent large randomized trials have demonstrated excess risk of mortality and stroke simultaneously with decreased risk of myocardial events in moderate- and high-risk patients who are newly treated with β -blockers in the periprocedural setting.^{34,35}

Implanted cardiac devices including pacemakers and implantable cardioverter-defibrillators also have important perioperative implications. A 2011 ASA practice advisory stressed

the importance of determining whether electromagnetic interference is likely to occur during the planned procedure, determining the current function and necessity of the implanted device, determining whether reprogramming or temporary disabling of the device is advantageous, having alternative therapy available for the time that the device is unavailable, and restoring device function in the postoperative period.³⁶

Pulmonary Disease

Chronic pulmonary disease is an increasingly recognized cause of morbidity and mortality in surgical patients. For patients with asthma or chronic obstructive pulmonary disease, exercise tolerance and the frequency and severity of exacerbations should be evaluated. A focused history, including prior admissions and intubations for exacerbations, should be obtained. Treatment with bronchodilators in the perioperative setting is appropriate, although there is no literature to either guide this care or to document a benefit from it. Most inhaled anesthetics act as bronchodilators.³⁷ Desflurane can be an airway irritant, and it is often avoided in patients with reactive airway disease.

The incidence of obstructive sleep apnea (OSA) has risen with the incidence of obesity. In 2014 the ASA published guidelines for perioperative management of patients with OSA. These guidelines highlight the importance of identifying patients with obstructive sleep apnea during preoperative evaluation and obtaining a sleep study if appropriate. They also highlight the importance of the development of protocols by anesthesiologists and surgeons to manage OSA in the perioperative setting. There is consensus that these patients should not be extubated until they are completely awake, and that they should be treated with

noninvasive positive pressure ventilation in the postoperative period as indicated.³⁸

Renal Disease

Management of anesthesia in patients with chronic renal insufficiency requires close attention to perioperative fluid management and acid-base and electrolyte homeostasis. Doses of opioids and neuromuscular agents are typically reduced and dosing intervals increased to compensate for decreased renal excretion. Cisatracurium is often chosen as the muscle relaxant in patients with severe renal insufficiency because its elimination is unchanged by renal failure. Sugammadex, a reversal agent for steroid-based neuromuscular blockers, is not currently recommended for use in patients with advanced chronic kidney disease or end-stage renal disease.

Hepatic Disease

Hepatic dysfunction has many causes, and it can compel significant changes in anesthetic care. First, anesthetic agents metabolized in the liver can accumulate in these patients and may have a longer duration of effect. To mitigate this, short-acting agents are strongly preferred in these patients. Hypoalbuminemia can paradoxically increase the free plasma levels of drugs, which can also exaggerate their effects. In patients with substantial ascites, high intra-abdominal pressure may increase the risk of passive gastric reflux, and thus many such patients are managed as if they have a full stomach, regardless of how long they have been NPO. In patients with significant hepatocellular dysfunction and/or portal hypertension, the combination of thrombocytopenia and coagulation factor deficiency not only increase the risk of bleeding associated with surgery, they also are relative or absolute contraindications to a variety of anesthetic techniques, such as subarachnoid blocks and epidural anesthesia. Presence of esophageal varices increases the risk of gastric tubes and transesophageal echocardiography.

Endocrine Disease

Perioperative management of the diabetic patient can be especially challenging. A hemoglobin A_{1c} level should be obtained if a recent level is not available, as an increased A_{1c} level is associated with an increase in perioperative complications including wound infections.³⁹⁻⁴¹ Several institutions have implemented protocols for glucose management for diabetic patients undergoing surgery, although recommendations differ on appropriate target glucose levels.^{39,42,43} Perhaps the most important thing for a practitioner to know and remember is that the difference between type 1 and type 2 diabetes is important, and that these two different diseases require different approaches to their management. In general, patients with type 2 diabetes have a lower risk of becoming hypoglycemic, tend to have higher blood sugars at baseline, and tolerate higher levels of serum glucose without significant acute hazard. Patients with type 1 diabetes, who are deficient in insulin production and thus require insulin administration to prevent ketosis, are far more likely to become hypoglycemic when subjected to stress, and they are also at risk for developing ketoacidosis with hyperglycemia. Patients with type 1 diabetes merit more careful monitoring of their blood sugars in the perioperative setting than patients with type 2 diabetes.⁴⁴⁻⁴⁷

Preoperative Fasting

The ASA has developed specific guidelines for preoperative fasting to mitigate the risk of aspiration of gastric contents. Table 46-6 shows guidelines for preoperative food and fluid intake for elective procedures. Individual patients may need lengthier fasting times than the guidelines indicate.

Table 46-6

Guidelines for food and fluid intake before elective surgery

TIME BEFORE SURGERY	FOOD OR FLUID INTAKE
Up to 8 hours	Food and fluids as desired
Up to 6 hours ^a	Light meal, infant formula
Up to 4 hours	Breast milk
Up to 2 hours	Clear liquids only

^aLight meal refers to a limited amount of easily digestible food, such as toast or crackers. Individual patients may need lengthier fasting times than these guidelines indicate.

Adapted with permission from Longnecker DE, Mackey SC, Newman MF, et al: *Anesthesiology*, 3rd ed. New York, NY: McGraw-Hill Education; 2018.

Notably, a rapid sequence induction and intubation should be considered in patients who are at higher risk for aspiration such as those with very symptomatic gastroesophageal reflux, achalasia, gastroparesis, or dysmotility, regardless of fasting status.⁴⁸

Patients With Advanced Directives

Patients with do not resuscitate (DNR) and/or do not intubate (DNI) orders present a unique challenge. Patients or their power-of-attorney may choose to rescind these directives in the perioperative period, maintain them as originally ordered, or modify them to allow for a limited resuscitation. Both the ASA and the American College of Surgeons recommend that preoperative discussions with the patient and their family clarify the patient's wishes, and both societies emphasize that policies that mandate uniform enforcement or disregarding of all DNR orders take away patients' right to self-determination.^{49,50}

Risk Estimation

Several risk calculators have been developed to estimate perioperative morbidity and mortality. The American College of Surgeons National Surgical Quality Improvement Program (NSQIP) surgical risk calculator allows for estimation of risk of eight different adverse outcomes, including mortality.⁵¹ The Society of Thoracic Surgeons risk calculator estimates risk of morbidity and mortality after cardiac surgical procedures.⁵² While such risk estimators can provide widely differing estimates or may be inaccurate in certain situations,⁵³ they are still invaluable aids for discussions with patients and their families about high-risk surgery.

INTRAOPERATIVE MANAGEMENT

General Anesthesia

General anesthesia remains the cornerstone of anesthesia practice; many surgical procedures cannot be done under regional techniques or monitored anesthesia care with sedation.

The induction of general anesthesia can precipitate catastrophic anesthetic complications. Many different techniques can be used to induce general anesthesia, each with significant advantages and disadvantages.

Intravenous induction, used primarily in adults, quickly produces unconsciousness, and depending on the agent used, apnea as well. Propofol, the most common induction agent currently used, can cause hypotension due to its myocardial depressing and vasodilatory properties. Hypertension and

tachycardia commonly occur during laryngoscopy or other significant airway stimulation.

The goal of a rapid sequence induction (RSI) is to achieve secure protection of the airway with a cuffed endotracheal tube without ever mask ventilating a patient. It is intended to prevent vomiting and aspiration, and it is routinely employed in patients at heightened risk for aspiration. There are no randomized controlled trials that demonstrate any kind of outcome benefit of rapid sequence induction in such patients, but it is nevertheless routinely employed for this purpose in the United States.

Pediatric patients are often not amenable to preoperative IV catheter placement. Hence, inhalation induction of anesthesia is commonly used in children, with IV placement occurring after induction. Even among children, however, patients at heightened risk for aspiration or with a full stomach may be best managed with preoperative IV placement and an IV induction. Patients with developmental delay may not be amenable to preoperative IV placement or inhalational induction of anesthesia. In such patients, intramuscular administration of an agent such as ketamine is often required to induce anesthesia.

Airway Management. Most anesthesiologists prefer to secure the airway of a patient undergoing general anesthesia, and this is usually accomplished immediately after anesthesia has been induced. The airway may be managed in several ways, including by face mask, with a laryngeal mask airway (LMA), or, most definitively, by endotracheal intubation with a cuffed endotracheal tube. Nasal and oral airways can help establish a patent airway in a patient being ventilated with a mask by creating an air passage behind the tongue.

The LMA is a cuffed supraglottic oral airway that is inserted through the oropharynx and ideally positioned just above the glottis opening. It is passed blindly, and the inflated cuff creates a seal around the laryngeal inlet. An LMA does not protect against aspiration and should generally not be used in patients with a high risk of aspiration.

Tracheal intubation requires a skilled operator and proper equipment. In most elective anesthetics, attempts to intubate the trachea are facilitated by the administration of muscle relaxants in a patient who is already under a general anesthetic. Intubation is typically performed under direct visualization with a laryngoscope, watching the endotracheal tube pass through the vocal cords into the trachea. To obtain a direct line of sight, the patient is placed in the sniffing position. The neck is flexed at the lower cervical spine and extended at the atlanto-occipital joint. This flexion and extension are amplified during laryngoscopy. Laryngoscope blades can be curved (Macintosh) or straight (Miller) blades. Laryngoscopic views are typically reported in a classification system developed by Cormack and Lehane (Fig. 46-5).

Management of the Difficult Airway. Some patients have physical characteristics or a history suggestive of difficulty in placing an endotracheal tube. A short neck, limited neck mobility, small interincisor distance, short thyromental distance, and high Mallampati classes may all represent a challenge to

Figure 46-5. Laryngoscopic views obtained per Cormack and Lehane.

Figure 46-6. Video laryngoscopy with the GlideScope.

endotracheal intubation. Several tools have been developed to assist in management of the difficult airway.

The Glidescope, a video laryngoscope, allows for visualization of the larynx on a video screen (Fig. 46-6). Having more of a bend than a standard curved Macintosh blade, it can be advantageous for visualizing and intubating the trachea in patients with large tongues or relatively anterior glottis openings. Placement of the endotracheal tube once the larynx has been visualized can still be challenging. A recent study of ICU patients requiring intubation showed that video laryngoscopy did not improve first-pass orotracheal intubation success rate and was associated with higher rates of severe life-threatening complications.⁵⁴

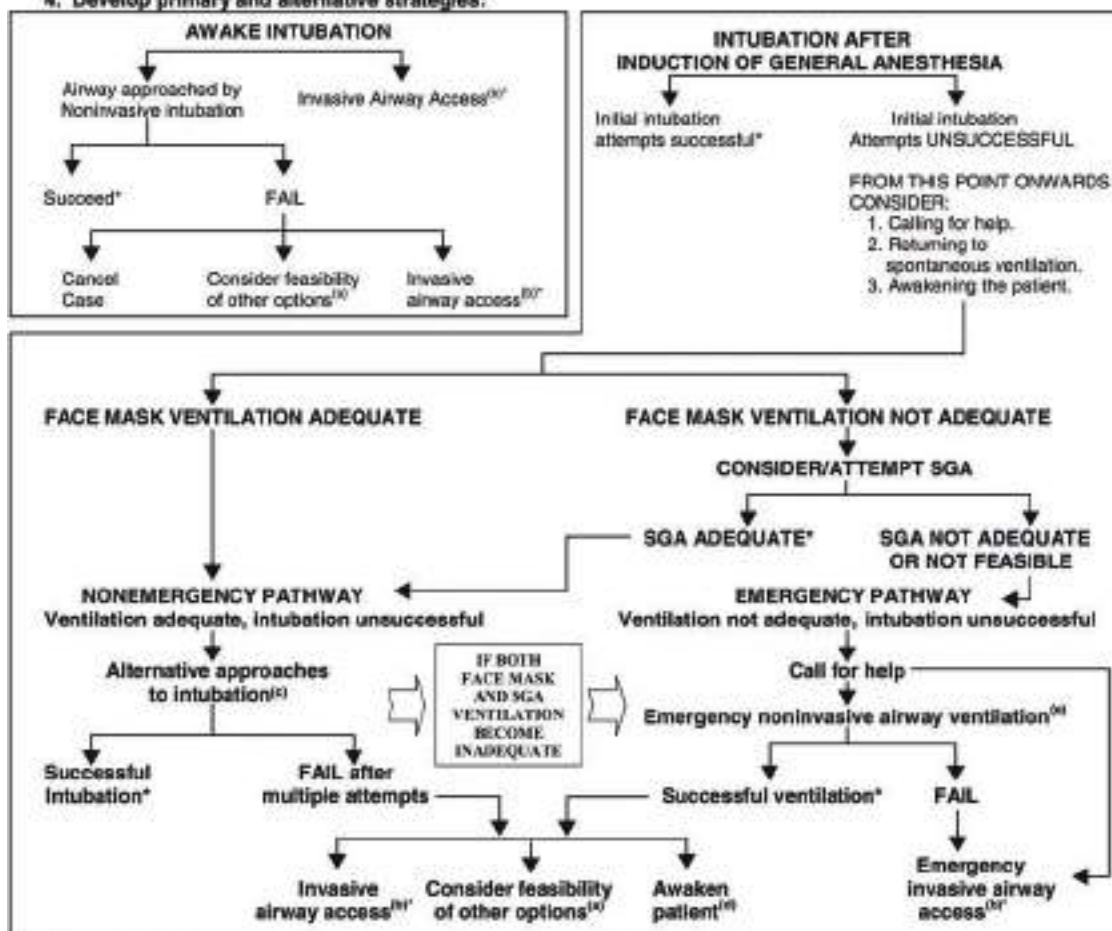

The intubating laryngeal mask airway (ILMA) is an advanced form of LMA designed to maintain a patent airway and facilitate tracheal intubation. The ILMA can be placed in anticipated or unexpectedly difficult airways as an airway rescue device and as a guide for intubating the trachea. The device itself is substantially more rigid than other laryngeal mask airways, and includes a handle which the operator can use to displace the opening of the device. A specially manufactured endotracheal tube can be passed blindly through the ILMA into the larynx, or the ILMA can be used as a conduit for a flexible fiberoptic scope. Experience with airway management in general and the use of this device in particular is essential for its effective use in emergency situations; operators with little experience will enjoy little success with this device.

The flexible fiberoptic intubation bronchoscope is the gold standard for difficult intubation. It is indicated in difficult or compromised airways where neck extension is not desirable or in cases with risk of dental damage. The flexible bronchoscope allows excellent visualization of the airway and glottic opening. This technique can be used for oral and nasal intubation, for awake or asleep intubation, and for intubation in the awake, spontaneously ventilating patient whose airway has been treated with topical local anesthetic.

The ASA has developed an algorithm for management of the difficult airway (Fig. 46-7).⁵⁵ Notably, in patients in whom

1. Assess the likelihood and clinical impact of basic management problems:
 - Difficulty with patient cooperation or consent
 - Difficult mask ventilation
 - Difficult supraglottic airway placement
 - Difficult laryngoscopy
 - Difficult intubation
 - Difficult surgical airway access
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:
 - Awake intubation vs. intubation after induction of general anesthesia
 - Noninvasive technique vs. invasive techniques for the initial approach to intubation
 - Video-assisted laryngoscopy as an initial approach to intubation
 - Preservation vs. ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

*Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO_2 .

a. Other options include (but are not limited to): surgery utilizing face mask or supraglottic airway (SGA) anesthesia (e.g., LMA, ILMA, laryngeal tube), local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.

c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (e.g., LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.

d. Consider reparation of the patient for awake intubation or canceling surgery.

e. Emergency noninvasive airway ventilation consists of a SGA.

Figure 46-7. ASA difficult airway algorithm. (Reproduced with permission from Apfelbaum JL, Hagberg CA, Caplan RA, et al: Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway, Anesthesiology. 2013 Feb;118(2):251-270.)

both intubation and ventilation are impossible, the algorithm calls for placement of an LMA with ventilation attempted through the LMA.

Monitored Anesthesia Care

Monitored anesthesia care (MAC) is when a patient undergoes a procedure under local anesthesia under the care of an anesthesiologist who can provide sedation as indicated. Sedation is administered to a level that allows the patient to maintain airway reflexes and breath spontaneously. Advantages of MAC anesthesia include reduced invasiveness, as the airway is not manipulated, and faster recovery. ASA standard monitors must be used, including capnography, which allows for rapid detection of apnea or hypoventilation. In some instances, most commonly for gastroenterology procedures, patients are administered an intravenous anesthetic that is often classified as a MAC, even though the patient is so deeply anesthetized that they have no significant response to significant airway stimulation; the airway is monitored by the anesthesia provider and secured if necessary.

Regional Anesthesia/Acute Pain

Regional anesthesia allows for selective blockade and is an excellent anesthetic option for several different types of procedures. Regional anesthesia can also provide excellent postoperative pain control. Regional techniques include neuraxial blockade, including spinal and epidural anesthetics, peripheral nerve blocks, and truncal blocks.

Spinal anesthetics (also referred to as subarachnoid blocks) can be used for lower extremity, lower abdominal, pelvic, and urologic and gynecologic procedures. A small caliber needle (typically 25-gauge or smaller) is inserted into the intrathecal space in the cauda equina and below the conus medularis, and a small volume of local anesthetic is injected. Duration and level of the block in the spinal cord is affected by the anesthetic used, the dose employed, and baricity of solution injected. Complications can include hypotension, bradycardia, postdural puncture headache, injury to local structures or nerves, and hematoma formation. The American Society of Regional Anesthesia publishes guidelines regarding safe intervals to perform neuraxial anesthetics after the administration of anticoagulant and antiplatelet agents.

An epidural catheter can be used as a primary anesthetic for a procedure, or it can be placed preoperatively and used in conjunction with a general anesthetic for postoperative pain control. Epidural catheters can be placed in the thoracic or lumbar spine and can remain in place for days after surgery. A dilute local anesthetic and/or opioid is administered through the catheter to provide analgesia. Complications of epidural anesthesia are similar to that of spinal anesthesia. In addition to improved pain control, benefits of epidural anesthesia include reduced pulmonary complications⁵⁶ and decreased duration of postoperative ileus.⁵⁷

Peripheral nerve blockade can also be used to provide surgical anesthesia as well as postoperative analgesia, particularly for surgeries of the upper or lower extremities. The nerve or plexus of interest is located with ultrasound and/or peripheral nerve stimulator, and local anesthetic is injected around the nerve. Single-shot nerve blocks allow for surgical anesthesia and immediate postoperative analgesia and can last for several hours. Flexible catheters can also be placed in proximity to nerves to allow for continuous infusion and blockade that can

continue for several days. Complications of peripheral nerve blocks include injury to nerves or nearby structures and local anesthetic systemic toxicity.

Recently, truncal blocks have become more commonly and widely used for the treatment of postoperative pain. Truncal blocks include the transversus abdominis plane (TAP) block, the rectus sheath block, the pectoral nerve block, and the serratus anterior plane block. These truncal blocks are usually done under ultrasound guidance with local anesthetic injected in the appropriate plane. Truncal blocks are typically performed as part of a multimodal approach to postoperative pain. Limited evidence suggests that use of truncal blocks decreases postoperative opioid requirements.^{58,59}

RECOVERY AND COMPLICATIONS

The Postanesthesia Care Unit

The advent of the modern postanesthesia care unit represents a major advance in the safety of perioperative care, as the close monitoring that occurs there can prevent or expedite the management of a variety of serious complications. Ventilation, oxygenation, hemodynamics, temperature, nausea, and pain are closely monitored in the PACU, with close attention also given to urine output, ongoing bleeding, and drainage. To be discharge eligible, patients should have returned to their baseline mental status, be oxygenating and ventilating adequately, have adequate pain control, and have stable vital signs. There are multiple scoring systems that can be used to assess suitability for discharge from PACU.⁶⁰⁻⁶² Postoperative hemorrhage, hypertension or hypotension, myocardial ischemia, arrhythmias, and altered mental status commonly manifest in the postoperative care unit. Postoperative nausea and vomiting (PONV) occurs in 20% to 30% of surgical cases,⁶³ and it is a common cause of increased PACU length of stay and increased cost of PACU stay.⁶⁴ For this reason, many or most patients undergoing general anesthesia receive prophylactic antiemetics.

Enhanced Recovery After Surgery Pathways

Enhanced recovery after surgery (ERAS) pathways are multimodal perioperative care pathways designed to hasten recovery after elective surgery. These pathways may include preoperative education and counseling, preoperative optimization, limiting preoperative bowel preparation, limiting preoperative fasting, providing multimodal analgesia (including regional anesthesia) as appropriate, minimizing intraoperative fluid administration, and early mobilization. ERAS pathways have been shown to reduce duration of hospitalization and reduce cost of perioperative care.⁶⁵⁻⁶⁷

Acute Postoperative Pain

The management of postoperative pain has changed dramatically in the modern era, with multimodal approaches and regional techniques reducing the use of opiates. Regardless, opioids remain the mainstay of intraoperative and postoperative analgesia, especially for larger and more invasive procedures. Patients with chronic pain or opiate tolerance can present a unique challenge in the perioperative period, and they can benefit from regional and multimodal approaches. Such patients may benefit from early involvement of an acute pain medicine specialist.

For the past decade, pain has been described as the fifth vital sign, and physicians have been strongly encouraged to

aggressively treat pain in their patients. Generally speaking, physicians sought to accomplish this goal through the more liberal use of opiates. Opioid prescription has thus soared in recent years. Some studies suggest that 3% to 7% of surgical patients prescribed opioids in the postoperative period continue to use them for a prolonged period after surgery,^{68,69} suggesting that opioid abuse often begins in the postoperative period. The U.S. Centers for Disease Control and Prevention has recently declared that prescription drug abuse is an epidemic.⁷⁰ Physicians and surgeons will have to continue to seek the fine line between adequate pain control and prescribing patterns that enable dependence.

Malignant Hyperthermia

Malignant hyperthermia (MH) is a hereditary, life-threatening, hypermetabolic disorder, developing during or after receiving general anesthesia. The clinical incidence of MH ranges from 1:10,000 to 1:250,000.⁷¹ A genetic predisposition and exposure to one or more triggering agents are necessary to evoke MH. Triggering agents include all volatile anesthetics (e.g., isoflurane, sevoflurane, and desflurane) and the depolarizing neuromuscular blocker succinylcholine. Volatile anesthetics and/or succinylcholine cause a rise in the myoplasmic calcium concentration in susceptible patients, causing persistent muscle contraction, the production of large quantities of carbon dioxide and lactic acid, and a relentless increase in body temperature.

MH is often an autosomal dominant disorder associated with several gene loci, predominantly the ryanodine receptor gene *RYR1*. MH can be diagnosed with the caffeine-contraction halothane test, which requires a muscle biopsy. Genetic testing can be helpful after an episode of MH. There is no simple, reliable blood screening test yet available for diagnosis.

The classic MH crisis entails a hypermetabolic state with tachycardia and increased end-tidal CO₂. Relentless muscle contraction causes respiratory and metabolic acidosis, as well as rhabdomyolysis, arrhythmias, hyperkalemia, and even sudden cardiac arrest. Hyperthermia typically occurs after the episode is well under way. Treatment must be aggressive and begin as soon as a case of MH is suspected. Volatile anesthetics should be stopped immediately and dantrolene given at an initial dose of 2.5 mg/kg intravenously. The national MH hotline should be contacted for help in managing any patient with MH. Patients should be monitored in the intensive care setting for possible recrudescence of MH.

Cardiovascular Complications

Hemodynamic perturbations are a common in the perioperative period. Arrhythmias may begin before, during, and after an anesthetic, and are particularly common after cardiothoracic and esophageal surgery. Hypotension may be due to anemia, hypovolemia, myocardial ischemia or dysfunction, or other less common events such as pulmonary embolism and anaphylactic reactions. Hypertension is also common, particularly when antihypertensive regimens are altered in the perioperative period.

Respiratory Failure

Respiratory insufficiency and failure occur frequently in the postoperative period. Respiratory depression can occur as a consequence of residual neuromuscular blockade, residual inhaled anesthetics, or opioids. Mechanical airway obstruction can be ameliorated by rescue maneuvers, or insertion of an oral or nasal

airway. It is imperative to evaluate and treat anesthesia-related causes of respiratory insufficiency. The opioid antagonist naloxone can be given for opioid related respiratory insufficiency, and an additional reversal agent can be given for residual neuromuscular weakness. Respiratory failure can reasonably be managed with noninvasive positive pressure ventilation in many cases⁷²; patients who fail this or are unlikely to benefit from it should be intubated. High-flow nasal cannula is increasingly being used for postextubation respiratory failure,⁷³ and several studies have demonstrated its benefit in postoperative patients.⁷⁴⁻⁷⁷

Neurologic and Psychiatric Complications

Perioperative neurologic and psychiatric complications include stroke, both ischemic and hemorrhagic, postoperative delirium, and postoperative cognitive dysfunction. Treatment of perioperative stroke may be difficult as initiation of anticoagulation or thrombolysis may not be safe after surgery. Postoperative delirium is common and transient. Treatment includes reorientation, treatment of pain, workup for metabolic, hemodynamic, or respiratory perturbations, and consideration of the side effects of the anesthetics and analgesics administered. Antipsychotics such as haloperidol can be useful in the treatment of postoperative delirium.⁷⁸ Postoperative cognitive dysfunction (POCD) is a decline in cognitive function that may last days or may persist for months. Risk factors for persistent POCD include advanced age, history of prior stroke, and lower educational level.⁷⁹ POCD rates among older adult patients have been shown to be as high as 40% at hospital discharge and 12% 3 months after surgery. Notably, a causal link has not been established between administration of anesthesia and development of POCD, suggesting that it may be the physiologic stress of the perioperative experience that may lead to a decline in cognitive function in such patients.⁸⁰

CONCLUSION

The practice of anesthesia has improved dramatically over the past century. Advances in training, pharmacology, anesthesia equipment, and monitoring have not only made anesthesia dramatically safer but have also allowed ever sicker patients to benefit from surgery.

			Summary	2056

INTRODUCTION

As the population ages, an increasing number of older adults will develop surgical diseases. The segment of the U.S. population age 65 and older is expected to double by 2050. Older adults present unique challenges in surgical management and decision-making. The accumulation of comorbid conditions and physiologic vulnerability that occurs with age put older adults at high risk for major morbidity and mortality after surgery. It is essential that surgeons approach this population with a new set of skills and knowledge to provide optimal care for this vulnerable population. A comprehensive understanding of the unique vulnerabilities of older adults—geriatric syndromes and risk factors—are required to accurately estimate surgical risk, inform surgical decision-making, and guide perioperative management. In this chapter, we will (a) discuss the physiologic conditions that are common in older adults that are essential for surgical risk assessment of older adults considering surgery, (b) describe best practices in perioperative care in the older adult, and (c) discuss special considerations and common pitfalls for surgical conditions that are common in the older adult.

GERIATRIC SYNDROMES

Approximately one-third of older individuals undergoing vascular and urologic surgery suffer from *geriatric syndromes*.^{1,2}

1▶ This term is used to describe clinical conditions that do not fit into discrete disease categories but that can substantially negatively impact quality of life and result in disability. Geriatric syndromes often involve multiple underlying factors and organ systems (i.e., multiple causation of a unified manifestation³) and include frailty, falls, delirium, malnutrition, dizziness, syncope, urinary incontinence, and pressure ulcers among others. These syndromes can be present before surgery and/or

develop as a result of surgery and hospitalization.^{1,2} Furthermore, close attention to both the presence and development of geriatric syndromes among surgical candidates is important and often overlooked, making caring for older surgical patients unique compared to their younger and healthier counterparts.

Frailty

Frailty is among the most widely studied geriatric syndrome in the surgical literature. Frail older individuals are at high risk for adverse events in the face of stressors such as surgery. They are more likely to experience surgical complications, delayed recovery, falls, and to develop functional impairment. Frailty is also associated with a higher risk of death. It is believed that frailty is a chronic, progressive condition that represents a spectrum; less frail individuals may be responsive to strategies or interventions to ameliorate its clinical manifestations, while more frail individuals may demonstrate an irreversible predeath condition with limited life expectancy.⁴

Frailty has been shown to be independently predictive of poor postoperative outcomes. Makary et al studied 594 older patients presenting for elective surgery at a university hospital and demonstrated that frail individuals were at increased risk of postoperative complications (OR 2.54; 95% CI 1.12–5.77), longer length of stay (incidence rate ratio 1.69; 95% CI 1.28–2.23), and discharge to a skilled or assisted living facility after previously living at home (OR 20.48; 95% CI 5.54–75.68).⁵ Similar findings have been echoed throughout the surgical literature inclusive of vascular, colorectal, cardiac, urologic, and other types of procedures.^{6–11}

Definitions of frailty fall into two broad models; a phenotypic model and a deficits accumulation model. The phenotypic model was originally described by Linda Fried using data from the Cardiovascular Health Study, which is an observational study of community-dwelling men and women age 65 years and

Key Points

- 1▶ Frailty, dementia, and functional impairment are significant contributors to morbidity and mortality after surgery. Assessment of these risk factors is essential in an older population.
- 2▶ Geriatric perioperative pathways are effective in preventing delirium, a morbid and costly postoperative complication that is associated with cognitive decline.
- 3▶ Population-based data demonstrate that mortality after emergency surgery and high-risk cancer surgery is substantially higher in older adults than in a younger population.
- 4▶ Impaired cardiac function is responsible for more than half of the postoperative deaths in older adult patients, so careful attention must be paid to intravascular volume status in the perioperative period.
- 5▶ Many frail elders experience significant and sustained functional decline after surgery.
- 6▶ Older adults with acute abdominal pathology—appendicitis, cholecystitis—often do not have fever, elevated white blood cell count, or physical findings of peritonitis.

older. Individuals in this cohort underwent baseline evaluations and had 4 to 7 years of follow-up with annual examinations and surveillance for the following outcomes: incident disease, hospitalization, falls, disability, and mortality. Based on observations in these individuals over time, the following criteria were identified to define frailty: weight loss, exhaustion, physical

activity, walk time, and grip strength (Table 47-1). The presence of one or two of these factors is associated with intermediate risk for poor outcomes, i.e., a “prefrail” phenotype, and the presence of three or more of these factors is associated with high risk for poor outcomes, i.e., a “frail” phenotype.¹² This study additionally demonstrated that frailty is strongly associated

Table 47-1

Criteria used to define frailty

- Weight loss: “In the last year, have you lost more than 10 pounds unintentionally (i.e., not due to dieting or exercise)?” If yes, then frail for weight loss criterion. At follow-up, weight loss was calculated as: $(\text{Weight in previous year} - \text{current measured weight}) / (\text{weight in previous year}) = K$. If $K \geq 0.05$ and the subject does not report that he/she was trying to lose weight (i.e., unintentional weight loss of at least 5% of previous year’s body weight), then frail for weight loss = Yes.
- Exhaustion: Using the CES-D Depression Scale, the following two statements are read. (a) I felt that everything I did was an effort; (b) I could not get going. The question is asked “How often in the last week did you feel this way?” 0 = rarely or none of the time (<1 day), 1 = some or a little of the time (1–2 days), 2 = a moderate amount of the time (3–4 days), or 3 = most of the time. Subjects answering “2” or “3” to either of these questions are categorized as frail by the exhaustion criterion.
- Physical Activity: Based on the short version of the Minnesota Leisure Time Activity questionnaire, asking about walking, chores (moderately strenuous), mowing the lawn, raking, gardening, hiking, jogging, biking, exercise cycling, dancing, aerobics, bowling, golf, singles tennis, doubles tennis, racquetball, calisthenics, swimming. Kcals per week expended are calculated using standardized algorithm. This variable is stratified by gender.
Men: Those with Kcal of physical activity per week <383 are frail.
Women: Those with Kcals per week <270 are frail.
- Walk Time, stratified by gender and height (gender-specific cutoff a medium height).

<i>Men</i>		<i>Cutoff for time to walk 15 feet criterion for frailty</i>
Height ≤173 cm		≥7 seconds
Height >173 cm		≥6 seconds
<i>Women</i>		
Height ≤159 cm		≥7 seconds
Height >159 cm		≥6 seconds
- Grip Strength, stratified by gender and body mass index (BMI) quartiles:

<i>Men</i>		<i>Cutoff for grip strength (Kg) criterion for frailty</i>
BMI ≤24		≤29
BMI 24.1–26		≤30
BMI 26.1–28		≤30
BMI >28		≤32
<i>Women</i>		
BMI ≤23		≤17
BMI 23.1–26		≤17.3
BMI 26.1–29		≤18
BMI >29		≤21

with several major chronic diseases, including cardiovascular disease, pulmonary disease, and diabetes; however, not all frail individuals demonstrated these associations. The same is true for disability. While there is some overlap between frailty and disability, not all frail individuals are disabled. These findings suggest that while there may be overlap between these three constructs in some individuals, frailty is a distinct process from both comorbidity and disability.¹²

Alternatively, the deficit accumulation model, developed by Rockwood et al, suggests that frailty is defined by discrete failures of redundant physiologic systems. The more deficits that occur, the more likely it is that adverse outcomes will result. Using data from the Canadian Study of Health and Aging, a longitudinal study of individuals age 65 and older, the authors developed a frailty index represented by the cumulative proportion of 92 accumulated deficits, which include symptoms, signs, functional impairments, and laboratory abnormalities. They demonstrated that deficits accumulated at a rate of 3% per year in their cohort, represented a gamma distribution, and increased with chronological age; they proposed that this model be used as a proxy for aging and mortality.¹³

While these models are helpful to conceptualize frailty, no one model is all inclusive, and each may have applicability in different settings. For example, the frailty phenotype does not include items on cognition or mood and may not be easily applicable to the busy clinical setting.¹⁴ The deficits accumulation model is ideal for use in large databases, such as the American College of Surgeons National Surgical Quality Improvement Project (ACS-NSQIP),¹⁵ and may be helpful for research and public health and policy purposes, but it is not practical for clinical care. Measurement of frailty in the clinical setting will be discussed later in this chapter.

While frailty is often defined as a geriatric syndrome, it is also plausible that other geriatric syndromes (i.e., urinary incontinence, falls, pressure ulcers, delirium, and functional decline) may demonstrate shared risk factors that lead to frailty. In turn, frailty may also cause more risk factors and more geriatric syndromes.¹⁶ Regardless of the association and directionality between frailty and other geriatric syndromes, identification of each is essential in the preoperative setting in order to help risk stratify and potentially to mitigate risk for patients considering surgical intervention.

Falls

Older adults are at markedly increased risk of falls, and one in three adults age 65 and older report falling in the last year. The incidence of falls increases with age, and close to 60% of individuals who have fallen in the last year will fall again within the following year. Falls are associated with subsequent declines in functional status, greater likelihood of nursing home placement, increased use of medical services, and development of a fear of falling. Approximately half of older individuals who fall are unable to get up, resulting in a “long lie,” which is further associated with lasting functional declines.¹⁷ In fact, falls can be so detrimental to older individuals that the Joint Commission (United States) established fall prevention as one of its national safety goals in 2015.¹⁸

Causes of falls can be multifactorial, as with other geriatric syndromes. Factors include age-related declines, chronic disease, medications, environmental factors, changing positions, routine activities, risk-taking behaviors, acute illness, or situational hazards such as the unfamiliar setting of hospitals and long-term care facilities.¹⁷

It has been shown that preoperative falls are associated with poor postoperative outcomes among patients undergoing elective surgery. One study looking at 7982 such patients found that a preoperative history of one, two, or three or more falls predicted postoperative falls at 30 days (adjusted OR 2.3, 3.6, 5.5, respectively) and 1 year (adjusted OR 2.3, 3.4, 6.9, respectively), in addition to predicting a decline in functional status at 30 days (adjusted OR 1.2, 2.4, 2.4, respectively) and 1 year (adjusted OR 1.3, 1.5, 3.2, respectively) and in-hospital complications (adjusted OR 1.2, 1.3, 2.0, respectively).¹⁸ Furthermore, preoperative falls are a major predictor of poor postoperative outcomes and may be a valuable preoperative assessment tool as part of routine preoperative care.

Delirium

Delirium is a disorder of attention and awareness that develops acutely and tends to fluctuate, as defined by the new *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* criteria. Delirium is so common among older adults that up to one third of patients age 70 and older admitted to the hospital experiences delirium, half of which have delirium on admission and the other half of which develop delirium during the hospitalization itself.¹⁹ Rates of delirium among older patients undergoing surgery ranges from 4% to 5% in cataract and urologic procedures to 50% to 60% in infrarenal AAA repair or hip fracture surgery.²⁰ Patients who develop postoperative delirium have a two- to threefold increased risk of mortality within the first year after surgery.²¹

Preoperative assessment should focus on the identification of risk factors for delirium including age 70 years or older, cognitive impairment, limited physical function, history of alcohol abuse, abnormal serum sodium, potassium or glucose, intrathoracic surgery, and AAA surgery. Preoperative assessment and documentation of mental status is imperative in order to establish a baseline for postoperative comparison. Intraoperative blood loss is another risk factor for postoperative delirium, and patients with a postoperative hematocrit less than 30% are at increased risk, irrespective of baseline risk factors. Postoperatively, undertreatment of pain is an important risk factor for delirium. Management of fluid, electrolyte and metabolic abnormalities, optimization of blood loss replacement, maintenance of circadian rhythms, and cautious prescription of medication and pain management are among the most important methods by which to minimize the risk of postoperative delirium among surgical patients.²⁰ Furthermore, many commonly used medications may induce delirium and should be avoided. They include drugs with anticholinergic properties, corticosteroids, merperidine, and sedative hypnotics. Finally, postoperative care bundles have been shown to successfully reduce the incidence of delirium. These strategies include sensory enhancement (glasses, hearing aids), early mobility, cognitive orientation and therapeutic activities, and sleep protocols. Treatment of postoperative delirium should focus on treatable etiologies (Fig. 47-1), and pharmacologic treatment should be reserved for patients who are at risk of harming themselves or others.

PREOPERATIVE ASSESSMENT

Preoperative assessment in older adults is more complex than in younger individuals, as there are many unique characteristics that require consideration. The purpose of the assessment

Is your patient acutely delirious?

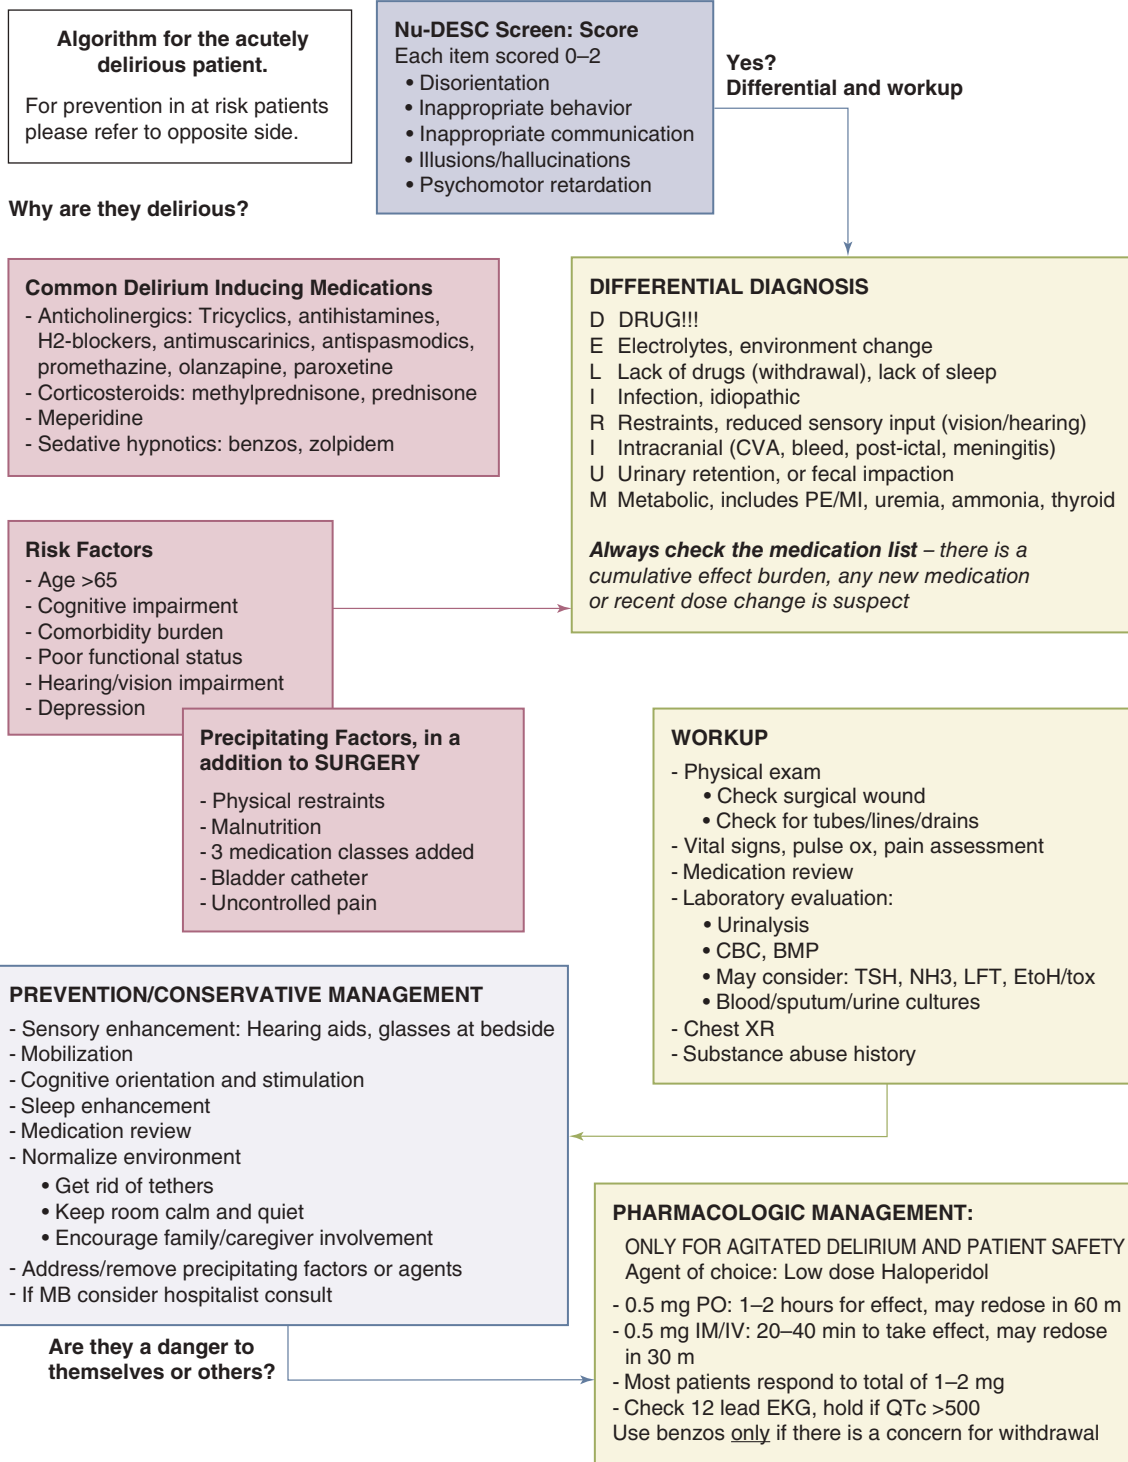

Figure 47-1. Useful algorithm to determine preoperative management of the acutely delirious patient.

is not to “clear” the patient for surgery but rather to minimize risks and optimize good outcomes. The ACS NSQIP and the American Geriatrics Society (AGS) published best practice guidelines to help optimize this process. Preoperative planning should be proactive, commencing at the time of surgical decision-making, if not sooner. To this end, the ACS NSQIP/AGS produced best practice guidelines and a preoperative management checklist to provide a framework for thinking about critical issues in this patient population (Table 47-2).²² In addition to these issues, they emphasize the importance of planning analgesia strategies,

making efforts to minimize opioid use and to prevent functional and cognitive decline, obtaining multidisciplinary consultation early and early involvement of allied health staff (i.e., physical or occupational therapy), and anticipating home health needs that may be required at discharge.²³

Best Practices: Preoperative Assessment

Functional Assessment. As previously discussed, poor physical function prior to surgery is associated with higher risk of major postoperative complications, increased need for intensive

Table 47-2

Immediate preoperative management checklist from the ACS NSQIP/AGS

1. Confirm and document patient goals and treatment preferences, including advance directives
2. Confirm and document patient's health care proxy or surrogate decision-maker
3. In patients with existing advance directives, discuss new risks associated with the surgical procedure and an approach for potentially life-threatening problems consistent with the patient's values and preferences
4. Consider shortened fluid fast (clear liquids up to two hours before anesthesia)
5. Adhere to existing best practices regarding antibiotic and venous thromboembolism prophylaxis
6. Ensure nonessential medications have been stopped and essential medications have been taken

Adapted with permission from Mohanty S, Rosenthal RA, Russell MM, et al: Optimal Perioperative Management of the Geriatric Patient: A Best Practices Guideline from the American College of Surgeons NSQIP and the American Geriatrics Society, *J Am Coll Surg*. 2016 May;222(5):930-947.

rehabilitation services, increased rates of discharge to a skilled or assisted nursing facility, and higher mortality.²⁴⁻²⁶ Assessment of physical function and performance status in the preoperative setting are recommended by the ACS NSQIP/AGS best practice guidelines.²² There are several methods by which to measure physical function. Overall functional status may be ascertained by assessing the ability of an individual to perform activities of daily living (ADLs) and instrumental ADLs. ADLs include dressing, bathing, toileting, transferring, continence, and eating independently.²⁵ Instrumental ADLs measure an individual's ability to live independently and include the ability to perform the following tasks: shopping, laundry, mode of transportation, ability to handle finances, responsibility for won medications, food preparation, and housekeeping.²⁷

In addition to assessment of ADLs and instrumental ADLs, the surgeon should also assess for deficits in vision, hearing, and swallowing, inquire about history of falls in the past year, evaluate for limitations in gait and mobility, and determine risk for falls, which can be performed via the timed up and go test (TUGT). This test measures gait and mobility impairment and is associated with increased risk for falls in ambulatory individuals. All that is required to perform this test are a chair, a mark 10 feet in front of the chair, and a stopwatch. Individuals are instructed to do the following while being timed:

1. Stand up from the chair (without using arm rests, if possible)
2. Walk to the mark (10 feet in front of them)
3. Turn
4. Walk back to the chair
5. Sit down in the chair

A time of ≥ 15 seconds indicates high risk of falls and should prompt referral to physical therapy for further assessment.

In a prospective cohort of individuals age 65 and older undergoing surgery, the TUGT times were stratified into three groups that strongly correlated with varying risk for postoperative complications and 1-year mortality. These groups were "slow" (≥ 15 seconds), "intermediate" (11–14 seconds), and

"fast" (≤ 10 seconds). Postoperative complications and 1-year mortality in the slow group were significantly higher compared to those in the fast group, 52% to 77% versus 11% to 13% for complications, and 31% compared to 3% for mortality, respectively.⁹

Frailty Assessment

As stated earlier, frailty is an important consideration in preoperative planning for older individuals. Measurement of frailty can take several forms. One method is to apply the operational definition put forth by Fried (see Table 47-1), which has been applied to surgical patients and shown to be an independent predictor of postoperative adverse events, increased length of stay, and higher likelihood of discharge to a skilled or assisted living facility.⁵

The frailty phenotype, however, may be cumbersome to apply in the busy clinical setting. To this end, Robinson proposed alternative definitions and methods for frailty measurement. One such method includes the following criteria: cognitive impairment (Mini-Cog score of ≤ 3), poor nutrition (serum albumin ≤ 3), history of falls (≥ 1 fall in the past 6 months), and low hematocrit ($< 35\%$).²⁶ A second definition includes functional impairment (TUGT ≥ 15 seconds and dependence in any ADL) and comorbidity (Charlson index score ≥ 3).²⁸

Cognitive and Behavioral Assessment

Preoperative cognitive impairment is strongly linked to postoperative delirium, worse surgical outcomes, longer hospital stays, increased risk of functional decline, and even mortality. History and cognitive assessment are important to consider early on in all surgical candidates age 65 years and older in the preoperative setting. The Mini-Cog, consisting of the three-item recall and clock draw tests, can be used to complete this assessment (Table 47-3). If possible, someone who knows the patient well (such as a spouse or family member) should be interviewed about the presence and evolution of any cognitive decline in the patient. If decline is present, the patient should be referred to a primary care physician, geriatrician, or mental health specialist for further evaluation. Documentation of preoperative cognitive status will further assist in the identification of any postoperative cognitive dysfunction.²² Risk factors for postoperative delirium should also be assessed in the preoperative period and are detailed in Table 47-4.

In addition to measuring cognitive status, assessing the patient's decision-making capacity is also important to determine the patient's ability to provide informed surgical consent. It is helpful to ask the patient to describe, in his/her own words, the important features of the discussion, the condition and indications for surgery, and the risks, benefits, and alternatives to surgery. There are four legally-relevant criteria for decision-making capacity²²:

1. The patient can clearly indicate his/her treatment choice.
2. The patient understands the relevant information communicated by the physician.
3. The patient acknowledges his/her medical condition, treatment options, and likely outcomes.
4. The patient can engage in a rational discussion about the treatment options.

Depression should also be screened for in the preoperative setting, as up to 11% of the population age 71 years and older in the United States suffer from this condition.²⁹ Risk factors

Table 47-3

Cognitive assessment: three-item recall and clock draw

1. Get the patient's attention and say:
*"I am going to say three words that I want you to remember now and later.
 These words are **banana, sunrise, chair.**
 Please say them for me now."*
 Give the patient three tries to repeat the words. If unable after three tries, go to next item.
2. Say all of the following phrases in the order indicated:
"Please draw a clock in the space below. Start by drawing a large circle. Put all the numbers in the circle and set the hands to show 11:10 (10 past 11)."
 If the subject has not finished clock drawing in 3 minutes, discontinue and ask for recall items.
3. Say: "What were the three words I asked you to remember?"

Scoring:

- 3 item recall (0-3 points): 1 point for each correct word
 - Clock draw (0-2 points): 0 points for abnormal clock; 2 points for normal clock
- A normal clock has all of the following elements:
1. All numbers 1-12, each only once, are present in the correct order and direction (clockwise) inside the circle.
 2. Two hands are present, one pointing to 11 and one pointing to 2.
 3. Any clock missing any of these elements is scored abnormal. refusal to draw a clock is scored abnormal

Total score of 0, 1, or 2 suggests possible impairment

Total score of 3, 4, or 5 suggests no impairment

Reproduced with permission from Borson S, Scanlan J, Brush M, et al. The mini-cog: a cognitive 'vital signs' measure for dementia screening in multi-lingual elderly, *Int J Geriatr Psychiatry*. 2000 Nov;15(11):1021-1027.

for depression in older adults include female gender, disability, bereavement, and sleep disturbance. Poor health status, cognitive impairment, living alone, and new medical illness may also contribute to depression.³⁰

The Patient Health Questionnaire-2 (PHQ-2) can be used to screen for depression via the following two questions³¹:

1. *In the past 12 months, have you ever had a time when you felt sad, blue, depressed, or down for most of the time for at least two weeks?*
2. *In the past 12 months, have you ever had a time, lasting at least two weeks, when you didn't care about the things that you usually care about or when you didn't enjoy the things that you usually enjoy?*

If a patient answers yes to either question, further reevaluation with a primary care physician, geriatrician, or psychiatrist is recommended.

Screening for alcohol and substance abuse is also recommended, as alcohol use is common among older adults. Up to 13% of men and 8% of women ≥ 65 years consume at least 2 drinks per day and 14.5% of men and 3.3% of women consume 5 or more drinks per day.³² Alcohol and substance abuse are associated with increased rates of postoperative mortality and complications including pneumonia, sepsis, wound infection and disruption, and prolonged length of stay.^{33,34} The ACS NSQIP/AGS recommend screening for alcohol and substance

Table 47-4

Risk factors for postoperative delirium

Cognitive and behavioral disorders:

- Cognitive impairment and dementia
- Untreated or inadequately controlled pain
- Depression
- Alcohol use
- Sleep deprivation

Disease or illness related:

- Severe illness or comorbidities
- Renal insufficiency
- Anemia
- Hypoxia

Metabolic:

- Poor nutrition
- Dehydration
- Electrolyte abnormalities

Functional impairments:

- Poor functional status
- Immobilization
- Hearing or vision impairment

Other:

- Older age ≥ 70 years
- Polypharmacy and use of psychotropic medications (benzodiazepines, anticholinergics, and antihistamines)
- Risk of urinary retention or constipation, presence of urinary catheter

Reproduced with permission from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society, *J Am Coll Surg*. 2012 Oct;215(4):453-466.

abuse among older individuals with the modified CAGE questionnaire in combination with prescribing daily multivitamins, including folic acid and high dose (100 mg) oral or parenteral thiamine to patients who drink alcohol.^{22,35}

Medical Assessment

A thorough medical assessment should be performed in all older operative candidates and should include a cardiac evaluation, pulmonary evaluation, nutritional assessment, and medication evaluation and management where appropriate.

Cardiac adverse events are the most common cause of serious perioperative morbidity and mortality among patients undergoing noncardiac operations and occur more commonly in older adults.^{36,37} For these reasons, cardiac evaluation may be helpful to identify older patients with higher risk for cardiac complications who may be candidates for perioperative optimization. This evaluation should follow the American College of Cardiology and the American Heart Association (ACC/AHA) algorithm for cardiac evaluation and care. This is a step-wise approach that incorporates the following factors: (a) urgency of surgery (whether the procedure is an emergency); (b) presence of active major cardiac risk factors (i.e., unstable coronary syndromes, decompensated heart failure, significant arrhythmias or severe valvular disease) that would necessitate referral to a cardiologist; (c) if risk factors for stable coronary artery disease are present, then calculation of risk for major adverse cardiac events using the ACS NSQIP calculator

is recommended; (d) if the patient is at low risk for major cardiac events (<1%) then no further testing is needed; (e) if the patient is at elevated risk of major cardiac events, then determination of functional capacity with an objective measure or scale may be helpful; (f) if functional capacity is poor, then additional testing such as pharmacological stress testing, may be helpful; and finally (g) if testing does not impact care, then one should proceed to surgery or consider alternative treatment strategies.³⁸ Routine electrocardiograms are not indicated in older patients undergoing low-risk surgery in the absence of other risk factors.³⁹⁻⁴¹

4▶ The combined effect of depletion of intravascular volume, age-related impairment of response to catecholamines, and increased myocardial relaxation time adversely affects the cardiac function of an older adult patient under stress in the perioperative period. Aging has been demonstrated to cause a decrease in cardiac output by approximately 1% per year. Older individuals fail to augment heart rate to the same extent as younger individuals. More importantly, the ability to increase cardiac output with aging is dependent on ventricular dilatation, which is determined by preload. Therefore, careful attention must be paid to volume status in the perioperative period. Over one half of all postoperative deaths in older adult patients and 11% of postoperative complications are a result of impaired cardiac function under physiologic stress. Incomplete emptying of the ventricle at end systole and subsequent reduction in ejection fraction is characteristic of the aging heart. Reduced distensibility, in addition to acute stressors, leads to impaired coronary perfusion and cardiac ischemia.

An important predictor of surgical outcomes and cardiac complications in the older adult is congestive heart failure (CHF). CHF is present in approximately 10% of patients older than 65 years and is the leading cause of postoperative morbidity and mortality. This prevalence will likely increase as percutaneous interventions and medical therapy prolongs survival from myocardial ischemia and acute myocardial infarction. Therefore, identifying correctable and uncorrectable cardiovascular disease is critical before elective surgical interventions.

Common pulmonary postoperative complications in older adults include atelectasis, pneumonia, and prolonged mechanical ventilation.⁴² These complications can contribute significantly to overall morbidity and mortality among older adults, affecting up to 15% of individuals ≥ 70 years in the postoperative setting.^{22,43} Risk factors for postoperative pulmonary complications include both patient and procedure-related factors. Patient-related factors include age >60 , chronic obstructive pulmonary disease (COPD), American Society of Anesthesiologists (ASA) class II or greater, functional dependence, congestive heart failure, obstructive sleep apnea, pulmonary hypertension, current cigarette use, impaired sensorium, preoperative sepsis, weight loss $>10\%$ in 6 months, serum albumin <3.5 mg/dL, and blood urea nitrogen (BUN) ≥ 7.5 mmol/L (≥ 1.5 mg/dL). Surgical related factors include prolonged operation of greater than 3 hours, surgical site, emergency operation, general anesthesia, perioperative transfusion, and residual neuromuscular blockade after an operation. Of note, obesity, well-controlled asthma, and diabetes are not risk factors for postoperative pulmonary complications. It is recommended that patients with COPD and asthma that is not well controlled undergo preoperative optimization of pulmonary function and other general recommendations include smoking cessation, preoperative intensive inspiratory muscle training, and selective chest radiograph and pulmonary function testing.²²

In general, the use of routine preoperative screening combined with the high cost of unnecessary testing dispute the use of a routine battery of preoperative screening tests in all patients. Instead, it is preferable to perform selected tests in high-risk patients based on history, physical exam, known comorbidities, and the type of procedure being planned.²²

Nutritional Assessment

Nutritional status should also be performed in older adults prior to surgery, as poor nutrition is potentially modifiable and related to increased risk of postoperative complications. The most common adverse events related to poor nutritional status are infectious complications (i.e., surgical site infections, pneumonia, urinary tract infections), wound complications (i.e., dehiscence and anastomotic leaks), and increased length of stay. The ACS NSQIP/AGS best practice guidelines recommend the following to screen for poor nutritional status:

1. **Document height and weight and calculate body mass index (BMI).** A BMI <18.5 kg/m² places an individual at risk and should prompt referral for full nutritional assessment.
2. **Measure baseline serum albumin and prealbumin levels.** Serum albumin <3.0 g/dL (with no evidence of hepatic or renal dysfunction) should prompt referral for full nutritional assessment.
3. **Inquire about unintentional weight loss in the last year.** Unintentional weight loss $>10\%$ to 15% in the past 6 months is associated with severe nutritional risk and should prompt assessment by a dietician.²²

The American Society for Parenteral and Enteral Nutrition (ASPEN) argues that measurement of serum albumin and prealbumin reflect the severity of the inflammatory response rather than true poor nutritional status. Instead, they favor a more individualized approach whereby the presence of any of the following six factors would classify an individual with malnutrition:

1. **Insufficient energy intake.** Severe malnutrition in the context of chronic illness is defined as $<75\%$ of estimated energy requirement for ≥ 1 month.
2. **Weight loss.** Severe malnutrition in the context of chronic illness is defined as $>5\%$ weight loss in 1 month, $>7.5\%$ weight loss in 3 months, $>10\%$ weight loss in 6 months, and $>20\%$ weight loss in 1 year.
3. **Loss of muscle mass.** Severe malnutrition is defined as severe muscle wasting of the temples, clavicles, shoulders, interosseous muscles, scapula, thigh, and calf.
4. **Loss of subcutaneous fat.** Severe malnutrition is defined as loss of subcutaneous fat (e.g., orbital, triceps, fat overlying the ribs).
5. **Localized or generalized fluid accumulation that may sometimes mask weight loss.** This can be demonstrated by fluid accumulation evident on exam (e.g., extremities, vulvar/scrotal edema, or ascites).
6. **Diminished functional status as measured by hand grip strength.** Measurements for grip strength are based on normative standards supplied by the manufacturer of the measurement device.⁴⁴

Regardless of the method used to measure nutritional status, attention to the diagnosis and management of malnutrition in the perioperative setting is imperative to optimize postoperative outcomes.

Psychosocial Considerations

Anxiety, depression, substance abuse, and social isolation are common, underdiagnosed conditions in older adults. Careful screening can identify these potential barriers to recovery, safe discharge after surgery, and maintenance of independence.

Medication Review

Careful review and documentation of the patient's complete medication history is important in the preoperative setting. The review should include the use of nonprescription agents, including over-the-counter, nonsteroidal anti-inflammatory drugs (NSAIDs), vitamins, eye drops, topical agents, and herbal products.

Additionally, it is important to discontinue medications that should be avoided prior to surgery in order to minimize potential adverse events and interactions. These include discontinuation of all nonessential medications that are associated with increased surgical risk and medications with potential for drug interactions with anesthesia. Herbal medication should be stopped at least 7 days prior to surgery, and the Beers criteria should be reviewed. Medications with potential for withdrawal (e.g., selective serotonin reuptake inhibitor [SSRIs], tricyclic antidepressants, benzodiazepines, antipsychotics, monoamine oxidase inhibitors [MAOIs], β -blockers, clonidine, statins, and corticosteroids) in addition to angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers should be continued unless hypertension is well controlled. Medications that are associated with increased risk for postoperative delirium should also be avoided and replaced with safer medications. For example, benzodiazepines should be stopped or reduced, where possible. Pain should be adequately controlled and meperidine should be avoided for pain management. Caution should be used when prescribing antihistamine H_1 antagonists (such as diphenhydramine/Benadryl) and medications with antihistamine effects. Of note, there is no increased risk associated with neuroleptics (antipsychotics) and digoxin and no conclusive evidence against using H_2 agonists, tricyclic antidepressants, anti-Parkinson medications, steroids, NSAIDs, and antimuscarinics in the perioperative setting.

Certain medications, such as β -blockers or statins, may be beneficial to start preoperatively in order to reduce risk of perioperative adverse events such as cardiac complications and stroke. There are ACC/AHA guidelines to support the use of perioperative β -blockers in patients who are already taking them, particularly those with independent cardiac indications such as arrhythmia or history of myocardial infarction and in patients who are undergoing intermediate risk or vascular surgery with no known coronary artery disease or with multiple clinical risk factors for ischemic heart disease. Statins should be started as soon as possible prior to surgery in patients who have known vascular disease, elevated low-density lipoprotein cholesterol, or ischemia on thallium testing. They may also be considered in patients undergoing vascular and intermediate-risk surgery.

Additionally, medication doses should be adjusted based on renal function. Older patients are at greater risk for renal impairment and chronic kidney disease; furthermore, adjustment of medications that are renally cleared is an important consideration. Glomerular filtration rate (GFR), rather than creatinine, is the best overall measure of renal function due to the fact that the ratio of GFR to creatinine decreases with increasing age.²²

Finally, medication use is very common among the older population, and older individuals should be monitored for

polypharmacy and potential adverse interactions. This is of real concern since 40% of individuals age 65 years and older are taking five or more medications prescribed by more than one doctor.⁴⁵ Additionally, 68% of older adults use over-the-counter medications, dietary supplements, or both concurrently with prescription medications.⁴⁶ Of note, polypharmacy has been associated with increased risk of cognitive impairment, morbidity, and mortality, and the risk of adverse drug reactions increases with a greater number of medications.^{45,47}

Patient Counseling

Determination of the patient's preferences and expectations prior to surgery is an essential component to preoperative assessment and decision making. One study demonstrated that agreement between patients and their surrogates (primary care providers and close family members) was poor, despite patients predicting that their physicians (90%) and family members (87%) would accurately represent their wishes. Instead, they found that percent of agreement ranged from 59% to 88%, suggesting that substituted judgement may not be a good proxy for an individual patient's wishes.⁴⁸ Another study looked at older patients with limited life expectancy due to cancer, congestive heart failure, or chronic obstructive pulmonary disease and found that 99% of patients would undergo a low-burden treatment to restore current health (with the alternative being death), but that 74% and 89% would forgo treatment if it resulted in severe functional or cognitive impairment, respectively.⁴⁹ Furthermore, it is imperative that the surgeon have a substantive discussion with the patient prior to surgery to determine their preferences and expectations and that family members and potential decision-making surrogates be involved. The ACS NSQIP/AGS Guidelines recommend that the following four points be included in these conversations:

1. Ensure that the patient has an advance directive and designated health care proxy.
2. Discuss treatment goals and plans with the patient to ensure that the physician understands the patient's preferences and expectations. This should be documented in the medical record.
3. The surgeon should describe the expected postoperative course and possible complications, including the potential for functional decline and need for rehabilitation or nursing home care, if relevant.
4. The physician should determine the patient's family and social support systems. If support is insufficient, then a referral to a social worker should be considered.²²

The American College of Surgeons has created a checklist for the optimal preoperative assessment of the geriatric surgical patient (see Table 47-2).

PREOPERATIVE PREPARATION

In the immediate preoperative period, careful planning is essential to optimize the care of the frail older patient.

Patient Goals, Preferences, and Advance Directives

It is important that surgeons have a good understanding of patients' goals and wishes surrounding their medical care, particularly towards the end of life. This should be established in the clinic setting prior to surgery and should be confirmed

and documented throughout the process. Additionally, patients should be encouraged to designate a health care proxy to help with this process, should they be unable to make their own medical decisions. The healthcare team should also consider early palliative care consultation in individuals with poor prognoses who are electing to undergo surgery, particularly if they have a life expectancy of less than 6 months.

Preoperative Fasting

Historically, preoperative fasting began at midnight the night before elective surgery, whereby, patients were not permitted to have any oral intake of either liquids or solids. However, more recent literature suggests that there may be no clear benefit to extended periods of fasting greater than 6 hours.⁵⁰ Based on the American Society of Anesthesiologists 2011 practice guidelines for all adults, fasting should take the form of stopping clear liquids at least 2 hours before elective procedures, stopping light food intake and/or nonhuman milk 6 hours before elective procedures and stopping fried, fatty foods and meat at least 8 hours before elective procedures. Of note, patients with comorbidities or diseases that can affect gastric emptying (i.e., diabetes, hiatal hernia) may require additional periods of fasting.

Antibiotic Prophylaxis and Venous Thromboembolism Prevention

Antibiotic prophylaxis for older adults should comply with standard guidelines put forth by The Society for Healthcare Epidemiology of America/Surgical Infection Society/American Society of Health-System Pharmacists/Infectious Disease Society. Older adults who receive appropriate preoperative antibiotics demonstrate a mortality benefit at 60 days.^{51,52} Appropriate antibiotics should be administered within 60 minutes prior to surgical incision.

Older adults are at higher risk for venous thromboembolism (VTE), making VTE risk stratification among this population essential. Older individuals undergoing orthopedic procedures (i.e., total hip or knee arthroplasty) or who have suffered a hip fracture should be treated with low molecular weight heparin (LMWH) (starting either 13 hours or more preoperatively or 12 hours or more postoperatively) for a minimum of 10 to 14 days and up to 35 days. Older adults undergoing nonorthopedic surgery (i.e., general, abdominopelvic, bariatric, vascular plastic/reconstructive, and thoracic surgery) should have LMWH or low-dose unfractionated heparin (LDUH) and mechanical prophylaxis with intermittent pneumatic compression (IPC). Older adults undergoing craniotomy/spinal surgery or cardiac surgery should have IPC. Finally, older individuals who experienced major trauma and spinal cord injury should use LDUH/LMWH and IPC if not contraindicated.²³

Surgical Prehabilitation

One purpose of the preoperative assessment is to identify potentially modifiable risk factors in order to optimize surgical outcomes. Several prehabilitation programs have emerged in order to help meet this need and have demonstrated promising results. One of the first of such programs was referred to as the Proactive Care of Older People undergoing surgery (POPS) study in the United Kingdom's National Health Service (NHS). This project was designed to decrease complications leading to increased hospital length of stay among at-risk older adults undergoing elective surgery. The authors performed a

structured geriatric team intervention to identify at-risk patients and to then facilitate coordinated multidisciplinary care in the form of daily inpatient rounds, weekly multidisciplinary meetings, and biweekly ward rounds led by a POPS consultant/clinical nurse specialist. Outcomes in surgical patients undergoing the POPS intervention were compared to those among patients not undergoing the intervention. The POPS group had fewer postoperative complications, including lower rates of pneumonia (4% vs. 20%, $P = 0.008$) and delirium (4% vs. 19%, $P = 0.028$), better pain control (2% vs. 30%, $P < 0.001$), lower rates of delayed mobilization (9% vs. 28%, $P = 0.12$) and lower rates of inappropriate catheter use (7% vs. 37%, $P = 0.046$). They also demonstrated a reduction in hospital length of stay by 4.5 days.⁵³

The Michigan Surgical Home and Optimization Program (MSHOP) is another example of a successful prehabilitation program. This is a structured, home-based preoperative training program that targets physical, nutritional, and psychological interventions. The intervention included the following four components: (a) a home-based walking program with daily reminders and feedback; (b) incentive spirometry instructions starting one week prior to surgery; (c) education on nutrition, stress management, and care planning; and (d) resources for smoking cessation, when appropriate. Eighty-two percent of individuals enrolled in the study were actively engaged in the program. Compared to individuals who did not undergo the intervention, patients enrolled in the trial demonstrated a 31% reduction in hospital length of stay and a 28% reduction in cost.⁶⁴ Collectively, the POPS study and the MSHOP studies are illustrative of the notion that attention to pre- and perioperative assessment in the older population result in improved postoperative outcomes that benefit the patient, hospital, and health care system.

Palliative Care Services for Older Surgical Patients

Among seriously ill individuals, palliative care services have the potential to increase quality of life, improve symptoms and patient satisfaction, and reduce caregiver burden.⁵⁵⁻⁵⁷ The role of palliative care in older surgical patients is not as well understood, and it is not widely understood in the surgical population.⁵⁸ Over a decade ago, the American College of Surgeons Palliative Care Workgroup identified core competencies of surgical palliative care.⁵⁹ The two key elements of palliative care—pain management and communication skills—are essential. For surgeons who frequently care for individuals at high risk of morbidity and mortality, there are six additional core competency domains: patient care, medical knowledge, practice-based learning, interpersonal skills, communication skills, and professionalism (Table 47-5).

Emerging data suggests that surgical patients benefit from the addition of palliative care principles and services. An interventional trial evaluating a decision-making intervention considering procedures that included information about health status and prognosis increased the likelihood of choosing less aggressive treatment options among patients with frailty (OR 3.41, 95% CI 1.39–8.39) or dementia (OR 1.66, 95% CI 1.06–2.64).⁶⁰ In a study of preoperative care consultation in frail older adults, Ernst et al found that preoperative palliative care consultations were associated with reduced mortality.⁶¹ Several studies have found that postoperative palliative care improves symptoms, including uncertainly, symptom distress, and depression, and improves quality of life.⁶²⁻⁶³

Table 47-5

Core Competencies in surgical palliative care

DOMAIN	COMPETENCY
Patient Care	<p>Possess the capacity to guide the transition from curative and palliative goals of treatment to palliative goals alone based on patient information and preferences, scientific and outcomes evidence, and sound clinical judgment</p> <p>Perform an assessment and gather essential clinical information about symptoms, pain, and suffering</p> <p>Perform palliative procedures competently and with sound judgment to meet patient goals of care at the end of life</p> <p>Provide management of pain and other symptoms to alleviate suffering</p> <p>Communicate effectively and compassionately bad news and poor prognoses</p> <p>Conduct a patient and family meeting regarding advance directives and end-of-life decisions</p> <p>Exercise sound clinical judgment and skill in the withdrawal and withholding of life support</p>
Medical knowledge	<p>Acute and chronic pain management</p> <p>Non-pain symptom management</p> <p>Ethical and legal basis for advance directives, informed consent, withdrawal and withholding of life support, and futility</p> <p>Grief and bereavement in surgical illness</p> <p>Quality of life outcomes and prognostication</p> <p>Role of spirituality at the end of life</p>
Interpersonal and communication skills	<p>Surgeons must be competent and compassionate communicators with patients, families, and other health care providers. They should be effective in communicating bad news and prognosis and in redefining hope in the context of cultural diversity. The interdisciplinary nature of palliative care requires that the surgeon is skilled as both a leader and a member of an interdisciplinary team and maintains collegial relationships with other health care providers.</p>
Professionalism	<p>Surgeons must maintain professional commitment to ethical and empathic care, which is patient focused, with equal attention to relief of suffering along with curative therapy. Respect and compassion for cultural diversity, gender, and disability is particularly important around rituals and bereavement at the end of life. Maintenance of ethical standards in the withholding and withdrawal of life support is essential.</p>
Systems-based practice	<p>Surgeons must be aware and informed of the multiple components of the health care system that provide palliative and end-of-life care. Surgeons should be knowledgeable and willing to refer patients to hospice, palliative care consultation, pain management, pastoral care, social services, etc., and to understand resource utilization and reimbursement issues involved.</p>

Data from Mohanty S, Rosenthal RA, Russell MM, et al: Optimal Perioperative Management of the Geriatric Patient: A Best Practices Guideline from the American College of Surgeons NSQIP and the American Geriatrics Society, *J Am Coll Surg*. 2016 May;222(5):930-947.

SPECIAL CONSIDERATIONS

Functional Recovery

In the past decade, there has been increasing attention to the examination of functional outcomes after major surgery in the geriatric population. In a large prospective cohort study of patients age 60 years and older undergoing abdominal surgery, Lawrence et al found that older adults required several months to fully return to basic activities of daily living (ADLs) and up to 6 months to become independent in more complex instrumental activities of daily living (IADLs).⁶⁵ Older adults are frequently discharged to postacute facilities even when they are functional dependent at baseline and have an uncomplicated postoperative course.⁶⁶

Among frail older adults, functional decline after surgery is often substantial and sustained. Studies examining functional

outcomes after surgery among nursing home residents have demonstrated that the majority of nursing home residents who undergo surgery do not return to baseline levels of function post-operatively.⁶⁷⁻⁶⁸ Among residents who underwent colectomy for cancer, 53% were dead after 1 year and over half of 1-year survivors experienced functional decline.⁶⁸ For residents who undergo lower extremity bypass, half die within a year of surgery.⁶⁷ At 1 year, 13% of the initial vascular surgery cohort was ambulatory, and 18% had maintained or improved their baseline functional status—calling into question the efficacy of this procedure in the nursing home. A study of hip fracture repair in nursing home residents found that over a third of residents died and over half of residents had died or experienced functional decline within 180 days after fracture. Residents with multiple comorbidities and advanced cognitive impairment and those who did not undergo surgical correction of the fracture experienced the worst outcomes.

Cancer Surgery

Approximately 50% of cancer diagnoses are currently made in patients age 70 years or older.⁶⁹ It is predicted that the increase in the older adult population will account for up to a 50% increase in the number of patients undergoing oncologic procedures by the year 2020. The increased life expectancy of the geriatric patient coupled with the increasing incidence of cancer with advancing age will lead to an increased prevalence of malignant disease requiring surgical intervention. This is an area of great interest given that randomized clinical trials to determine the outcomes of older adult patients undergoing curative resections, as well as neoadjuvant and adjuvant therapy, are lacking. In addition, older adult patients are rarely included in clinical trials; therefore, treatment decisions are often based on individual surgeon experience and nongeriatric data, and they may be flawed by inherent biases regarding the outcome of complete oncologic resections in older adult patients. Surgeons may also be reluctant to expose older patients to the toxic effects of chemotherapy and radiation without proven efficacy in this geriatric population. This highlights the need for research targeting the specific needs of older adult patients with malignancy to aid in the development of specific treatment guidelines for various cancers within this age cohort.

Numerous studies have documented increased risk of postoperative morbidity and mortality in older adults with cancer. Evaluation of a national surgical registry found that older adults undergoing major gastrointestinal surgery have substantially higher risks of complications and death than individuals younger than 65 years.⁷⁰ The impact of age on risk was present across all operations but had most impact in liver and rectal surgery. Surgeons are challenged to decide whether major surgery is justified in older adult patients, especially those with limited life expectancy. Effectiveness of oncologic surgery in older adult patients depends on whether a cure can be achieved safely without compromise to functional status or quality of life. Postoperative life expectancy should be improved by surgery, or, at the very least, not diminished.

Emergency Surgery

Emergent surgery carries exceptionally high risk for older adult patients. In an analysis of patients age 90 years and older, 90-day mortality after emergency gastrointestinal procedures was 54%.⁷¹ In a large cohort of patients undergoing endovascular repair for ruptured aortic aneurysm, 30-day mortality was 35% after primary aortic repair and 52% after open conversion of endovascular aortic repair.⁷²

Frail institutionalized elders are at substantial risk for poor surgical outcomes after emergent surgery. In an analysis of over 70,000 nursing home residents who underwent emergent abdominal operations (surgery for bleeding ulcer, cholecystectomy, appendectomy, and colectomy), operative mortality was two- to threefold higher than among matched community-dwelling elders.⁷³ In addition, invasive life-sustaining interventions after surgery were significantly higher in the nursing home population than among noninstitutionalized Medicare enrollees, ranging from 18% vs. 5%, respectively, after cholecystectomy to 55% vs. 43%, respectively, after ulcer surgery.

The combined effects of poor nutrition, decreased cognition, and immune impairments due to nutritional or pharmacologic factors create a treacherous circumstance for older adult patients with poorly defined symptoms or who present with more advanced disease. In acute abdominal conditions,

such as acute appendicitis and acute cholecystitis, one-third of older adult patients will lack an elevated white blood cell count, one-third will lack fever, and one-third will lack physical findings of localized peritonitis.⁷⁴ These deficits contribute to a threefold higher rate of perforated appendicitis and of gangrene of the gallbladder in older adult patients compared to young patients. An “unimpressive” physical exam in an older adult patient with acute onset of abdominal symptoms should never be taken as a sign of the absence of surgical disease.

Cardiovascular Surgery

With advances in cardiopulmonary bypass technique, myocardial protection, and improved perioperative care, coronary artery bypass grafting (CABG) and valve replacement operations have become safer in older patients. When considering cardiovascular surgery in elders, it is essential to consider that advanced age is not the strongest predictor of poorer outcomes or increased mortality compared in older patients. It has been demonstrated that emergency operations, preoperative New York Heart Association (NYHA) functional class 3 or greater, and chronic renal failure are the strongest independent predictors of increased operative mortality.⁷⁵ In one study, preoperative renal dysfunction, cerebrovascular disease, valve surgery, and catastrophic state were independent predictors of increased mortality in older adult patients.⁷⁶ Older adult patients with non-dialysis-dependent renal dysfunction had a 60% chance of death during a 5-year follow-up period compared to 25% in older adult patients without a history of renal dysfunction. Similarly, the presence of cerebrovascular disease resulted in a two-fold increase in mortality among older adult patients.⁷⁶ Even patients who were 80 years of age or more did not have any significant increase in surgical risk and within this population, and the 4-year actuarial survival was 70.5% with an event-free survival of 60.6%.

There has been an increase in definitive operative intervention to older patients with operable coronary artery disease. The Society of Thoracic Surgeons reports that perioperative mortality rates range from 1.6% in patients 51 to 60 years of age to 7.7% in those 81 to 90 years of age.⁷⁷ Older patients are more likely to have significant three-vessel disease accompanied by poor ejection fraction, left ventricular hypertrophy, significant valvular disease, and previous history of myocardial infarction than are younger patients.⁷⁷ Older patients also are more likely to be classified as NYHA functional class 3 or higher and are more likely to present on an emergent basis, in part because of reluctance to provide elective surgical intervention because of presumptive poorer outcome. Despite the increased risk of morbidity and mortality compared to younger patients, older adult patients, including those >80 years old, can undergo CABG with acceptable mortality risk. The overall mortality rate is approximately 7% to 12% for older adult patients, including those in whom CABG is performed under emergency conditions. The mortality rate decreases to approximately 2.8% when CABG is performed electively with careful preoperative evaluation.⁷⁸

Valve Replacement

As the population ages, the incidence of senile calcific aortic stenosis and referral for aortic valve replacement are increasing. The operative mortality from aortic valve replacement is estimated to be between 3% and 10%, with an average of approximately 7.7%.⁷⁶ If aortic stenosis is allowed to progress without operative intervention, CHF will ensue. The average survival of these patients is approximately 1.5 to 2 years. If a patient is deemed fit for operative intervention, age should not

6► The combined effects of poor nutrition, decreased cognition, and immune impairments due to nutritional or pharmacologic factors create a treacherous circumstance for older adult patients with poorly defined symptoms or who present with more advanced disease. In acute abdominal conditions,

be a deterrent, especially considering the potential to increase life expectancy. It has been recommended that the carefully selected, minimally symptomatic octogenarian with aortic stenosis should be considered a low-risk patient and be expected to experience an uneventful operative course and expedient recovery. More importantly, if elective procedures are delayed until symptoms or left ventricular dysfunction develop, patients may suffer from unnecessary increased operative risk and mortality.⁷⁵ Early intervention results in a demonstrable improvement in quality of life in these patients, with many improving their NYHA functional classification.

Older patients are candidates for mitral valve surgery when ischemic regurgitation is present. Surgery for mitral valve disease carries a higher morbidity and mortality risk than for aortic intervention, with an estimated mortality rate as high as 20%.⁷⁷ Left ventricular function usually is compromised in patients requiring intervention, leading to a poorer outcome in these patients. The surgical outcome for mitral valve procedures depends on the extent of the disease, age of the patient, presence of pulmonary hypertension, and extent of coronary artery disease. The presence of comorbid conditions combined with the emergent nature of surgery in a large percentage of older patients further worsens the outcome. Therefore, a decision regarding management of mitral valve disease should be individualized to each patient. Another concern regarding older patients who are candidates for valve disease surgery is the additional need for coronary revascularization—an important contributor to morbidity and mortality from surgical intervention. To mitigate risk, an older patient with multiple comorbid conditions in need of a combined procedure should only have critically stenosed vessels bypassed.⁷⁹ Neurologic complications from valve surgery are particularly common in older patients. It has been estimated that approximately 30% of patients >70 years old who undergo valve procedures develop either transient or permanent neurologic dysfunction.²² This often is a result of embolism from debris dislodged from the valve during the procedure or from a formed thrombus in the right atrium.

An important consideration in valve replacement procedures in older patients is the type of prosthesis to be used. Older patients are at increased risk from bleeding-associated anticoagulation complications. This risk is especially significant in patients who have experienced falls and minor trauma that have resulted in intracranial hemorrhage. To avoid the lifelong requirement for anticoagulants, bioprosthetic valves should be used in place of mechanical valves whenever possible.⁷⁹ Although the bioprosthetic valves are not as durable as mechanical valves, studies demonstrate excellent structural integrity 10 years post procedure, making it an appropriate choice in older patients.

Transcatheter aortic valve implantation/replacement (TAVI/TAVR) is increasingly being used to treat aortic stenosis. Initially, this technique was reserved for individuals with high surgical risk. A systematic review of transcatheter aortic valve implantation versus surgical aortic valve replacement revealed that, compared to surgical repair, the transcatheter approach may have similar or better early and midterm outcomes, including among low- to intermediate-risk patients.⁸⁰ Furthermore, there is increasing evidence that suggests TAVI results in acceptable long-term results in the older adult population.^{81,82}

Endovascular Aortic Surgery

With increasing use of screening abdominal CT scans and ultrasounds for evaluation of various abdominal complaints,

abdominal aortic aneurysms (AAA) are being identified with greater frequency. The percentage of AAA rises from about 1% at age 55 to 60 years to approximately 10% in patients 80 years of age or older.⁸³ Historically, very old patients were deemed poor operative candidates for the traditional open repair given the frequent presence of comorbid conditions and limited cardiopulmonary reserve to tolerate a major operation or the many hours of required operative time and general anesthesia. The dissemination of endovascular techniques for repair of AAA, however, has shifted the risk-benefit ratio for operative intervention, allowing greater life expectancy for the elective repair of this potentially life-threatening condition with the benefits of a minimally invasive approach.

Multiple studies have demonstrated that endovascular aortic repair (EVAR) is feasible and efficacious in older adult patients, including those previously considered unfit for open repair. EVAR is a minimally invasive technique in which a prosthetic graft is introduced into the aortic lumen via the common femoral artery to exclude the aortic aneurysm sac. EVAR significantly reduces operative and anesthesia times, blood loss, intensive care needs, length of stays, and major postoperative morbidity associated with open AAA repair. This procedure also can be done using epidural anesthesia for high-risk candidates who may tolerate general anesthesia poorly (Fig. 47-2).

Careful consideration of the life expectancy and the risk of rupture dictate the necessity for intervention. EVAR remains a viable option in older adult patients. Nonoperative management is justified in frail older adult patients with multiple comorbidities and reduced life expectancy whose operative risks outweigh the risk of rupture and in those who are unlikely to survive long enough to benefit from the repair.

Palliative Surgery

Palliative surgery is defined as surgical intervention targeted to alleviate a patient's symptoms, thus improving the patient's quality of life despite minimal impact on the patient's survival.⁵⁴ With an increasing number of older patients presenting with advanced disease, surgeons must be familiar with the concept of palliation to control symptoms. This concept focuses on providing the maximal benefit to the patient using the least-invasive intervention. Ideally, this intervention leads to symptom relief and preservation of the quality of life in terminal disease states by alleviating symptoms such as intractable vomiting and severe pain. The success of palliative surgery is a careful balance between achieving symptom relief without the development of new symptoms from the intervention itself. A recent meta-analysis of outcomes after palliative surgery for malignant bowel obstruction from peritoneal carcinomatosis revealed that although palliative surgery can benefit some patients, many patients experience serious complications, incomplete resolution of symptoms, and substantial hospitalization relative to the patient's remaining survival time.⁸⁴ It is essential to provide patients with realistic information about expected outcomes after palliative surgery to ensure that this surgical intervention is in line with their care preferences. The core competencies for surgical palliative care are shown in Table 47-5.

SUMMARY

Major surgery in older adults requires careful consideration. In addition to chronic medical conditions, many elders have geriatric syndromes that put them at high risk for increased morbidity,

Figure 47-2. Endovascular repair of abdominal aortic aneurysms (AAAs) has gained favor for suitable older adult patients to prevent rupture. Through minimal groin incisions, this 82-year-old patient underwent repair of an AAA and right iliac artery aneurysm and was discharged on post-op day 2.

mortality, and poor functional recovery after surgery. Screening for and optimization of multiple domains of vulnerability is essential to improve outcomes in this vulnerable population. Furthermore, the incorporation of palliative care principles into the surgical care of frail elders will improve patient-centered decision-making, symptom management, and quality of life.

Dedicated to the advancement of surgery along its scientific and moral side.

June 10, 1926, dedication on the Murphy Auditorium, the first home of the American College of Surgeons

WHY ETHICS MATTER

Ethical concerns involve not only the interests of patients but also the interests of surgeons and society. Surgeons choose among the options available to them because they have particular opinions regarding what would be good (or bad) for their patients. Aristotle described practical wisdom (Greek: *phronesis*) as the capacity to choose the best option from among several imperfect alternatives (Fig. 48-1).¹ Frequently, surgeons are confronted with clinical or interpersonal situations in which there is incomplete information, uncertain outcomes, and/or complex personal and familial relationships. The capacity to choose wisely in such circumstances is the challenge of surgical practice.

DEFINITIONS AND OVERVIEW

Biomedical ethics is the system of analysis and deliberation dedicated to guiding surgeons toward the “good” in the practice of surgery. One of the most influential ethical “systems” in the field of biomedical ethics is the principlist approach as articulated by Beauchamp and Childress.² In this approach to ethical issues, moral dilemmas are deliberated using four guiding principles: autonomy, beneficence, nonmaleficence, and justice.²

The principle of autonomy respects the capacity of individuals to choose their own destiny, and it implies that individuals have a right to make those choices. It also implies an obligation for physicians to permit patients to make autonomous choices about their medical care. Beneficence requires that

proposed actions aim at and achieve something good whereas nonmaleficence aims at avoiding concrete harm: *primum non nocere*.^{*} Justice requires fairness where both the benefits and burdens of a particular action are distributed equitably.

The history of medical ethics has its origins in antiquity. The Hippocratic Oath along with other professional codes has guided the actions of physicians for thousands of years. However, the growing technical powers of modern medicine raise new questions that were inconceivable in previous generations. Life support, dialysis, and modern drugs, as well as organ and cellular transplantation, have engendered new moral and ethical questions. As such, the ethical challenges faced by the surgeon have become more complex and require greater attention.

The case-based paradigm for bioethics is used when the clinical team encounters a situation in which two or more values or principles come into apparent conflict. The first step is to clarify the relevant principles (e.g., autonomy, beneficence, nonmaleficence, and justice) and values at stake (e.g., self-determination, quality of life). After identifying the principles and values that are affecting the situation, a proposed course of action is considered given the circumstances.

Much of the discourse in bioethics adopts this “principlist” approach in which the relevant principles are identified, weighed, and balanced, and then applied to formulate a course of action. This approach to bioethics is a powerful technique for thinking through moral problems because the four principles help identify what is at stake in any proposed course of action. However, the principles themselves do not resolve ethical dilemmas. Working together, patients and surgeons must use wise judgment to choose the best course of action for the specific case.

*“First do no harm.”

Key Points

- 1▶ The physician should document that the patient or surrogate has the capacity to make a medical decision.
- 2▶ Sufficient details regarding diagnosis and treatment options should be disclosed to the patient so that the patient can provide informed consent.
- 3▶ Living wills are written to anticipate treatment options and choices in the event that a patient is rendered incompetent by a terminal illness.
- 4▶ The durable power of attorney for healthcare identifies surrogate decision makers and invests them with the authority to make healthcare decisions on behalf of patients in the event that they are unable to speak for themselves.
- 5▶ Surgeons should encourage their patients to complete a living will and clearly identify their surrogates early in the course of treatment.
- 6▶ Earlier referrals and wider use of palliative and hospice care may help more patients achieve their goals at the end of life.
- 7▶ Seven requirements for the ethical conduct of clinical research studies have been articulated: value, scientific validity, fair subject selection, favorable risk-benefit ratio, independent review, informed consent, and respect for enrolled subjects.
- 8▶ Individuals working together on research endeavors should have clear discussions early in the planning process about authorship, and those discussions should be continued throughout the project or study.
- 9▶ Disclosure of error is consistent with recent ethical advances in medicine toward more transparency, openness with patients, and the involvement of patients in their care.

Choosing wisely requires the virtue of practical wisdom first described by Aristotle (see Fig. 48-1). Along with the other cardinal virtues of courage, justice and temperance, practical wisdom is a central component of virtue ethics which complement principlalist ethics by guiding choices toward the best options for treatment. Practical wisdom cannot be learned from books and is developed only through experience. The apprenticeship model of surgical residency fosters the development of practical wisdom through experience. More than teaching merely technical mastery, surgical residency is also moral training. In fact, the sociologist Charles Bosk argues that the “postgraduate training of surgeons is above all things an ethical training.”³

SPECIFIC ISSUES IN SURGICAL ETHICS

Informed Consent

Although a relatively recent development, the doctrine of informed consent is one of the most widely established tenets of modern biomedical ethics. During the nineteenth and early twentieth centuries, most physicians practiced a form of benign paternalism whereby patients were rarely involved in the decision-making process regarding their medical care, relying instead on the beneficence of the physician. Consensus among the wider public eventually changed such that surgeons are now expected to have an open discussion about diagnosis and treatment with the patient to obtain informed consent. In the United States, the legal doctrine of *simple* consent dates from the 1914 decision in *Schloendorff vs. The Society of New York Hospital* regarding a case in which a surgeon removed a diseased uterus after the patient had consented to an examination under anesthesia, but with the express stipulation that no operative excision should be performed. The physician argued that his decision was justified by the beneficent obligation to avoid the risks of a second anesthetic. However, Justice Benjamin Cardozo stated:

*Every human being of adult years and sound mind has a right to determine what shall be done with his body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages . . . except in cases of emergency, where the patient is unconscious, and where it is necessary to operate before consent can be obtained.*⁴

Having established that patients have the right to determine what happens to their bodies, it took some time for the modern concept of *informed* consent to emerge from the initial doctrine of *simple* consent. The initial approach appealed to a *professional practice standard* whereby physicians were obligated to disclose to patients the kind of information that experienced surgeons customarily disclosed.⁵ However, this disclosure was not always adequate for patient needs. In the 1972

Figure 48-1. Bust of Aristotle. Marble, Roman copy after a Greek bronze original by Lysippos from 330 B.C. (From http://en.wikipedia.org/wiki/File:Aristotle_Altemps_Inv8575.jpg: Ludovisi Collection, Accession number Inv. 8575, Palazzo Altemps, Location Ground Floor, Branch of the National Roman Museum. Photographer/source Jastrow [2006] from Wikipedia.)

landmark case, *Canterbury vs. Spence*, the court rejected the professional practice standard in favor of the *reasonable person standard* whereby physicians are obliged to disclose to patients all information regarding diagnosis, treatment options, and risks that a “reasonable patient” would want to know in a similar situation. Rather than relying on the practices or consensus of the medical community, the reasonable person standard empowers the public (reasonable persons) to determine how much information should be disclosed by physicians to ensure that consent is truly informed. The court did recognize, however, that there are practical limits on the amount of information that can be communicated or assimilated.⁵ Subsequent litigation has revolved around what reasonable people expect to be disclosed in the consent process to include the nature and frequency of potential complications, the prognostic life expectancy,⁶ and the surgeon-specific success rates.⁴ Despite the litigious environment of medical practice, it is difficult to prosecute a case of inadequate informed consent so long as the clinician has made a concerted and documented effort to involve the patient in the decision-making process.

Adequate informed consent entails at least four basic elements: (a) the physician documents that the patient or surrogate has the capacity to make a medical decision; (b) the surgeon discloses to the patient details regarding the diagnosis and treatment options sufficiently for the patient to make an informed choice; (c) the patient demonstrates understanding of the disclosed information before (d) authorizing freely a specific treatment plan without undue influence (Fig. 48-2). These goals are aimed at respecting each patient’s prerogative for autonomous self-determination. To accomplish these goals, the surgeon needs to engage in a discussion about the causes and nature of the patient’s disease, the risks and benefits of available treatment options, as well as details regarding

what patients can expect after an operative intervention including possible outcomes and complications.⁷⁻¹⁴

Certain clinical settings make obtaining informed consent challenging. For example, obtaining consent for emergency surgery can be difficult, as the clinical team is forced to make decisions with incomplete information. Emergency consent requires the surgeon to consider if and how possible interventions might save a patient’s life, and if successful, what kind of disability might be anticipated. Surgical emergencies are one of the few instances where the limits of patient autonomy are freely acknowledged, and surgeons are empowered by law and ethics to act promptly in the best interests of their patients according to the surgeon’s judgment. Most applicable medical laws require physicians to provide the standard of care to incapacitated patients, even if it entails invasive procedures without the explicit consent of the patient or surrogate. If at all possible, surgeons should seek the permission of their patients to provide treatment, but when emergency medical conditions render patients unable to grant that permission, and when delay is likely to have grave consequences, surgeons are legally and ethically justified in providing whatever surgical treatment the surgeon judges necessary to preserve life and restore health.⁴ This justification is based on the social consensus that most people would want their lives and health protected in this way, and this consensus is manifest in the medical profession’s general orientation to preserve life. It may be that subsequent care may be withdrawn or withheld when the clinical prognosis is clearer, but in the context of initial resuscitation of injured patients, incomplete information makes clear judgments about the patient’s ultimate prognosis or outcome impossible.

The pediatric population also presents unique challenges for the process of consent. For many reasons, children and adolescents cannot participate in the process of giving informed

Figure 48-2. Algorithm for navigating the process of informed consent. (Modified with permission from Childers R, Lipsett A, Pawlik T. *Informed consent and the surgeon*, J Am Coll Surg. 2009 Apr;208(4):627-634.)

consent in the same way as adults. Depending on their age, children may lack the cognitive and emotional maturity to participate fully in the process. In addition, depending on the child's age, their specific circumstances, as well as the local jurisdiction, children may not have legal standing to fully participate on their own independent of their parents. The use of parents or guardians as surrogate decision makers only partially addresses the ethical responsibility of the surgeon to involve the child in the informed consent process. The surgeon should strive to augment the role of the decision makers by involving the child in the process. Specifically, children should receive age-appropriate information about their clinical situation and therapeutic options delivered in an appropriate setting and tone so that the surgeon can solicit the child's "assent" for treatment. In this manner, while the parents or surrogate decision makers formally give the informed consent, the child remains an integral part of the process.

Certain religious practices can present additional challenges when treating minor children whose parents disallow medically indicated blood transfusions; however, case law has made clear the precedent that parents, regardless of their held beliefs, may not place their minor children at mortal risk. In such a circumstance, the physician should seek counsel from the hospital medicolegal team, as well as from the institutional ethics team. Legal precedent has, in general, established that the hospital or physician can proceed with providing all necessary care for the child.

Obtaining "consent" for organ donation deserves specific mention.¹⁵ Historically, discussion of organ donation with families of potential donors was performed by transplant professionals, who were introduced to families by intensivists after brain death had been confirmed and the family had been informed of the fact of death. In other instances, consent might be obtained by intensivists caring for the donor, as they were assumed to know the patient's family and could facilitate the process. However, issues of moral "neutrality" as part of end-of-life care in the intensive care unit have caused a shift in how obtaining "consent" for organ donation is handled. Responsibility for obtaining consent from the donor family is now vested in trained "designated requestors" (or "organ procurement coordinators")¹⁶ or by "independent" intensivists who do not have a therapeutic clinical relationship with the potential donor.¹⁷ In this way, the donor family can be allowed to make the decision regarding donation in a "neutral" environment without erosion of the therapeutic relationship with the treating physician or perceived undue pressure from the transplant team.

The process of informed consent also can be limited by the capacity of patients to assimilate information in the context of their illness. For example, despite the best efforts of surgeons, evidence suggests that patients rarely retain much of what is disclosed in the consent conversation, and they may not remember discussing details of the procedure that become relevant when postoperative complications arise.¹⁸ It is important to recognize that the doctrine of informed consent places the most emphasis on the principle of autonomy precisely in those clinical situations when, because of their severe illness or impending death, patients are often divested of their autonomy.

The Boundaries of Autonomy: Advance Directives and Powers of Attorney

Severe illness and impending death can often render patients incapable of exercising their autonomy regarding medical

decisions. One approach to these difficult situations is to make decisions in the "best interests" of patients, but because such decisions require value judgments about which thoughtful people frequently disagree, ethicists, lawyers, and legislators have sought a more reliable solution. Advance directives of various forms have been developed to carry forward into the future the autonomous choices of competent adults regarding healthcare decisions. Furthermore, the courts often accept "informal" advance directives in the form of sworn testimony about statements the patient made at some time previous to their illness. When a formal document expressing the patient's advance directives fails to exist, surgeons should consider the comments patients and families make when asked about their wishes in the setting of debilitating illness.

Living wills are written to anticipate treatment options and choices in the event that a patient is incapacitated by a terminal illness. In the living will, the patient indicates which treatments she wishes to permit or prohibit in the setting of terminal illness.

3▶ The possible treatments addressed often include mechanical ventilation, cardiopulmonary resuscitation, artificial nutrition, dialysis, antibiotics, or transfusion of blood products. Unfortunately, living wills are often too vague to offer concrete guidance in complex clinical situations, and the language ("terminal illness," "artificial nutrition") can be interpreted in many ways. Furthermore, by limiting the directive only to "terminal" conditions, it does not provide guidance for common clinical scenarios like advanced dementia, delirium, or persistent vegetative states where the patient is unable to make decisions, but is not "terminally" ill. Perhaps even more problematic is the evidence that demonstrates that healthy patients cannot reliably predict their preferences when they are actually sick. This phenomenon is called "affective forecasting" and applies to many situations. For example, the general public estimates the health-related quality of life (HRQoL) score of patients on dialysis at 0.39, although dialysis patients themselves rate their HRQoL at 0.56.¹⁹ Similarly, patients with colostomies rated their HRQoL at 0.92, compared to a score of 0.80 given by the general public for patients with colostomies.¹⁹ For these and other reasons, living wills are often unable to provide the extent of assistance they promise.²⁰

An alternative to living wills is the durable power of attorney for healthcare in which patients identify surrogate decision makers and invest them with the authority to make healthcare decisions on their behalf in the event that they are unable to speak for themselves. Proponents of this approach hope that the surrogate will be able to make decisions that reflect the choices that the patients themselves would make if they were able. Unfortunately, several studies demonstrate that surrogates are not much better than chance at predicting the choices patients make when the patient is able to state a preference. For example, a recent meta-analysis found that surrogates predicted patients' treatment preferences with only 68% accuracy.²¹ These data reveal a flaw in the guiding principle of surrogate decision making: Surrogates do not necessarily have privileged insight into the autonomous preferences of patients. However, the durable power of attorney at least allows patients to choose the person who will eventually make prudential decisions on their behalf and in their best interests; therefore, respecting the judgment of the surrogate is a way of respecting the self-determination of the incapacitated patient.²²

There is continuing enthusiasm for a wider use of advance directives. In fact, the 1991 Patient Self Determination Act requires all U.S. healthcare facilities to (a) inform patients of

their rights to have advance directives, and (b) to document those advance directives in the chart at the time any patient is admitted to the healthcare facility.⁴ However, only a minority of patients in U.S. hospitals have advance directives despite concerted efforts to teach the public of their benefits and provide resources to help patients prepare and maintain them. For example, the ambitious SUPPORT trial used specially trained nurses to promote communication between physicians, patients, and their surrogates to improve the care and decision making of critically ill patients. Despite this concerted effort, the intervention demonstrated “no significant change in the timing of do not resuscitate (DNR) orders, in physician-patient agreement about DNR orders, in the number of undesirable days (patients’ experiences), in the prevalence of pain, or in the resources consumed.”²³

Some of the reluctance around physician-patient agreement about DNR orders may reflect patient and family anxiety that DNR orders equate to “do not treat.” Patients and families should be assured, when appropriate, that declarations of DNR/do not intubate will not necessarily result in a change in ongoing routine clinical care. The issue of temporarily rescinding DNR/do not intubate orders around the time of an operative procedure may also need to be addressed with the family.

Patients should be encouraged to clearly identify their surrogates, both formally and informally, early in the course of treatment and before any major elective operation. Often, **5▶** around the time of surgery or at the end of life, there are limits to patient autonomy in medical decision-making. Seeking an advance directive or surrogate decision maker requires time that is not always available when the clinical situation deteriorates. As such, these issues should be clarified as early as possible in the patient-physician relationship.

Withdrawing and Withholding Life-Sustaining Therapies

The implementation of various forms of life support technology raise a number of legal and ethical concerns about when it is permissible to withdraw or withhold available therapeutic technology. There is general consensus among ethicists that there are no philosophic differences between withdrawing (stopping) or withholding (not starting) treatments that are no longer beneficial.²⁴ However, the right to refuse, withdraw, and withhold beneficial treatments was not established before the landmark case of Karen Ann Quinlan. In 1975, Quinlan lapsed into a persistent vegetative state requiring ventilator support. After several months without clinical improvement, Quinlan’s parents asked the hospital to withdraw ventilator support. The hospital refused, fearing prosecution for euthanasia. The case was appealed to the New Jersey Supreme Court where the justices ruled that it was permissible to withdraw ventilator support.²⁵ This case established a now commonly recognized right to withdraw “extraordinary” life-saving technology if it is no longer desired by the patient or the patient’s surrogate.

The difference between “ordinary” and “extraordinary” care, and whether there is an ethical difference in withholding or withdrawing “ordinary” vs. “extraordinary” care, has been an area of much contention. The 1983 Nancy Cruzan case highlighted this issue. In this case, Cruzan had suffered severe injuries in an automobile crash that rendered her in a persistent vegetative state. Cruzan’s family asked that her tube feeds be withheld, but the hospital refused. The case was appealed to the U.S. Supreme Court, which ruled that the tube feeding could

be withheld if her parents demonstrated “clear and convincing evidence” that the incapacitated patient would have rejected the treatment.²⁶ In this ruling, the court essentially ruled that there was no legal distinction between “ordinary” vs. “extraordinary” life-sustaining therapies.²⁷ In allowing the feeding tube to be removed, the court accepted the principle that a competent person (even through a surrogate decision maker) has the right to decline treatment under the Fourteenth Amendment of the U.S. Constitution. The court noted, however, that there has to be clear and convincing evidence of the patient’s wishes (consistent with the principle of autonomy) and that the burdens of the medical intervention should outweigh its benefits (consistent with the principles of beneficence and nonmaleficence).

In deliberating the issue of withdrawing vs. withholding life-sustaining therapies, the principle of “double effect” is often mentioned. According to the principle of “double effect,” a treatment (e.g., opioid administration in the terminally ill) that is intended to help and not harm the patient (i.e., relieve pain) is ethically acceptable even if an unintended consequence (side effect) of its administration is to shorten the life of the patient (e.g., by respiratory depression). Under the principle of double effect, a physician may withhold or withdraw a life-sustaining therapy if the surgeon’s *intent* is to relieve suffering, not to hasten death. The classic formulation of double effect has four elements (Fig. 48-3).

Withholding or withdrawing of life-sustaining therapy is ethically justified under the principle of double effect if the physician’s intent is to relieve suffering, not to kill the patient. Thus, in managing the distress of the dying, there is a fundamental ethical difference between titrating medications rapidly to achieve relief of distress and administering a very large bolus with the

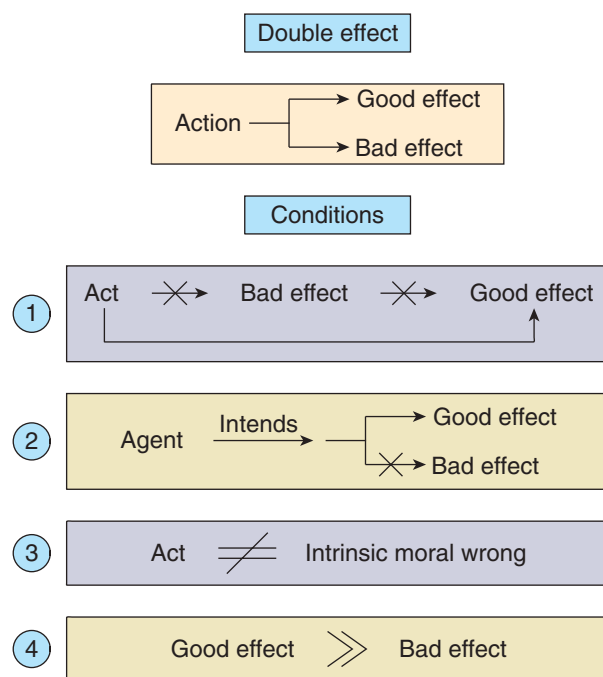

Figure 48-3. The four elements of the double effect principle: (1) The good effect is produced directly by the action and not by the bad effect. (2) The person must intend only the good effect, even though the bad effect may be foreseen. (3) The act itself must not be intrinsically wrong, or needs to be at least neutral. (4) The good effect is sufficiently desirable to compensate for allowing the bad effect.

intent of causing apnea. It is important to note, however, that although the use of opioids for pain relief in advanced illness is frequently cited as the classic example of the double effect rule, opioids can be used safely without significant risk. In fact, if administered appropriately, in the vast majority of instances the rule of double effect need not be invoked when administering opioids for symptom relief in advanced illness.²⁸

In accepting the ethical equivalence of withholding and withdrawing of life-sustaining therapy, surgeons can make difficult treatment decisions in the face of prognostic uncertainty.²⁴ In light of this, some important principles to consider when considering withdrawal of life-sustaining therapy include: (a) Any and all treatments can be withdrawn. If circumstances justify withdrawal of one therapy (e.g., IV pressors, antibiotics), they may also justify withdrawal of others; (b) Be aware of the symbolic value of continuing some therapies (e.g., nutrition, hydration) even though their role in palliation is questionable; (c) Before withdrawing life-sustaining therapy, ask the patient and family if a spiritual advisor (e.g., pastor, imam, rabbi, or priest) should be called; and (d) Consider requesting an ethics consult.

Although the clinical setting may seem limited, a range of options usually exists with respect to withdrawing or withholding treatment, allowing for an incremental approach, for example (a) continuing the current regimen without adding new interventions or tests; (b) continuing the current regimen but withdrawing elements when they are no longer beneficial; and (c) withdrawing and withholding all treatments that are not targeted to relieve symptoms and maximize patient comfort.³⁴

The surgeon might consider discussing the clinical situation with the patient or proxy decision maker, identify the various therapeutic options, and delineate the reasons why withholding or withdrawing life-sustaining therapy would be in the patient's best interest. If the patient (or designated proxy decision maker) does not agree with withholding or withdrawing life-sustaining therapy, the surgeon should consider involving consultants who have participated in the patient's care, experts in palliative or end-of-life care or recommend a second medical opinion. If the second opinion corroborates that life-sustaining therapy should be withheld or withdrawn but the patient/family continues to disagree, the surgeon should consider assistance from institutional resources such as the ethics committee and hospital administration. Although the surgeon is not ethically obligated to provide treatment that he or she believes is futile, the surgeon is responsible for continued care of the patient, which may involve transferring the patient to a surgeon who is willing to provide the requested intervention.²⁴

Living Donor Liver Transplantation

One unique ethical issue that deserves special mention is that of living donor liver transplantation. Living donor kidney transplantation has been practiced for almost 50 years and has become a routine part of clinical care, but living donor liver transplantation was first performed in the late 1980s with parent-to-child grafts and in the late 1990s for adult-to-adult grafts. These procedures are unique in that there are two patients, one with a diseased organ who requires intervention to be made well and one who is healthy and is being made unwell, albeit usually temporarily, during the intervention. Performing an ethical analysis of this situation requires considering both risks and benefits to each of the patients individually.

For the recipient, the benefits of receiving a living donor organ as opposed to a deceased donor organ are many: first,

there is reduced risk of death on the waitlist, and second, there is a potential for improved post-transplant outcomes due to improved matching between relatives and the absence of hemodynamic instability often present before organ procurement in a deceased donor.³⁰ Furthermore, the use of living donor organs is supported by the principle of utility, maximizing efficient use of organs.³²

The benefit to the organ donor is in fulfillment of an altruistic ideal and satisfaction associated with having extended the recipient's life, while the risks are those associated with partial hepatectomy, a procedure that is not without risks including postoperative complications and mortality, the risk of which is estimated to be 0.15%.²⁹ The ethical concern in this case is having possibly violated the principle of nonmaleficence.

This particular ethical issue emphasizes the importance of truly informed consent. The donor should be provided with information on local complication and mortality rates and allowed sufficient time to consider the risks and benefits without pressure from healthcare workers.³⁰ Furthermore, experienced centers have recommended that living donors have access to sufficient resources and strong support from an institutions' ethics committee, given substantial pressure exerted by the critical illness of a family member.³¹

PALLIATIVE CARE

General Principles of Palliative Care

Palliative care is a coordinated, interdisciplinary effort that aims to relieve suffering and improve quality of life for patients and their families in the context of serious illness.³³ It is offered simultaneously with all other appropriate medical treatment, and its indication is not limited to situations associated with a poor prognosis for survival. Palliative care strives to achieve more than symptom control, but it should not be confused with noncurative treatment.

The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."³⁴ Palliative care is both a philosophy of care and an organized, highly structured system for delivering care.

Palliative care includes the entire spectrum of intervention for the relief of symptoms and the promotion of quality of life. No specific therapy, including surgical intervention, is excluded from consideration. Therefore, surgeons have valuable contributions to make to palliative care. In fact, the term *palliative care* was coined in 1975 by Canadian surgeon, Balfour Mount. Furthermore, *surgical palliative care* can be defined as the treatment of suffering and the promotion of quality of life for seriously or terminally ill patients under the care of surgeons.³⁶ The standard of palliative treatment lies in the agreement between patient and physician that the expected outcome is relief from distressing symptoms, lessening of pain, and improvement of quality of life. The decision to intervene is based on the treatment's ability to meet the stated goals, rather than its impact on the underlying disease.

The fundamental elements of palliative care consist of pain and nonpain symptom management, communication among patients, their families, and care providers, and continuity of care across health systems and through the trajectory

Table 48-1

Indications for palliative care consultation

Patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits
Assistance in clarification or reorientation of patient/family goals of care
Assistance in resolution of ethical dilemmas
Situations in which patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only
Patients who are expected to die imminently or shortly after hospital discharge
Provision of bereavement support for patient care staff, particularly after loss of a colleague under care

of illness. Additional features of system-based palliative care are team-based planning that includes patient and family; close attention to spiritual matters; and psychosocial support for patients, their families, and care providers, including bereavement support.

Indications for palliative care consultation in surgical practice include: (a) patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits; (b) assistance in clarification or reorientation of patient/family goals of care; (c) assistance in resolution of ethical dilemmas; (d) situations in which a patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only; (e) patients who are expected to die imminently or shortly after hospital discharge; and (f) provision of bereavement support for patient care staff, particularly after loss of a colleague under care³⁶ (Table 48-1). Although all patients, regardless of prognosis, may benefit from the services of a palliative care physician, hospice care is a specific form of palliative care intended for patients who have an estimated prognosis of 6 months or less to live. Hospice care is covered under Medicare Part A, and benefits may be continued beyond the original 6 months of estimated survival if physicians certify that life expectancy remains limited to 6 months or less.

6▶ Although most Americans indicate a preference to die at home, nearly 75% die in an institutional setting. Earlier referral and wider use of the hospice benefit may help more patients achieve their goal of dying at home.

Concepts of Suffering, Pain, Health, and Healing

Palliative care specifically addresses the individual patient's experience of suffering due to illness. Indeed, the philosophical origins of palliative care began with attention to suffering and the existential questions suffering engenders. More than mere technologic evolution in the management of symptoms, the early proponents of palliative care sought a revolution in the moral foundations of medicine that challenged the assumptions that so often seemed to result in futile invasive intervention, and identified many of the problems that were subsequently taken up by medical ethicists. This reorientation of the goals of medical care from a focus on disease and its management to the patient's experience of illness focuses attention on the purpose of medicine and the meaning of health and healing.

Over the past half century, several concepts and theories about the nature of pain, suffering, and health have been proposed in service of the evolving conceptual framework of palliative care. For example, while considering the differences between disease-oriented and illness-oriented approaches to the care of seriously ill patients, psychiatrist Arthur Kleinman wrote, "There is a moral core to healing in all societies. [Healing] is the central purpose of medicine . . . the purpose of medicine is both control of disease processes and care for the illness experience. Nowhere is this clearer than in the relationship of the chronically ill to their medical system: For them, the control of disease is by definition limited; care for the life problems created by the disorder is the chief issue."³³

The relief of pain has been the clinical foundation for hospice and palliative care. Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."³⁸ For purposes of interdisciplinary palliative care, Saunders's concept of "total pain"³⁷ is a more useful definition and is frequently used as the basis for palliative assessments. Total pain is the sum total of four principal domains of pain: physical, psychologic, social or socioeconomic, and spiritual. Each of these contributes to, but is not synonymous with, suffering.

Effective Communication and Negotiating the Goals of Care

Changing the goals of care from cure to palliation near the end of life can be both emotionally and clinically challenging. It depends on determination of a clear prognosis and can be aided by effective communication. Unfortunately, prognostication can be notoriously difficult and inaccurate in advanced illness, and Christakis has argued that, to a large degree, physicians have abdicated their traditional responsibility to provide clear prognosis regarding incurable disease and approaching death.⁴⁰ However, there are validated tools for prognosis in critical illness (APACHE, MODS, etc.), and with most advanced diseases, functional status is the most powerful predictor of survival. For example, patients with advanced metastatic cancer who are resting or sleeping for 50% or more of normal waking hours and require some assistance with activities of daily living (ADL) have a projected survival of weeks, and patients who are essentially bedfast and dependent for ADL have a projected survival of days to a week or two at best. Table 48-2 shows a simple prognostic tool to aid clinicians in recognizing patients nearing the end of life.

Alternatively, the Karnofsky Performance Scale is a scale of functional status ranging from 100 (high level of function) to 0 (death). It is commonly used in palliative care to roughly assess a patient's anticipated needs as well as prognosis. The Palliative Performance Scale⁴¹ is a validated⁴² expansion of the Karnofsky Performance Scale that includes five palliative-focused domains, including ambulation, activity level, self-care, intake, and level of consciousness, in addition to evidence of disease. The Missoula-Vitas Quality of Life Index is a 25-question scale specifically for palliative care and hospice patients that scores symptoms, function, interpersonal relationships, well-being, and spirituality. Updates and Spanish versions are available.³⁹

Regardless of the prognostic tool used, the prognosis should be conveyed to the patient and family. If done well, communication and negotiation with patients and families about advanced terminal illnesses can potentially avoid great

Table 48-2

Simple prognostication tool in advanced illness (especially cancer)

FUNCTIONAL LEVEL	PERFORMANCE STATUS (ECOG)	PROGNOSIS
Able to perform all basic ADLs independently and some IADLs	2	Months
Resting/sleeping up to 50% or more of waking hours and requiring some assistance with basic ADLs	3	Weeks to a few months
Dependent for basic ADLs and bed-to-chair existence	4	Days to a few weeks at most

These observations apply to patients with advanced, progressive, incurable illnesses (e.g., metastatic cancer refractory to treatment). Basic ADL = activities of daily living (e.g., transferring, toileting, bathing, dressing, and feeding oneself); IADL = instrumental activities of daily living (e.g., more complex activities such as meal preparation, performing household chores, balancing a checkbook, shopping, etc.); ECOG = Eastern Cooperative Oncology Group functional (performance) status.

psychologic harm and help make a difficult transition easier. To communicate effectively and compassionately, it is helpful to pursue an organized process similar to the structured history and physical central to the evaluation of any patient. One such structured approach to delivering unfavorable news proposes six steps that can be easily learned by clinicians: (a) getting started by selection of the appropriate setting, introductions, and seating; (b) determining what the patient or family knows; (c) determining what the patient or family wants to know; (d) giving the information; (e) expressing empathy; and (f) establishing expectations, planning, and aftercare (Table 48-3).⁴³ Success with this approach to breaking bad news is critically dependent upon the clinician's ability to empathically respond to the patient's (and family's) reaction to the news.⁴⁴ The empathic response does not require the surgeon to share the same emotions of the patient, but it does require the surgeon to identify the patient's emotion and accurately reflect that awareness back

Table 48-3

Communicating unfavorable news: important principles

- **Setting:** Find a quiet, private place to meet. Sit down close to the patient.
- **Listen:** Clarify the patient's and/or the family's understanding of the situation.
- **"Warning shot":** Prepare patient and family and obtain their permission to communicate bad news (e.g., "I'm afraid I have bad news.>").
- **Silence:** Pause after giving bad news. Allow patient/family to absorb/react to the news.
- **Encourage:** Convey hope that is realistic and appropriate to the circumstances (e.g., patient will not be abandoned; symptoms will be controlled).

to the patient. Such effective communication may be facilitated by involving other members of the healthcare team who have developed relationships with the patient and their family. Patient assessment in these conversations should give the highest priority to identifying and responding to the most immediate source of distress. Relieving a pressing symptom is prerequisite for a more thorough search for other potential sources of suffering, and the assessment process itself can be therapeutic if conducted in a respectful and gentle manner.

CARE AT THE END OF LIFE

The process of dying and the care of a patient at the time of death is a distinct clinical entity that demands specific skills from physicians. The issues specific to dying and the available tools for compassionate care at the end of life are addressed in this section.

The Syndrome of Imminent Demise^{34,45}

In a patient who has progressed to the terminal stage of an advanced illness (e.g., cancer), a number of signs provide evidence of imminent death. As terminally ill patients progress toward death, they become increasingly bedbound, requiring assistance for all basic ADL. There is a steady decrease in desire and requests for food and fluids. More distressing to the dying patient is a progressively dry mouth that may be confused by the treating team as thirst. It is often exacerbated by anticholinergic medications, mouth breathing, and supplemental oxygen (O₂) administered without humidification.

With progressive debility, fatigue, and weight loss, it is common for terminally ill patients to experience increasing difficulty swallowing. This may result in aspiration episodes and an inability to swallow tablets, requiring alternative routes for medication administration (e.g., IV, SC, PR, sublingual, buccal, or transdermal). In addition to the increased risk of aspiration, patients near death develop great difficulty clearing oropharyngeal and upper airway secretions, leading to noisy breathing or the so-called "death rattle." As death approaches, the respiratory pattern may change to increasingly frequent periods of apnea often following a Cheyne-Stokes pattern of rapid, progressively longer breaths leading up to an apneic period. As circulatory instability develops near death, patients may exhibit cool and mottled extremities. Periods of confusion are often accompanied by decreasing urine output and episodes of fecal and urinary incontinence.

A number of cognitive changes occur as death approaches. Patients who are in the last days of life may demonstrate some signs of confusion or delirium. Agitated delirium is a prominent feature of a difficult death. Other cognitive changes that may be seen include a decreased interest in social interactions, increased somnolence, reduced attention span, disorientation to time (often with altered sleep-wake cycles), and an altered dream life, including vivid "waking dreams" or visual hallucinations. Reduced hearing and visual acuity may be an issue for some patients; however, patients who appear comatose may still be aware of their surroundings. Severely cachectic patients may lose the ability to keep their eyes closed during sleep because of loss of the retro-orbital fat pad.

Common Symptoms at the End of Life and Their Management^{34,45,46}

The three most common, major symptoms that threaten the comfort of dying patients in their last days are respiratory

distress, pain, and cognitive failure. General principles that are applicable to symptom management in the last days of life include (a) anticipating symptoms before they develop; (b) minimizing technologic interventions (usually manage symptoms with medications); and (c) planning alternative routes for medications in case the oral route fails. It may be possible to cautiously reduce the dose of opioids and other medications as renal clearance decreases near the end of life, but it is important to remember that increased somnolence and decreasing respirations are prominent features of the dying process independent of medication side effects. Sudden cessation of opioid analgesics near the end of life could precipitate withdrawal symptoms, and therefore medications should not be stopped for increasing somnolence or slowed respirations.

The principles of pharmacotherapy for pain and non-pain symptoms in the palliative care setting are outlined in Table 48-4. The World Health Organization,³⁵ the United States Agency for Healthcare Policy and Research,⁴⁷ the Academy of Hospice and Palliative Medicine,⁴⁸ and many other agencies have endorsed a “step ladder” approach to cancer pain management that can predictably result in satisfactory pain control in most patients (Table 48-5). More refractory pain problems require additional expertise, and occasionally, more invasive approaches (Tables 48-6 and 48-7).

Table 48-4

Principles of pharmacotherapy in palliative care

- Believe patient report of symptoms.
- Modify pathologic process when possible and appropriate.
- In terminally ill patients, avoid medications not directly linked to symptom control.
- Use a multidisciplinary approach.
- Consider nonpharmacologic approaches whenever possible.
- Engage participation of clinical pharmacist in treatment plan.
- Select drugs that can multitask (i.e., use haloperidol for agitated delirium and nausea).
- For pain, use adjuvant medications when possible (see Table 48-7).
- When using opioids, spare when possible (adjuvant medication, local or regional anesthetics, surgical interventions, etc.).
- Avoid fixed combination drugs.
- Avoid excessive cost.
- Select agents with minimum side effects.
- Anticipate and prophylax against side effects.
- For older adult patients, the hypoproteinemic, the azotemic: “Start low and go slow.”
- Oral route whenever possible and practical.
- No intramuscular injections.
- Scheduled dosing, not as needed, for persistent symptoms.
- Stepwise approach. (See the World Health Organization Analgesic Ladder for pain, Table 48-5.)
- Reassess continuously and titrate to effect.
- Use equianalgesic doses when changing opioids (see Table 48-5).
- Assess the patient’s and family’s comprehension of management plan.

Table 48-5

The World Health Organization’s three-step ladder for control of cancer pain³⁰

- Step 1: mild pain (visual analogue scale, 1–3)
Nonopioid ± adjuvant medication
- Step 2: moderate pain (visual analogue scale, 4–6)
Opioid for mild to moderate pain and nonopioid ± an adjuvant
- Step 3: severe pain (visual analogue scale, 7–10)
Opioid for moderate to severe pain ± nonopioid ± an adjuvant

The primary treatment of dyspnea (air hunger) in the dying is opioids, which should be cautiously titrated to increase comfort and reduce tachypnea to a range of 15 to 20 breaths per minute. Air movement across the face generated by a fan can sometimes be quite helpful. If this is not effective, empirical use of supplemental O₂ by nasal cannula (2–3 L/min) may bring some subjective relief, independent of observable changes in pulse oximetry. Supplemental O₂ should be humidified to avoid exacerbation of dry mouth. Typical starting doses of an immediate release opioid for breathlessness should be one-half to two-thirds of a starting dose of the same agent for cancer pain. For patients already on opioids for pain, a 25% to 50% increment in the dose of the current immediate release agent for breakthrough pain often will be effective in relieving breathlessness in addition to breakthrough pain.

The availability and variety of drugs should not prevent consideration of nonpharmacologic therapy. Massage therapy, music therapy, art therapy, guided imagery, hypnosis, physical therapy, pet therapy, and others play a constructive role not only for the relief of symptoms but also for promoting a sense of hope through improving function, aesthetic pleasure, and social connectedness. Talents and capacities neglected during the treatment and progression of disease can be recovered even in the most advanced stages of illness.

Pain is often less of a problem in the last days of life because the reduced activity level is associated with lower incident pain. This, combined with lower renal clearance of opioids, may result in greater potency of the prescribed agents. Severe pain crises are fortunately rare, but when they are inadequately addressed, can cause great and lasting distress (complicated grief) for loved ones who witness the final hours or days of agony. Such situations may require continuous administration of parenteral opioids. As death approaches and patients become less verbal, it is important to assess pain frequently, including the use of close observation for nonverbal signs of distress (e.g., grimacing, increased respiratory rate). Adequate dosing of opioid analgesics may require alternate route(s) of administration other than oral as patients become more somnolent or develop swallowing difficulties. Opioids should not be stopped abruptly, even if the patient becomes nonresponsive, because sudden withdrawal can cause severe distress.^{49,50}

Cognitive failure at the end of life is manifested in most patients by increasing somnolence and delirium. Gradually increasing somnolence can be accompanied by periods of disorientation and mild confusion, and it may respond to the reassuring presence of loved ones and caregivers with minimal need for medications. A more distressing form of delirium also can

Table 48-6

Analgesics for persistent pain

DRUG	INITIAL DOSING (ADULT, >60 kg)	COMMENTS
Mild persistent pain, visual analogue scale (VAS) 1–3 Acetaminophen (Tylenol)	325–650 mg PO four times a day Maximum = 3200 mg/24 h	Use <2400 mg if other potentially hepatotoxic drugs taken. Acetaminophen contained in concurrent nonprescription medications can easily exceed maximum daily allowable dose.
Aspirin	600–1500 mg PO four times a day	Gastric bleeding, platelet dysfunction
Choline magnesium trisalicylate (Trilisate)	750–1500 mg PO twice a day	Useful for avoiding platelet dysfunction
Ibuprofen (Advil, Motrin)	200–400 mg PO four times a day Maximum = 3200 mg/24 h	Gastropathy, nephropathy, decreased platelet aggregation
Naproxen (Naprosyn)	250 mg PO twice a day Maximum = 1300 mg/24 h	Available as a transcutaneous gel
Moderate persistent pain, VAS 4–6 Hydrocodone (Vicodin, Lortab)	5–7.5 mg PO every 4 hours	Most prescribed drug in the United States Acetaminophen in compounded drug limits use to moderate pain
Oxycodone	5 mg PO every 4 hours	Sold as single agent or compounded with aspirin or acetaminophen Slow release form available (Oxycontin)
Severe persistent pain, VAS 7–10 Morphine	10 mg PO every 2–4 hours 2–4 mg IV, SC every 1–2 hours	Standard drug for comparison to alternative opioids. Avoid or caution when giving to older adults, patients with diminished glomerular filtration rate, or liver disease. Slow release PO form available (MS Contin).
Hydromorphone	1–3 mg PO, PR every 4 hours 1 mg IV, SC every 1–2 hours	Suppository form available Oral dose forms limited to 4 mg maximum
Fentanyl, transdermal	12 µg/h patch every 72 hours	Not for acute pain management. Do not use on opioid-naïve patients. Absorption unpredictable in cachectic patients.
Methadone	Consultation with pain management, clinical pharmacists, or palliative care/hospice services skilled in methadone use is recommended for those inexperienced in prescribing methadone.	Not a first-line agent, although very effective, especially for pain with a neuropathic component Very inexpensive Can be given PO, IV, SC, PR, sublingually, and vaginally Its long half-life makes dosing more difficult than alternative opioids and close monitoring is required when initiating. Numerous medications, alcohol, and cigarette smoking can alter its serum levels. Physicians who write methadone prescriptions for pain should specify this indication. Methadone use for drug withdrawal treatment requires special licensure.

Risk factors for NSAID-induced nephropathy include: advanced age, decreased glomerular filtration rate, congestive heart failure, hypovolemia, pressors, hepatic dysfunction, concomitant nephrotoxic agents. Dose reduction and hydration reduce risk.

Opioids compounded with aspirin or acetaminophen are limited to treatment of moderate persistent pain because of dose-limiting toxicities of acetaminophen and aspirin.

Slow-release preparations of morphine and oxycodone may be given rectally.

Timed-release tablets or patches should never be crushed or cut.

Opioid analgesics are the agents of choice for severe cancer-related pain. Sedation is a common side effect when initiating opioid therapy. Tolerance to this usually develops within a few days. If sedation persists beyond a few days, a stimulant (methylphenidate 2.5–5 mg PO twice a day) can be given.

Initiate bowel stimulant prophylaxis for constipation when prescribing opioids unless contraindicated.

Adjuvant or coanalgesic agents are drugs that enhance analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, or provide independent analgesia for specific types of pain (e.g., a tricyclic antidepressant for treatment of neuropathic pain). Coanalgesics can be initiated for persistent pain at any visual analogue scale level. Gabapentin is commonly used as an initial agent for neuropathic pain.

No place for meperidine (Demerol), propoxyphene (Darvon, Darvocet, or mixed agonist-antagonist agents [Stadol, Talwin]) in management of persistent pain.

Always consider alternative approaches (axial analgesia, operative approaches, etc.) when managing severe persistent pain.

Note: These are not recommendations for specific patients. The inter- and intraindividual variability to opioids requires individualizing dosing and titration to effect.

Table 48-7

Examples of adjuvant medications for treatment of neuropathic, visceral, and bone pain^a

DRUG CLASS	INITIAL DOSING (ADULT, >60 kg)	COMMENTS
<p>Tricyclic antidepressants</p> <p>Best for continuous burning or tingling pain and allodynia</p> <p>Efficacy for pain not due to antidepressant effect</p> <p>Dose generally less than that required for antidepressant effect</p> <p>Dose titrated up every few days until effect. Pain may respond to alternative antidepressants if no response to initial agent.</p>	<p>Amitriptyline 10–25 mg PO before bed</p> <p>Nortriptyline 10–25 mg PO one per day</p> <p>Doxepin 10–25 mg PO before bed</p> <p>Imipramine 10–25 mg PO one per day</p>	<p>Sedating properties may be useful for relief of other concurrent symptoms. Side effects may precede benefit. Avoid in older adult patients due to anticholinergic side effects.</p> <p>Less anticholinergic effect</p>
<p>Anticonvulsants</p> <p>For shooting, stabbing pain</p>	<p>Gabapentin 100–1200 mg PO three times a day. Titrate up rapidly as needed. Max: 3600 mg daily in divided doses</p> <p>Carbamazepine 200 mg PO every 12 hours</p> <p>Pregabalin starting dose 25–50 mg PO three times a day</p> <p>Valproic acid 250 mg PO three times a day</p>	<p>Commonly used first-line agent. Generally well tolerated. Does not require blood level monitoring.</p> <p>Effective. Well studied. Requires blood monitoring.</p> <p>Does not require blood monitoring.</p>
<p>Local anesthetics</p> <p>Systemic use requires monitoring. Nebulized local anesthetics (lidocaine, bupivacaine) can be used for severe, refractory cough.</p>	<p>Lidocaine transdermal patch 5%. Apply to painful areas. Max: 3 simultaneous patches over 12 hours (each patch contains 700 mg lidocaine).</p> <p>Lidocaine/prilocaine topical. Apply to painful areas.</p>	<p>Systemic toxicity can result from applying more than recommended number per unit time and in patients with liver failure. Effective for postherpetic neuralgia.</p>
Miscellaneous	<p>Bisphosphonates (pamidronate, zoledronic acid)</p> <p>Calcitonin nasal spray</p> <p>Dexamethasone</p> <p>Radionuclides (Sr-89)</p> <p>Octreotide</p>	<p>For bone pain and reduced incidence of skeletal complications secondary to malignancy—best results in myeloma and breast cancer. Contraindicated in renal failure.</p> <p>Refractory bone pain</p> <p>For bone pain, acute nerve compression, visceral pain secondary to tumor infiltration or luminal obstruction by reducing inflammatory component of tumor</p> <p>For malignant bone pain secondary to osteoclastic activity. 4–6 wk delay in benefit. Requires adequate bone marrow reserve. For prognosis of more than 3 mo.</p> <p>Reduces GI secretions that contribute to visceral pain</p>

^aRecommendations are based on experience of practitioners of hospice and palliative medicine and in some instances do not reflect current clinical trials.

develop, manifested by increasing agitation that may require the use of neuroleptic medications. Increasing amounts of opioids and/or benzodiazepines may exacerbate the delirium (especially in the elderly).

Pronouncing Death⁵¹

If the body is hypothermic or has been hypothermic, such as a drowning victim pulled from the water in the winter, the physician should not declare death until warming attempts have been made. In the hospital, hospice, or home setting, the declaration of death becomes part of the medical or legal record of the event. There are a number of physical signs of death a physician should look for in confirming the patient's demise: complete lack of responsiveness to verbal or tactile stimuli, absence of heart beat and respirations, fixed pupils, skin color change to a waxen hue as blood settles, gradual poikilothermia, and sphincter relaxation with loss of urine and feces. For deaths in the home with patients who have been enrolled in hospice, the hospice nurse on call should be contacted immediately. In some states, deaths at home may require a brief police investigation and report. For deaths in the hospital, the family must be notified (in person, if possible). A coroner or medical examiner may need to be contacted under specific circumstances (e.g., deaths in the operating room), but most deaths do not require their services. The pronouncing physician will need to complete a death certificate according to local regulations. Survivors may also be approached, if appropriate, regarding potential autopsy and organ donation. Finally, it is important to accommodate religious rituals that may be important to the dying patient or the family. *Bereavement* is the experience of loss by death of a person to whom one is attached. *Mourning* is the process of adapting to such a loss in the thoughts, feelings, and behaviors that one experiences after the loss.⁵² Although grief and mourning are accentuated in the immediate period around death, it is important to note that patients and families may have begun the process of bereavement well before the time of death as patients and families grieve incremental losses of independence, vitality, and control. In addition to the surviving loved ones, it is important to acknowledge that caregivers also experience grief for the loss of their patients.^{53,54}

Aid in Dying

Five European countries, Canada, and six U.S. states have legalized physician-assisted suicide, medical assistance in dying, or aid-in-dying, in some form, ranging from hospital-based programs to provision of fatal doses of medications for home self-administration.⁵⁵⁻⁵⁷ Medical assistance in dying is a complex ethical and legal issues with divergent opinions among the public and healthcare providers.^{58,59} While aid-in-dying laws passed in the United States vary somewhat, these laws essentially all allow physicians to prescribe a lethal dose of medication to mentally, competent, terminally ill adult patients for the purpose of achieving the end of life.^{60,61} Key areas of ethical consideration in this area include the benefit and harm of death; the relationship between passive euthanasia, active euthanasia, withholding treatment, and withdrawing treatment; the morality of physician and nursing participation in deliberately causing death; and the management of conscientious objection.^{60,62} Although surgeons outside of the critical care arena may only infrequently be asked to participate in aid-in-dying, it is important to be familiar with local legislation so that appropriate information can be provided to patients who request it.

PROFESSIONAL ETHICS: CONFLICT OF INTEREST, RESEARCH, AND CLINICAL ETHICS

Conflict of Interest

Conflicts of interest for surgeons can arise in many situations in which the potential benefits or gains to be realized by the surgeon are, or are perceived to be, in conflict with the responsibility to put the patient's interests before the surgeon's own. Conflicts of interest for the surgeon can involve actual or perceived situations in which the individual stands to gain monetarily by his or her role as a physician or investigator. In the academic community, monetary gain may not be the primary factor. Instead, motivators such as power, tenure, or authorship on a publication may serve as potential sources of conflict of interest. For example, the accrual of subjects in research studies or patients in surgical series may ensure surgeons better authorship or more financial gains. The dual-role of the surgeon-scientist therefore needs to be considered because the duty as surgeon can conflict with the role of scientist or clinical researcher.

Research Ethics

Over the last three decades in the United States, the ethical requirements for the conduct of human subject research have been formalized and widely accepted. Although detailed informed consent is a necessary condition for the conduct of ethically good human subject research, other factors also determine whether research is designed and conducted ethically. Emanuel and colleagues⁶³ described seven requirements for all clinical research studies to be ethically sound: (a) value—enhancement(s) of health or knowledge must be derived from the research; (b) scientific validity—the research must be methodologically rigorous; (c) fair subject selection—scientific objectives, not vulnerability or privilege, and the potential for and distribution of risks and benefits, should determine communities selected as study sites and the inclusion criteria for individual subjects; (d) favorable risk-benefit ratio—within the context of standard clinical practice and the research protocol, risks must be minimized, potential benefits enhanced, and the potential benefits to individuals and knowledge gained for society must outweigh the risks; (e) independent review—unaffiliated individuals must review the research and approve, amend, or terminate it; (f) informed consent—individuals should be informed about the research and provide their voluntary consent; and (g) respect for enrolled subjects—subjects should have their privacy protected, the opportunity to withdraw, and their well-being monitored.⁶³

Special Concerns in Surgical Research

A significant issue for clinical surgical research is that many surgical studies are retrospective in nature and are not commonly undertaken in a prospective, double-blind, randomized fashion. For a randomized trial to be undertaken, the researchers should be in a state of equipoise—that is, there must be a state of genuine uncertainty on the part of the clinical investigator or the expert medical community regarding the comparative therapeutic merits of each arm in a trial.⁶⁴ To randomize subjects to receive two different treatments, a researcher must believe that the existing data are not sufficient to conclude that one treatment strategy is better than another. In designing surgical trials, surgeons usually have biases that one treatment is better than another and often have difficulty maintaining the state of equipoise. As such, it is frequently difficult to demonstrate that a

randomized trial is necessary or feasible, and treatment options that question the validity of clinical tenets are difficult to accept. Meakins has suggested that a slightly different hierarchy of evidence applies to evidence-based surgery.⁶⁵

A second major issue for surgical trials is whether it is ethically acceptable to have a placebo-controlled surgical trial. Some commentators have argued that sham surgery is always wrong because, unlike a placebo medication that is harmless, every surgical procedure carries some risk.⁶⁶ Others have argued that sham operations are essential to the design of a valid randomized clinical trial because, without a sham operation, it is not possible to know if the surgical intervention is the cause of improvement in patient symptoms or whether the improvement is due to the effect of having surgery.^{67,68} Most surgeons readily agree that designing an appropriately low-risk sham surgical procedure would create problems for the surgeon-patient relationship in that the surgeon would need to keep the sham a secret.⁶⁹ In this sense, a sham surgical arm of a trial is very different from a placebo medication in that there cannot be blinding of the surgeon as to which procedure was undertaken. As a result, to have a sham surgery arm in a clinical trial, the interactions between the surgeon and the subject must be limited, and the surgeon performing the procedure should not be the researcher who follows the subject during the trial. Despite difficulties with designing a surgical trial in which the surgeon could ethically perform a sham operation, there are specific circumstances that allow for placebo operations to be conducted, so long as certain criteria are met and are analyzed on a case by case basis.^{70,71}

Surgical Innovation

An important issue is whether surgical innovation should be treated as research or as standard of care. Throughout history, many advances in surgical techniques and technologies have resulted from innovations of individual surgeons crafted during the course of challenging operations—such innovations and technologies have served to move the field of surgery forward.⁷² In the Korean and Vietnam wars, military guidelines for treatment of vascular injuries recommended ligation and amputation rather than interposition grafting of vascular injuries. Individual surgeons chose to ignore those guidelines and subsequently demonstrated the value of the reconstructive techniques that ultimately became the standard of care. It is debated whether modifications to an accepted surgical technique in an individual patient based on their circumstances and within the skill and judgment of an individual surgeon should require the same type of prior approval that enrollment in a clinical trial would warrant.⁷³ However, if a surgeon decides to use a new technique on several occasions and to study the outcomes, Institutional Review Board approval and all other ethical requirements for research are necessary. These situations require strict oversight as well as explicit consent by the patient.⁷⁴ In particular, when developing new and innovative techniques, the surgeon should work in close consultation with his or her senior colleagues, including the chairperson of the department. Frequently, more senior individuals can provide sage ethical advice regarding what constitutes minor innovative changes in a technique vs. true novel research.

Compared to the formalized process for new drug approval by the Food and Drug Administration, the process for a surgeon developing an innovative operation can be relatively unregulated and unsupervised.

The Ethics of Authorship

Authorship specifies who is responsible for published research. It confers both recognition for academic achievement as well as responsibility for the academic integrity of the published content. Authorship is the stock in trade of productivity for academic surgeons, and it plays a significant role in promotion and tenure. It can also be commodified in the form of intellectual property and patents in which the author and the author's institution have vested interests. Yet it can also become a liability if a given piece of work becomes embroiled in accusations of plagiarism, data fabrication, or other academic misconduct.

In the past, criteria for authorship were unspecified: Those submitting manuscripts simply listed the authors with little or no need to substantiate their contribution to the work. Unfortunately, this informal process led to confusion and even abuse. For example, there has been a long tradition of awarding authorship to the investigator who supervised or obtained funding for research, regardless of that person's specific contribution to the manuscript. However, current recommendations specify that supervision and funding, by themselves, are insufficient criteria for authorship, and thus such individuals should only be included as authors if they make direct contributions to the work.^{75,76} A more disturbing example is the practice of "ghost writing" by which senior investigators publish industry-written research under their own name to bolster their productivity while providing a luster of academic integrity to industry.

To address these conflicts of interest and to provide guidance to investigators, the International Committee of Medical Journal Editors (ICMJE) provides recommendations on criteria for authorship so that individuals who contributed to the intellectual content of a work get appropriate credit and that all those listed as authors take responsibility and are accountable for the published work. The ICMJE recommendations for authorship can be found in Table 48-8.⁷⁵ Furthermore, the ICMJE recommends that each author should be able to identify the contribution that each other author made to the work and be confident regarding the integrity of their co-authors. The ICMJE also recommends that individuals who do not meet these criteria be acknowledged in the manuscript, providing appropriate procedures for such acknowledgement. Additionally, the ICMJE

Table 48-8

ICMJE criteria for authorship

According to ICMJE best practices recommendations, authors should fulfill each of the following four criteria⁶⁷:

1. Substantial contributions to the conception or design of the work; or the acquisition, analysis, or interpretation of data for the work
2. Drafting the work or revising it critically for important intellectual content
3. Final approval of the version to be published
4. Agreement to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved

Contributors who do not fulfill all four criteria should be named in the manuscript in the acknowledgment section.

Adapted with permission from Cameron JL: *Current Surgical Therapy*, 9th ed. Philadelphia, PA: Elsevier; 2008.

specifically excludes certain types of contributions including acquisition of funding, general supervision of a research group, administrative support, writing assistance, technical editing, language editing, and proofreading.⁷⁵

Many journals have adopted these criteria, operationalizing them at the time of submission by having each author specify his or her contributions. These contributions are then disclosed in the published manuscript to further specify how credit and responsibility is shared.⁷⁷ This approach has been shown to provide valuable information and has proved feasible in several journals, including *The Lancet*.⁷⁸

As research becomes increasingly interdisciplinary with ever-expanding teams of contributors, it can be difficult to determine which contributions warrant full authorship rather than simple acknowledgement. Individuals working together on

8► research endeavors should have clear discussions early in the planning process about authorship, and those discussions should be continued throughout the project or study.

Clinical Ethics: Disclosure of Errors

Disclosure of error—either in medical or research matters—is important, but often difficult (see Chapter 12). Errors of judgment, errors in technique, and system errors are responsible for most errors that result in complications and deaths. Hospitals are evaluated based on the number of complications and deaths that occur in surgical patients, and surgeons traditionally review their complications and deaths in a formal exercise known as the *mortality and morbidity conference*, or *M&M*. The exercise places importance on the attending surgeon’s responsibility for errors made, whether he or she made them themselves, and the value of the exercise is related to the effect of “peer pressure”—the entire department knows about the case—on reducing repeated occurrences of such an error. Although a time-honored ritual in surgery, the M&M conference is nonetheless a poor method for analyzing causes of error and for developing methods to prevent them. Moreover, the proceedings of the M&M conference are protected from disclosure by the privilege of “peer review,” and the details are thus rarely shared with patients or those outside the department.

A report from the United States Institute of Medicine titled “To Err Is Human” highlighted the large number of medical errors that occur and encouraged efforts to prevent patient harm.⁷⁹ Medical errors are generally considered to be “preventable adverse medical events.”⁸⁰ Medical errors occur with some frequency, and the question is what and how should patients be informed that a medical error has occurred.⁸¹

Disclosure of error is consistent with the ethical virtue of candor (e.g., transparency and openness) and the ethical principle of respect for persons by involving patients in their care.

9► In contrast, failing to disclose errors to patients undermines public trust in medicine and potentially compromises adequate treatment of the consequences of errors and effective intervention to prevent future errors. In addition, failure to self-disclose medical errors can be construed as a breach of professional ethics, as it is a failure to act in the patient’s best interests. Information regarding a medical error may be needed so that patients can make independent and well-informed decisions about future aspects of their care. The principles of autonomy and justice dictate that surgeons need to respect individuals by being fair in providing accurate information about all aspects of their care—even when an error has occurred.

Disclosing one’s own errors is therefore part of the ethical standard of honesty and putting the patient’s interests above

one’s own. Disclosing the errors of others is more complicated and may require careful consideration and consultation. Surgeons sometimes discover that a prior operation has included an apparent error; an injured bile duct or a stenotic anastomosis may lead to the condition for which the surgeon is now treating the patient. Declaring a finding as an “error” may be inaccurate, however, and a nonjudgmental assessment of the situation is usually advisable. When clear evidence of a mistake is at hand, the surgeon’s responsibility is defined by his or her obligation to act as the patient’s agent.

INTRODUCTION

Modern surgery can save lives, help expand economies, and offer hope to individuals and communities. Prior to the acceptance and availability of aseptic technique to prevent or decrease infections, and improved anesthesia for controlling pain, surgery as a specialty was held in very low esteem by medical doctors and the general public. Over the last 100 years, surgery has developed into a highly regarded discipline that not only provides opportunities for curing certain diseases but also fulfills a special role in preventing and mitigating disability.

Yet, surgery is currently unavailable to most people worldwide. The vast majority—90%—of the world's population receives only 10% of the surgical care delivered. Said another way, 90% of surgical resources are consumed by the most privileged 10% of the world's population. More than 5 billion people lack access to safe, timely, and affordable surgical care.¹ Very few surgical procedures occur in countries spending less than U.S. \$100 per person on health care per year compared to countries spending greater than U.S. \$1000 per person (Fig. 49-1).²

Examples of disparities abound. In many countries, including the wealthiest, islands of poverty coexist within cities replete with material resources. Tertiary level hospitals operate within eyesight of slums whose inhabitants have no access to even basic care. Most of the people without access—people in rural areas and in countries with poor infrastructure—are the very people most at risk for death or disability due to lack of surgical care. Often the poor accept and endure many painful and potentially correctable fatal conditions as a fact of life.³⁻⁶ Care for trauma and obstetrical emergencies is considered a basic surgical need but is absent in many rural regions. Other chronic conditions—often equally debilitating—progress to death or serious disability due to lack of available, safe surgery and anesthesia.

Many factors contribute to the disparity in access to surgical care. Poverty, a primary risk factor for all types of diseases, is a major obstacle hindering access to surgery. Healthcare professionals, including surgeons, migrate from areas of need due

to a lack of infrastructure (hospitals, roadways, and stable electrical sources), limited supplies and equipment, lack of human resources, few opportunities for professional development, and concerns for personal safety. Until recently, there has been a significant lack of information regarding the burden of surgical disease and surgery's positive impact on communities. Current research substantiates that investment in surgical care improves economies and is an integral and necessary component of global health.^{7,8}

Disparities in care and outcomes are multidimensional, and no simple solution exists to improve access to appropriate and affordable surgical care. Yet, five major forces are reshaping priorities and strategies leading the charge for the globalization of surgical care.

1. *The epidemiologic transition of diseases* from primarily infectious to more chronic conditions
2. *The mobile nature of the world's populations*, allowing people to move freely between more isolated areas of the world, leading to a more integrated global community
3. *Ubiquitous information access* exponentially enabling widespread participation in understanding and designing innovative opportunities for high-quality surgical care
4. *A revolution for equity and human rights* where the world's poor are demanding benefits to surgical care similar to those found in high-income countries (HICs)
5. *Recognition of the cost-effectiveness of surgical care* and its potential to build economies, demonstrating the value of including surgery in global health strategies⁹⁻¹²

The greatest burden of disease occurs in areas where human resources—physicians, nurses, pharmacists, and other healthcare workers—are scarce (Fig. 49-2).¹³ The proportion of physicians is low both in high-population areas and in areas where the population is growing most rapidly (Fig. 49-3).^{14,15} Fully trained surgeons and anesthesiologists comprise only a small proportion of the total number of the Human Resources in Health (HRH), and efforts to meet the

Key Points

- 1▶ There are five major forces reshaping priorities and strategies for the globalization of surgical care:
 - a. The epidemiologic transition of diseases
 - b. The mobile nature of the world's populations
 - c. Ubiquitous information access
 - d. A revolution for equity and human rights
 - e. Recognition of the cost-effectiveness of surgical care for treatment and prevention of disease
- 2▶ The burden of disease is greatest in areas where human resources—physicians, nurses, pharmacists, and other healthcare workers—are the least.
- 3▶ Surgery should be viewed as an investment rather than a cost.
- 4▶ The key components of the global surgery ecosystem include technology, education, community, healthcare, business, and multidisciplinary engagement between a variety of disciplines.
- 5▶ Understanding and addressing the necessary communication, energy, and transportation technologies along with the underlying cultural context represent the foundation critical to implementing sustainable infrastructure for appropriate surgical care.
- 6▶ There has been a significant shift from communicable, maternal, neonatal, and nutritional causes of disease to noncommunicable causes, many of which require surgical care.
- 7▶ Patients and their communities in low- and middle-income countries (LMICs) bear a much greater share of the burden of cancer than high-income countries (HICs).
- 8▶ Globally, trauma has become a leading cause of death and disability; 90% of trauma deaths occur in LMICs.
- 9▶ Essential surgical services should be integrated into comprehensive health care delivery, with the potential to avert 1.5 million deaths per year in LMICs.
- 10▶ Surgery is gaining an increasingly recognized role for improving public health, having a role in prevention as well as treatment.
- 11▶ The cost-effectiveness of surgical care has been demonstrated, and its value as a public health investment is increasingly understood by policymakers.
- 12▶ Developing capabilities for surgical care has the ability to promote system-strengthening in resource-poor countries and to mitigate migration of health professionals at all levels.
- 13▶ Academic global surgery provides a unique environment to study health systems, identify solutions and implement them collaboratively, fulfilling many institutions' missions to strengthen multidisciplinary training, advocacy, and research.
- 14▶ Surgical innovations that bring value by balancing cost with quality designed for challenging energy environments will foster equity in surgical care for LMICs.

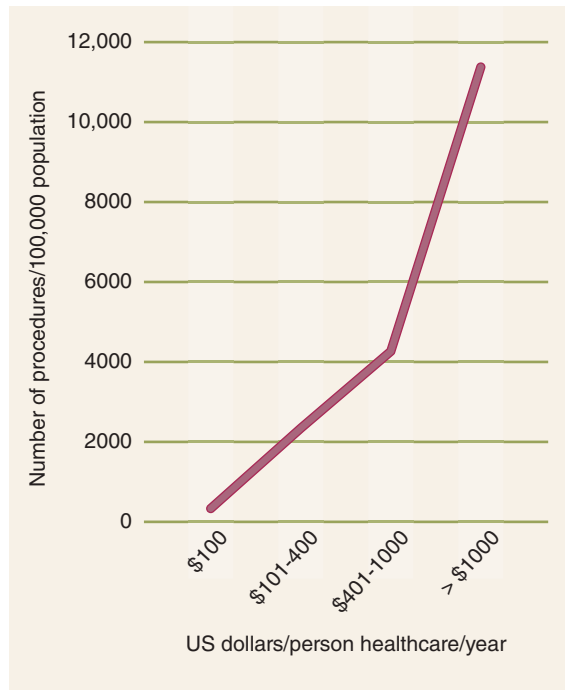

Figure 49-1. Worldwide distribution of surgical procedures. (Data from Weiser TG, Regenbogen SE, Thompson KD, et al. An estimation of the global volume of surgery: a modelling strategy based on available data, *Lancet*. 2008 Jul 12;372(9633):139-144.)

surgical needs are now embracing a multifaceted approach, including advanced care practitioners. The Lancet Commission on Global Surgery estimates that an additional 143 million surgical procedures are needed each year in LMICs to prevent death and disability caused by lack of care.¹⁶

The potential benefits of surgical care for economic productivity are astounding. Considering that the annual economic loss from road traffic injuries alone exceeds U.S. \$500 billion globally, a panel of expert economists at the Copenhagen Consensus of 2012, including four Nobel prize laureates, prioritized strengthening surgical capacity as the eighth most cost-effective investment for addressing the world's most pressing problems. The Consensus reconvened in 2015, synchronizing their recommendations to the United Nations' Sustainable Development Goals, and reaffirmed that surgery-related initiatives (i.e., circumcision and skilled obstetrical support), offer the best "value-for-money" in terms of alleviating world poverty.¹⁷⁻¹⁹ The Lancet Commission on Global Surgery, a research and advisory working group with contributors from 110 nations, echoed these sentiments. Surgery should be viewed as an investment rather than a cost.^{16,20}

Much of the economic modeling and strengthening of political will related to surgical and anesthesia care has been carried out by collaborative groups and consortia including academic, nongovernmental, and other organizations. The efforts of these groups truly coalesced in 2015, when several major consensus statements from governmental organizations, such as the World Bank and the World Health Assembly, recognized the importance of surgery in public health for the first time.

Figure 49-2. Distribution of healthcare workers by burden of disease in WHO regions. (Reproduced with permission from *Intermountain Healthcare*.)

The third edition of World Bank’s *Disease Control Priorities (DCP3)* and the World Health Assembly’s *Resolution 68.15* both specifically discuss the vital nature of surgical care as part of any health system.^{7,21} Such resolutions represent a sea change in terms of how the global policy community views surgical care for LMICs and, indeed, the entire world.

This chapter examines the ongoing need to expand and strengthen surgical care globally, explores some of the significant challenges of global surgery, and presents potential guiding concepts along with examples of successful strategies for sustainable surgical development.

DEFINING GLOBAL SURGERY

Global Surgery Ecosystem

To understand how surgery fits into healthcare systems and to understand its unique needs, it is helpful to consider global surgery as an ecosystem. The emerging field of global surgery considers surgical care to be a fundamental component of global health. As a system with both local and international scope, global surgery encompasses not just the medical and technical aspects of surgical care, but also the societal and environmental context in which surgery is performed. Global surgery also refers to a worldwide lens through which we view challenges collaboratively; thus, global surgeons may focus on resource-limited areas where needs are profound, but the ultimate goal should be to make surgical care equitable, accessible, and affordable for every human being.²² Surgery as an ecosystem considers the diverse but interrelated systems that must be functional for quality surgical care to be delivered. Only part of these systems falls within the traditional training of surgeons. Yet, modern surgical care requires these systems to work in a coordinated fashion to support three priorities critical for expanding surgery globally—accessibility, affordability, and innovation (Fig. 49-4). Global surgery is a way to consider a “systems-based practice” beyond a single

hospital or community, for the benefit of people worldwide. Many interrelated components of this surgical ecosystem originate outside the hospital.

Disparities in surgical care have geographical, socioeconomic, and cultural components. Most people who live in major cities in the northern and western hemispheres take for granted a functioning energy grid. The development of energy beyond major cities has enabled wealthier communities to imagine, and indeed, to expect healthcare to be available at all times and affordable. Yet, a lack of reliable energy sources is a major limiting factor. Communication and transportation technologies, for example, the mobile phone and air and ground travel, have dramatically progressed in high- and middle-income countries but are still rudimentary in poor countries. Many of the current disparities in health care, particularly surgical care, are due to the lack of penetration of these technologies. Understanding and addressing the necessary communication, energy, and transportation deficits as well as the underlying cultural nuances are necessary to support the sustainable development of surgical care.

Electricity is necessary for all modern surgery. Anesthesia monitoring, operating room lighting, cautery, suction, and patient warming devices all require sources of electricity that are stable, without huge electrical surges. Only in the last 50 years or so could stable electricity be expected in most wealthy cities. However, in rural areas of even wealthy countries, electricity remains unpredictable (Fig. 49-5).²³

In poorer countries, the cost and availability of electricity is frequently the limiting factor for more advanced diagnostic and therapeutic technology—from laboratories that require refrigeration to radiology in all of its various branches. Modern design for surgical devices has, for the most part, not taken into account the wide range of energy environments where surgery is practiced. Fragile instruments and monitors that cannot survive the rigors of the real working environment limit the types of surgery that can be provided.

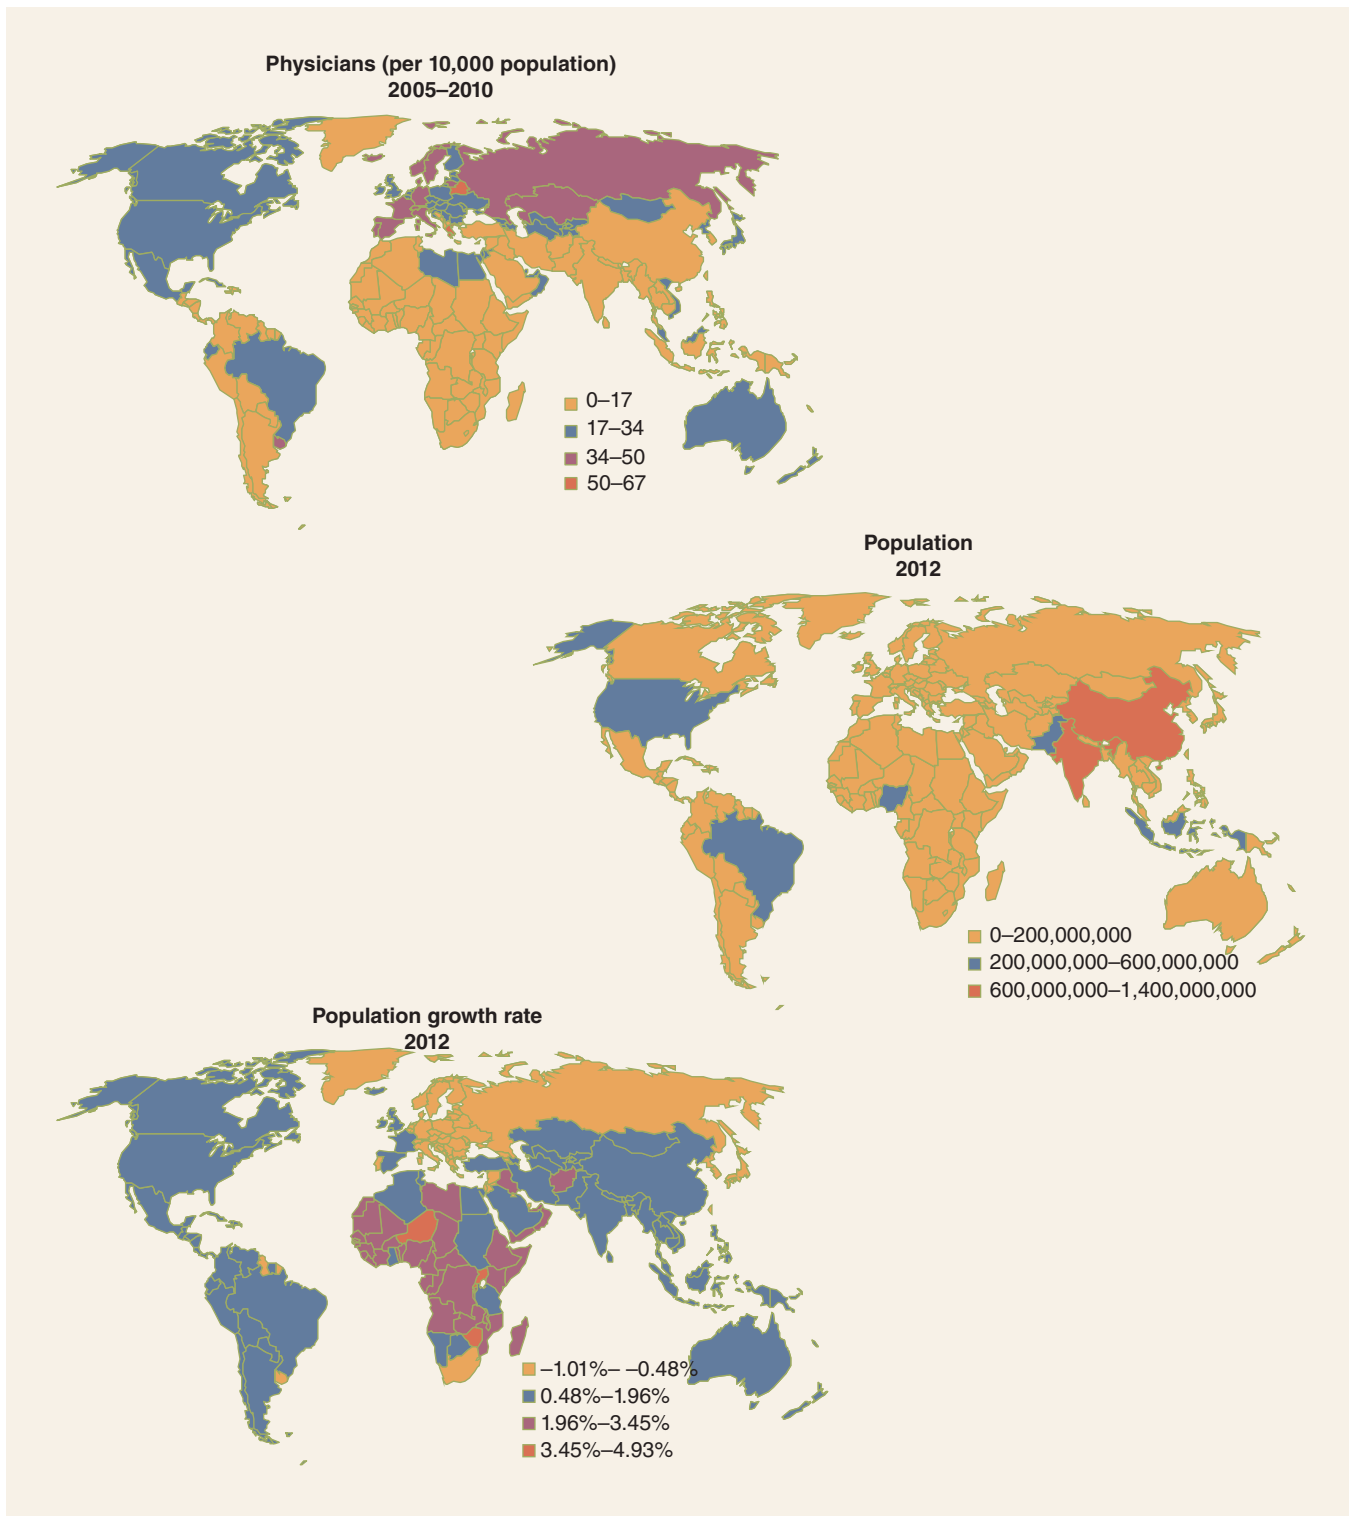

Figure 49-3. Number of physicians, world populations, and world population growth rates. (Reproduced with permission from World Health Organization, 2018 (*Density of Physicians [total number per 1000 population]*); 2013 World Population Data Sheet Interactive Map; World Bank, population growth (annual %) map.)

Components of the Global Surgery Ecosystem. Improvements in energy, transportation, and communication are critical to support the growth of surgical care.⁹ Building capacity for surgical care requires interaction between the various components that create a functioning, sustainable system. When

surgeons think of surgery, they usually think in terms of science and hands-on technical expertise. However, global surgery requires a broader understanding of systems in other disciplines. Surgeons must work collaboratively with engineers and business leaders to develop technology that can function in lower

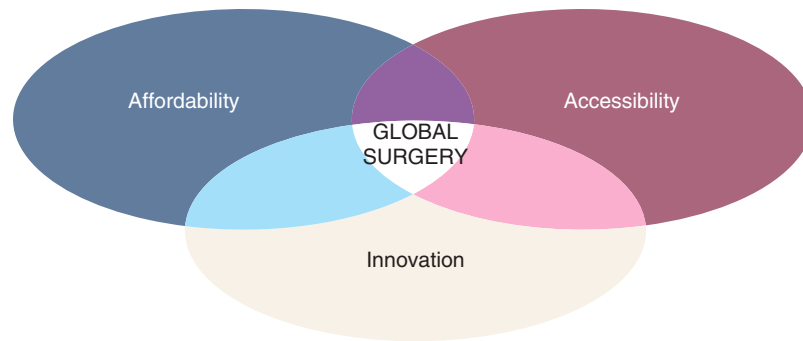

Figure 49-4. Global surgery priorities. (Reproduced with permission from University of Utah Center for Global Surgery and Intermountain Healthcare.)

resource environments. These innovations can provide a source of economic growth for the community, which in turn supports better health care (Fig. 49-6).

No sustainable surgical system in the modern age can function without specialists in bioengineering, sterile process, supply chain, hospital safety, and waste management. These often unappreciated colleagues make possible the daily practice of surgery. Similarly, specialists in anesthesia, nursing, and the diagnostic specialties of radiology, pathology, and laboratory services are fundamental to a fully functional surgical service.

Human Resources

Primary care physicians, nurses, midwives, or advanced care practitioners (ACPs) provide much of the basic surgical and anesthetic care in LMICs. Where regulations allow, “task sharing,” or training ACPs to deliver surgery and anesthesia services previously allowed only under the purview of fully trained specialists, can provide expanded access to care.²⁴⁻²⁶ Non-MD practitioners, known as *assistant medical officers* (AMOs) or “*tecnicos de cirurgia*” in Mozambique, often have extensive operative experience, including obstetrical care, and are the primary surgical providers in some regions.²⁷⁻²⁹ Task sharing with ACPs also occurs in the United States and other countries where they fill a need otherwise unmet by specialists even in major tertiary care centers.³⁰ However, concerns about the quality of care, lack of adequate supervision, and the effect on prestige and

professional development for specialists and ACPs, continue to be topics for debate.^{31,32}

Migration of practitioners to economically and culturally favorable locales is universal and not restricted to low-resource countries.^{33,34} However, the net impact on poor countries is greater. In a 2004 study, more than 23% of U.S. physicians received their medical training from other countries; of these 64% were from low-income countries.³⁵ Using 2013 data, another study showed annual emigration rates of sub-Saharan physicians to the United States are increasing, despite a World Health Organization Global Code of Practice in 2010 aimed at LMIC workforce retention.³⁶ Investments in training greater numbers of doctors in these countries, including surgical specialists, have been only partially successful in meeting demand in poor countries. Until economic conditions improve or opportunities for professional development increase, and incentives enticing migration of health care workers to high-income countries abate, it is unlikely that the most skilled practitioners will remain in resource-poor areas beyond their immediate obligations.³⁷⁻⁴¹

Burden of Surgical Disease

Epidemiologic Transition of Disease. The population on Earth currently stands at more than 7 billion. While the rate of growth has slowed in recent years, projections estimate that

Figure 49-5. Map of world electrification. (Reproduced with permission from NASA, Visible Earth, Available at: <http://visibleearth.nasa.gov/view.php?id=79765>.)

Figure 49-6. The global surgery ecosystem requires broad integration of many fields in a multidisciplinary context. (Reproduced with permission from Intermountain Healthcare.)

the population will continue to grow to 9 billion by 2050.⁴² Population characteristics are changing rapidly. According to United Nations' estimates, the entire world is aging even in low-income countries, and by 2050, 2 billion people will be over the age of 60. Currently, Asia is home to 55% of the world's population over the age of 60.⁴³ Just before the year 2020, the percentage of the world's population over age 65 years is predicted to surpass the percentage of children under age 5 years, on an unprecedented reversal of trajectories for both age demographics. While this represents a victory for infectious disease control, the dramatic increase in longevity will present new challenges in terms of treating noncommunicable disease in the older adult population.⁴⁴ At the same time, Sub-Saharan Africa's population is experiencing a much different trend: a current "baby boom" will lead the region to quadruple its population, from 960 million to 4 billion, by the year 2100.⁴⁵

Until recently, infectious diseases dominated public health strategy. Now with major scourges like polio isolated to relatively small regions of the world, and HIV and malaria decreasing in their relative impact worldwide, chronic diseases and their complications, as well as the effects of aging, are gaining dominance in health care needs. Many of these chronic diseases are best approached by surgery.

6► The lack of metrics and paucity of data identifying the unmet burden of surgical need in many countries have been obstacles facing global surgery initiatives. The 2010 Global Burden of Disease Study was the first worldwide comprehensive burden of disease evaluation since the initial 1990 epidemiologic study. Using the disability-adjusted life year (DALY), a metric that captures both premature mortality and the prevalence and severity of illnesses, disease burdens were calculated for 291 causes in 21 regions of the world

(including 187 countries) for 1990, 2005, and 2010 to enable identification of significant trends over time.⁴⁶ While the global DALYs remained stable from 1990 to 2010, the study identified a significant shift from communicable, maternal, neonatal, and nutritional causes of disease to noncommunicable causes (Fig. 49-7).⁴⁷

In 2015, the previous estimate by the second edition of *Disease Control Priorities* in 2006 of an 11% global surgical disease burden was updated to 30%, obtained from provider-based survey data from the Lancet Commission.^{1,10} Using country-wide population surveys (the Surgeons OverSeas Assessment of Surgical Need Survey [SOSAS]) in Sierra Leone, Rwanda, and Nepal, the overall presence of surgically treatable conditions was 11.2%, with 25.6% of deaths potentially avoidable had surgical care been available. Applying these percentages to the 48 low-income countries, as defined by the World Bank, suggests that there are 288.2 million people currently living with surgically treatable conditions; providing improved access to surgical care could prevent 5.6 million deaths per year.⁴⁸⁻⁵⁰ Untreated acute and chronic surgical conditions represent a significant unmet burden of disease that has major impact on the economies of these nations.^{7,16,51}

Cancer. Patients and their communities in LMICs bear a much greater share of the burden of cancer than HICs. The 7► dramatic increase in the proportion of reported cancer cases in LMICs is a result of population growth, aging populations, and decreased mortality from infectious diseases. In 1970, only 15% of newly reported cancer cases worldwide were from the developing world; by 2008, this proportion rose dramatically to 58% and is expected to grow to 70% by 2030.⁵² Since 2013, the second leading cause of death worldwide has been cancer, and an estimated 20% of all global surgery is now cancer-related.⁵³ Previously thought to be a

Figure 49-7. Shift in disease burden 1990–2010. (Reproduced with permission from Intermountain Healthcare.)

disease almost exclusive to high-income countries, nearly two-thirds of the 7.6 million cancer deaths worldwide occur in LMICs. Mortality from cancer correlates inversely with a country's economy for certain treatable cancers, including breast, testicular, and cervical cancer—LMICs have higher case fatality rates than HICs (Fig. 49-8).^{52,54}

For example, breast cancer case fatality rates illustrate the great disparity in outcomes between regions. Case fatality rates in East Africa reach an unacceptable 59% compared to 19% in the United States.⁵⁴ In LMICs, patients have very limited access to screening. They present for care with much later stages of cancer. In Haiti, after the great earthquake in 2010, with its initial onslaught of orthopedic injuries, many aid organizations found themselves faced with the unmet underlying burden of disease, including late-stage breast cancer and other tumors (Fig. 49-9). The *DCP3* has devoted an entire chapter to cancer screening in LMICs, emphasizing the importance of proper infrastructure for screening and treatment, as well as

considering cost-effectiveness and ethical concerns related to screening and subsequent treatment of detected cancers.⁵⁵ The number and quality of training programs in surgical oncology is also inversely related to a country's income, leaving LMICs with few adequately trained providers. Collaborative training programs between HIC and LMIC centers, as well as tele-teaching and mobile consultation, may address this shortage in a relatively low-cost, high-impact way.⁵⁶

Trauma. Trauma has become a leading cause of death (5.8 million people per year) and disability around the world; 90% of trauma deaths occur in LMICs.⁵⁷ Approximately 32% more people die as a result of injuries than from malaria, tuberculosis, and HIV/AIDS combined, representing 10% of the world's deaths (Fig. 49-10).^{58,59} The major causes of death from injuries are road traffic accidents (RTAs), suicides, homicides, falls, drownings, and burns; in every category except burns, almost twice as many men die compared to women.⁶⁰

Figure 49-8. Ratio of mortality to incidence by solid tumor type and country income (2008). (Reproduced with permission from Intermountain Healthcare.)

Figure 49-9. Underlying unmet cancer burden in Haiti (2010). (Reproduced with permission from Intermountain Healthcare. Photo contributor: R. Dirk Noyes, MD.)

Over 1.25 million people die from RTAs, causing LMICs to lose 3% of their GDP; 50 million more people incur nonfatal injuries, many with resulting lifelong disabilities.⁶¹ Globally, RTAs are the main cause of death for young people between the ages of 15 and 29. Forty-nine percent of all traffic deaths are among pedestrians, cyclists, and motorcycles.⁶² In the United States, a patient presenting with an injury in a rural community has a higher mortality than those from an urban setting.⁶³ This disparity is much more pronounced in economically disadvantaged societies, where seriously injured patients from road traffic accidents are twice as likely to die compared to similarly injured patients in a high-income setting (Fig. 49-11).^{58,64} Additionally, death is much more likely to occur in the prehospital settings for injured patients from low-income countries. The lack of integrated communication

and emergency transportation systems contribute to prehospital risk, while the lack of infrastructure, supplies, and personnel contribute to inhospital mortality.

The number of deaths from RTAs has remained the same between 2007 and 2013. The predicted increase in mortality from RTAs, expected from the increase in population and global motorization, did not materialize, suggesting that interventions to improve global road safety (i.e., The Decade of Action for Road Safety 2011–2020) may be having some success in preventing deaths from RTAs.⁶²

Burns. The World Health Organization estimates that 265,000 people die of burn injuries each year, mostly (95%) from LMICs; the vast majority never present for medical care.⁶⁵ Scalds and electrical burns represent another significant source of death and disability. Women and children in LMICs are most likely to be burned in domestic kitchens; men are more likely to be burned in the workplace. The economic and social impact from long hospitalizations and from the resulting disfigurement provides a significant negative stigma causing ostracism and rejection.

Of all the forms of trauma worldwide, burns are the only type that predominantly afflict women and children. Southeast Asia accounts for 27% of burn-related deaths worldwide; 70% of people dying from burns in this region are women.⁶⁶ Cooking on wood, charcoal, or low kerosene stoves also puts children at risk, particularly from scalding (Fig. 49-12). Small children in the WHO African region have triple the number of burn deaths as children worldwide. Contrast this with the United States, where more burns and burn deaths affect men.

People living in rural areas suffer disproportionately because there are fewer facilities capable of managing the acute and chronic aspects of burns and because the population is generally poorer. Surgical grafting and management of contractures is often best done in specialized burn centers, but these are rare in LMICs. Telemedicine has been shown to be effective in managing burns and preventing complications, and now, in the era of high resolution mobile phones, it can effectively diagnose and triage many burn patients appropriately.⁶⁷ Telemedicine can also be useful in providing much-needed education of rural providers in basic burn care (**Box:** Telemedicine and Tele-education at the University of Utah).⁶⁸

Figure 49-10. Injuries and violence: the scale of the problem. (Reproduced with permission from World Health Organization, Geneva. *Injuries and violence: the facts*. http://www.who.int/violence_injury_prevention/key_facts/VIP_key_fact_1.pdf.)

Figure 49-11. Change in traffic fatality risk (deaths per 10,000 persons, 1975–1998). (Reproduced with permission from Intermountain Healthcare.)

Telemedicine and Tele-education at the University of Utah

The University of Utah’s Burn Center has utilized Project ECHO (Extension for Community Healthcare Outcomes), an HIPAA-compliant tele-education platform developed at the University of New Mexico. Project ECHO provides live, free, interactive educational materials to rural physicians, nurses, and EMTs in eight surrounding states.⁶⁹ This model has been expanded internationally through the University of New Mexico to 21 countries, with the potential to drastically improve the knowledge base of providers in many resource-limited settings.⁷⁰

Direct patient care has also been achieved at the University of Utah’s Burn Center, through their Telemedicine outreach program. “TeleBurn” currently provides approximately 400 video consultations per year, serving 80 sites in five surrounding states that lack specialized burn care. For a region like the Intermountain West, where travel can be limited by inclement weather and long distances, the TeleBurn program provides better access to specialty care, at lower costs to patients.⁷¹

Figure 49-12. Domestic kitchen: risk factor for burns in women and children in LMICs. (Used with permission from James H. Kenney, Jr.)

Essential Surgery: Current and Evolving Concepts

Dr. Jim Yong Kim, President of the World Bank, aptly stated that surgery is an “indivisible, indispensable part of health care.”⁷² The wisdom of this statement has been supported by the findings of two landmark publications in 2015: *Disease Control Priorities*, third edition (DCP3), and the *Lancet Commission on Global Surgery 2030* (LCGS).^{7,16} According to the DCP3, “the provision of essential surgical procedures would avert 1.5 million deaths a year or 6.7% of all avertable deaths in LMICs,” and according to the Lancet Commission, 5 billion people do not have access to safe, affordable surgical and anesthesia care when needed. Taken together, these and other findings suggest that without the provision of accessible, affordable essential surgical care in all LMICs, the lofty goal of another Lancet Commission report, *Global Health 2035: A World Converging Within a Generation*, would be unachievable.⁷³ This earlier Lancet Commission believes that, with adequate investment in global health, all countries could reduce their infectious, maternal, and childhood mortality rates down to those currently seen in the best-performing middle-income countries (e.g., the 4C countries: Chile, China, Costa Rica, and Cuba) within a generation by 2035. They also make the interesting observation that the LMICs can use their own resources for much of the funding needed.

The critical role of essential surgical and anesthesia services in global health, in general, and in saving lives and disabilities in LMICs, in particular, has been established by fact-based evidence and analysis provided by the two landmark publications of 2015, DCP3 and LCGS. Table 49-1 summarizes the key findings and recommendations of the two publications.

The DCP3 adopted a working definition of essential surgical conditions as those that (a) are primarily or extensively treated by surgery; (b) have a large health burden; and (c) can be successfully treated by a surgical procedure that is cost-effective and feasible to promote globally. Using this definition, the DCP3 identified 44 essential procedures, most of which can be performed in first-level hospitals (Table 49-2).⁷⁴ The first-level (district) hospital is the appropriate platform to provide essential surgical service. These procedures rank among the most cost-effective of all interventions and include those that treat injuries, obstetric complications (including fistulas), abdominal emergencies, cataracts, and congenital anomalies.

The LCGS Report, based on extensive research and analysis of factual evidence, provides recommendations to improve access to safe, affordable anesthesia and surgical care in LMICs. Essential surgical services should be integrated into a comprehensive platform of healthcare delivery. At the core of delivery of essential surgery is the first (district) hospital, which must be capable of delivering three bellwether essential surgery procedures (hysterectomy, laparotomy, and treatment of an open fracture). A hospital that can provide these three procedures safely is presumed to have the necessary expertise in general and orthopedic surgery, obstetrics, and anesthesia to perform all essential surgical procedures.

The cost of untreated surgical conditions is huge and, until now, not recognized. At the present time, some 33 million individuals face catastrophic health expenditure for surgical and anesthesia care in LMICs. The LCGS estimates that it would cost U.S. \$420 billion to scale up the surgical workforce

Table 49-1

Key findings and recommendations from the Disease Control Priorities (DCP3) and the Lancet Commission for Global Surgery (LCGS)

DCP3	LCGS
Provision of essential surgery in LMICs would prevent 1.5 million deaths, or 6.7% of all avertable deaths	5 billion people lack access to safe, affordable surgical and anesthesia care when needed
Essential surgical procedures rank among the most cost-effective of all health interventions	143 million more operations are needed in LMICs, where only 6% of all worldwide procedures are now done
Effective and affordable measures (such as task-sharing) increase access to surgical care	33 million face catastrophic health expenditure from surgery and anesthesia care each year
Investments must be made to expand capacity building	Without urgent investment, LMICs will lose US \$12.3 trillion in economic productivity between 2015 and 2030
Substantial disparities exist between countries in safety of surgical and anesthetic care. Feasible and affordable measures (e.g., surgical safety checklist) improve safety and quality	Surgery is an indivisible, indispensable part of health care. Surgical care should be part of the National Health Care System, and should be “available, accessible, safe, timely, and affordable.”
Universal coverage of essential surgery should be publicly financed early on the path to universal health coverage	

LMIC = Low and Middle Income Country

Table 49-2

Essential surgical procedures that can be performed in first level (District) hospitals (DCP3)

Obstetric Complications

Severe postpartum hemorrhage, obstructed labor, prolonged labor, eclampsia, prolapsed cord, fetal distress, tubal pregnancy, postabortion endometritis/myometritis, postabortion sepsis, intrauterine fetal death

Trauma and Violence

Major limb fracture/injury, joint dislocation, major soft tissue injury, pneumo/hemothorax, ruptured spleen

Acute Surgical Emergencies

Strangulated hernia, intestinal obstruction, intestinal perforation, appendicitis, liver abscess, major wound infection, osteomyelitis/septic arthritis

Nonacute Surgical Conditions

Congenital hernia, hernia, breast cancer, chronic osteomyelitis, hydrocele, urethral stricture, prostatic hypertrophy, cataract, eye injury

to have 20 surgical, anesthetic, and obstetric providers (SAOPs) per 100,000 population in LMICs by 2030. This figure must be compared to the U.S. \$20.7 trillion loss in global economy that surgical conditions would be responsible for.

Recent studies have shown that essential surgical conditions account for about 18% of the global burden of disease. Investment in essential surgical services is critical and should be done early in the path towards universal health coverage (UHC). The barriers to essential surgical services in LMICs are formidable. The shortage in surgical workforce is huge, and it is clear that the deficit cannot be satisfactorily addressed without task sharing. Infrastructure deficits (clinics, hospitals, equipment, drugs, blood banks, etc) are equally enormous. The first (district) hospital is the important platform for delivery of essential surgical services. The *DCP3* estimates that it would cost U.S. \$43 million annually of additional spending to provide universal coverage of essential surgery applicable to first-level hospitals worldwide.

Outreach and Engagement

Many models for outreach and engagement have had a positive impact on the accessibility of surgery. Organizations participating in outreach are guided by a wide range of motivations and resources (Fig. 49-13). Some organizations are purely humanitarian and service oriented; others are primarily educational. Some even use the promise of healthcare to advance political, religious, or personal agendas.

Many patients have benefited from the multitude of service-oriented volunteer “missions” providing much needed surgical care that would otherwise have been unavailable. While volunteerism and medical missions provide needed clinical surgical care for underserved populations, they may not be a sustainable solution to long-term manpower shortages for health.⁷⁵ Comprehensive initiatives are necessary to engage local healthcare professionals and organizations, governments, and academic institutions to build sustainable capacity.⁷⁶

Charitable Surgical Delivery Platforms. A significant burden of surgical disease is addressed through charitable organizations. The *DCP3* divides these charitable surgical delivery platforms into two types: temporary delivery platforms and specialty surgical hospitals (Table 49-3).⁷⁷

Short-term charitable surgical platforms bring entire surgical teams along with equipment and supplies needed to operate in local facilities for a short period of time. Local physicians provide the majority of follow-up care.⁷⁸⁻⁸⁰ Self-contained platforms bring the entire surgical infrastructure (fully functional operating rooms, postoperative recovery capability) through various modes of transportation: airplanes, ships, trucks, and buses. These self-contained platforms tend to stay in-country longer, may still provide short-term care, and tend not to leave behind any physical structure.^{78,80,81}

Little information exists on outcomes and cost-effectiveness of these temporary surgical platforms. Where no other services

exist, they may provide needed services. However, some of these charitable organizations report higher complications rates in lower-resource settings, which seem to increase even more with complex procedures. Some of these platforms include education for local care providers along with clinical care. While some question their ability to sustainably train local surgical teams, one charitable partnership with short-term, concentrated surgical training trips over 9 years documented a countrywide transition from open cholecystectomy to laparoscopic cholecystectomy in Mongolia.⁸²

Specialty surgical hospitals establish entire hospitals or facilities within existing hospitals. Some target specific diseases (Addis Ababa Fistula Hospital) while others provide a wide range of surgical and medical services (Pan-African Academy of Christian Surgeons [PAACS] mission hospitals); many are supported through partnerships with various charitable and governmental organizations.⁷⁷

International Organizations

United Nations. Committed to maintaining international peace, developing friendly relations between nations, and promoting better standards of living (conquering hunger, disease, and illiteracy) and human rights, representatives from 51 nations in 1945 signed the United Nations (UN) Charter at the United Nations Conference on International Organization in San Francisco, California.⁸³ There are now 193 member states.⁸⁴ The UN promotes a social justice agenda advocating for worldwide health, engagement of philanthropies, and civil society in global health initiatives, and it supports the sustainable development goals (SDGs).⁸⁵

Sustainable Development Goals. In September 2000, the UN led a worldwide, organized effort to set benchmarks for social, economic, and environmental development. Leaders from 189 countries agreed on eight specific “millennium development goals” (MDGs), spanning poverty, mortality, education, sustainability, and development.⁸⁶

The MDGs created a framework for improvement that some criticized as unattainable; nevertheless nearly 1 billion people were lifted out of extreme poverty, and primary education for girls made measurable improvements.⁸⁷ Still, many challenges, including some related to lack of surgical care, remained. In 2015, the UN General Assembly reconvened to raise the bar yet again, in what was declared a “supremely ambitious and transformative vision.”⁸⁸ Eight MDGs became 17 SDGs with 169 specific

Table 49-4

Sustainable development goals

1	No poverty
2	Zero hunger
3	Good health and well-being
4	Quality education
5	Gender equality
6	Clean water and sanitation
7	Affordable and clean energy
8	Decent work and economic growth
9	Industry, innovation, and infrastructure
10	Reduced inequalities
11	Sustainable cities and communities
12	Responsible consumption and production
13	Climate action
14	Life below water
15	Life on land
16	Peace, justice, and strong institutions
17	Partnerships for the goals

targets, to be achieved by 2030 (Table 49-4).⁸⁵ Most relevant to the global surgeon is SDG #3, “good health and well-being,” which builds upon the MDGs’ primarily maternal- and child-mortality focus, as well as communicable disease prevention. SDG #3 broadens the focus to nine health targets, including a one-third reduction in deaths by noncommunicable diseases, as well as halving the rate of deaths and injuries from road traffic accidents by 2020. In addition, a novel push to strengthen and retain the global health workforce and systems for protection and prevention of disease also falls squarely within the realm of the surgical provider. Finally, the SDGs have garnered praise for closely involving local stakeholders, versus the expert consensus that produced the MDGs. Funding to work towards achievement of the SDGs is also divided between wealthier and poorer nations, whereas the MDGs relied primarily on funding from HICs to support their mission.⁸⁹

World Health Organization. The initial UN Conference in 1945 voted to establish a new international health organization. The Constitution of the World Health Organization (WHO) was approved and ratified in 1948.⁸³ The first World Assembly in 1948 established malaria, tuberculosis, venereal diseases, maternal and child health, sanitary engineering, and nutrition as WHO priorities. One of the WHO’s greatest public health stories is the worldwide eradication of smallpox that began with the USSR proposal for the WHO-led program in 1958 culminating in the last identified case in Somalia in 1977.

While the disease burden from communicable diseases has abated in large part from these successful international cooperative interventions, little has been done to address the growing global burden of surgical disease. Despite the laudable aims of the 1978 Declaration of Alma Alta, which expressed the need for urgent action for the world community to protect and promote health for all people, the declaration did so by crowning primary health care as the key to achieving the goal of health for all—which was then accepted by the member countries in the World Health Organization.⁹⁰ Although the Alma Ata slogan

Figure 49-14. Emergency and essential surgery: an integral component of primary care. (Reproduced with permission from *The World Health Report 2008—primary Health Care (Now More Than Ever)*. <http://www.who.int/whr/2008/en/>.)

“health for all by 2000” did not materialize, it did galvanize efforts for global partnerships for healthcare improvements and poverty reduction. In 2015, the World Health Assembly (WHA) published resolution WHA 68.15, which proclaimed surgical and anesthesia care as a crucial component of primary care worldwide—for the first time in history. The resolution urged member states to complete nine actions, including prioritizing a core set of emergency and essential surgery and anesthesia services at the primary care level, ensuring access to essential medications and infection control techniques, and developing policies for providers’ minimum skills, among others. Additionally, the Director-General of the WHO was asked to complete ten actions related primarily to policy- and advocacy-related endeavors at the international level. The resolution was voted in unanimously by 194 member states.⁹¹

The Violence and Injury Prevention Program (VIP) and the Global Initiative for Emergency and Essentials Surgical Care (GIEESC) are two programs related to surgery within the WHO that began before 2008. But as a response to a growing recognition of the significant unmet surgical need, in 2008 the WHO for the first time included basic surgery as a component for community primary health care (Fig. 49-14).⁹²

The Global Initiative for Emergency and Essential Surgical Care. The Clinical Procedures (CPR) team in the WHO Department of Essential Health Technologies (EHT) convened a multidisciplinary group of experts from various surgical disciplines, professionals, and civic leaders from national and international organizations, as well as representatives from various WHO departments, in December 2005 in Geneva, Switzerland to formally organize the Global Initiative for Emergency and Essential Surgical Care (GIEESC).⁹³ GIEESC’s main aim was to assist member states with capacity strengthening in the safe

and appropriate use of emergency and essential surgical care (procedures, equipment) at resource-limited healthcare facilities through training and education programs. The training program was built around the WHO Integrated Management of Emergency and Essential Surgical Care (IMEESC) tool kit.⁹⁴ The tool kit included best practice protocols, guidelines on policies, training curriculum, emergency equipment, teaching slides, and monitoring and evaluation instructions. Additionally, low-cost editions of the manual *Surgical Care at the District Hospital* have been made available in local languages. As of 2015, GIEESC had over 2100 members in 140 countries.⁹⁵ A Mongolian edition facilitated early expansion of GIEESC throughout the country. Mongolia has improved basic infrastructure, human resources, and capabilities; and the use of the tool kit system has led to its incorporation into the countrywide healthcare plan⁹⁶ (**Box: Mongolia GIEESC**).

Mongolia GIEESC

The WHO situational analysis tool, developed in 2007 to assess the availability of emergency and essential surgical care (EESC) at individual health facilities, has been utilized to document limited infrastructure, human resources, procedures, equipment, and supplies available for even basic EESC in many countries.⁹⁵ For example, there were no trained surgeons or anesthetists at 44 first-referral hospitals in Mongolia.³ Only 66% of the facilities had electricity, and 45% had running water (Fig. 49-15).

Most facilities lacked any policy for EESC, disaster preparedness, basic equipment to provide EESC, or any

Figure 49-15. First Level (Soum) Hospital (left); Suturing of lacerated tongue by natural light (right). (Reproduced with permission from *Intermountain Healthcare*. Photo contributor: Raymond R. Price, MD.)

access to training for EESC. Adopting a health systems strengthening approach to rectify these glaring deficiencies, Mongolia implemented a nationwide EESC program involving 14 of the 21 provinces (Aimags) from 2004 to 2010 (Fig. 49-16).⁹⁶ In 6 years, dramatic improvements in short-term process measures were identified using the WHO Monitoring and Process form: 57.1% increase in availability of emergency rooms; 59.1% increase in the supply of emergency tool kits; and a 73.6% increase in the recording of emergency cases (Figs. 49-17 and 49-18).⁹⁶ More importantly, countrywide morbidity and mortality dropped significantly (Fig. 49-19).⁹⁷

Violence and Injury Prevention. The Violence and Injury Prevention (VIP) program promotes numerous activities to assist countries to prevent and mitigate the consequences of violence and injury.⁹⁸ While injury prevention is paramount, VIP provides guidance for strengthening trauma systems in countries of all economic levels to improve emergency care and rehabilitation. VIP encourages development of systematic data collection and analysis to better guide appropriate interventions. Prevention programs include the WHO Helmet initiative, while the Essential Trauma Care Project (EsTC) creates standards for the care of injured patients and promotes systematic capacity building. VIP advocates support for the UN Decade of Action for Road Safety 2011–2020 and initiatives to achieve SDG 3.6,

Figure 49-16. EESC Project: Mongolia 2004–2010. halving the number of global deaths and injuries from road traffic accidents by 2020, and SDG 11.2, which aims to provide access to safe, affordable, accessible, and sustainable transport systems for all by 2030.⁹⁹

WHO Safe Surgery Saves Lives Initiative. Surgeons have always sought ways to prevent perioperative complications. Aseptic technique, one of the greatest forms of prevention in surgical care, requires vigilant reinforcement to prevent serious wound infections. In resource-limited areas inadequate perioperative monitoring, lack of critical medications, and poor documentation place patients at increased risk for serious complications. The WHO Safe Surgery Saves Lives Initiative is a worldwide attempt to prevent perioperative complications.¹⁰⁰

Deaths from surgery occur at 0.4% to 0.8% globally; however, they may exceed 5% to 10% in developing countries. There are about 1 million deaths and 7 million disabling complications related to surgery worldwide, 50% of which are estimated to be preventable. The WHO Safe Surgery Saves

Lives initiative targets preventable surgical injuries.¹⁰⁰ The initiative identified 10 basic and essential objectives that can help prevent perioperative injuries (Table 49-5).¹⁰¹ A simple, three-stage checklist (initiated as the patient enters the operating room, just before the procedure, and just prior to the patient leaving the room) implemented in eight high-, middle-, and low-income countries found a 50% reduction in the failure to meet basic safety standards resulting in a 50% decrease in mortality (Fig. 49-20).¹⁰²

Global Surgery and Public Health

Surgical care is increasingly recognized as an integral component of public health. Traditional teaching portrays surgery as the antithesis of public health: treating the individual instead of the community, reactionary instead of preventative, and too expensive especially for countries with developing economies. Yet in reality, surgery and public health share many priorities and would benefit from greater integration in many areas (Fig. 49-21). For example, providing access to obstetrical care or birth attendants for every delivery could

Figure 49-18. Pilot Soum hospitals' evaluation 2 years post training. (Reproduced with permission from Henry JA, Orgoi S, Govind S, et al: *Strengthening surgical services at the soum (first-referral) hospital: the WHO emergency and essential surgical care (EESC) program in Mongolia*, World J Surg. 2012 Oct;36(10):2359-2370.)

prevent the majority of vesicovaginal fistulas and markedly decrease the most common cause of maternal death—hemorrhage—for entire communities. Ninety percent of mortality from injury occurs in LMICs, providing another area for

surgical teams to lead preventative, population-based strategies to improve public health.¹⁰³ Male circumcision is another example of a well-documented preventative, minor surgical procedure, capable of reducing the transmission of HIV.^{104,105}

Table 49-5

Ten basic and essential objectives for safe surgery (WHO*)

1. Operate on the correct patient at the correct site
2. Use method known to prevent harm from anesthetic administration, while protecting the patient from pain
3. Recognize and effectively prepare for life-threatening loss of airway or respiratory function
4. Recognize and effectively prepare for risk of high blood loss
5. Avoid inducing any allergic or adverse drug reaction known to be a significant risk for the patient
6. Consistently use method known to minimize risk of surgical site infection
7. Prevent inadvertent retention of instruments or sponges in surgical wounds
8. Secure and accurately identify all surgical specimens
9. Effectively communicate and exchange critical patient information for the safe conduct of the operation
10. Establish routine surveillance of surgical capacity, volume, and results

*WHO: World Health Organization.
Data from WHO Guidelines for Safe Surgery 2009.

Even after Learmonth presented his landmark lecture in 1949 “The Contributions of Surgery to Preventive Medicine” at the University of London’s Heath Clark Lecture series, surgery has been neglected as a component of public health.^{106,107} *DCP3*

Figure 49-21. Overlapping priorities of surgery and public health. (Reproduced with permission from Intermountain Healthcare.)

devotes an entire volume to essential surgery, emphasizing its importance as a key part of health worldwide.⁷ There are three significant developments helping to accelerate the integration of surgery and public health:

1. Improved understanding of the burden of surgical disease and its significant component of the overall burden of global disease
2. Recognition that surgery has a primary, secondary, and tertiary preventative role (Table 49-6)
3. Documentation that surgical care can be cost-effective for community-based healthcare

Table 49-6

Prevention strategies

PREVENTION STRATEGY	TARGET	GOAL
1. Primary	Root causes of disease	Eliminate or reduce risk of developing illness
2. Secondary	Illness or disease at earliest stages	Limit progression of disease
3. Tertiary	Disease at later stages	Cure or limit the effect of existing disease

Data from deVries C, RR Price: *Global Surgery and Public Health: A New Paradigm*, 1st ed. Sudbury, MA: Jones & Bartlett Learning, LLC; 2012.

Strategies for Integration of Global Surgery and Public Health. Three areas stand out as opportunities for integration of global surgery and public health: education, professional societies, and multinational health policy organizations. From an education standpoint, several universities in HICs have developed formal programs for the study of surgery and public health.^{108,109}

Diseases commonly present in very late stages in LMICs and in disadvantaged populations in developed countries. Many morbid conditions could have been cured while localized in their earlier stages and likely eradicated by a local surgical procedure. Early recognition and treatment of surgically correctable diseases is a critical preventive role for surgery. Many surgical procedures are not only a form of tertiary prevention, but are also forms of primary prevention (Table 49-7).¹¹⁰

Assigning Disease Priorities. Global surgery interventions can be prioritized to identify those conditions in which clinicians and public health professionals should collaborate most closely—targeting those diseases that impose the largest burden on a society and have a highly successful surgical outcome (Table 49-8).^{94,111} There are four broad, high-priority areas where surgery has an important role for public health interventions:

Table 49-7

The role of surgery for primary prevention of cancer

TERTIARY SURGICAL PROCEDURE	PRIMARY CANCER PREVENTED
Breast lumpectomy for ductal carcinoma in situ	Breast
Colonoscopic polypectomy	Colon
Colposcopy and excision	Cervical
Resection of actinic keratosis	Skin
Resection of leukoplakia and erythroplakia	Oral

Data from Riviello R, Meara JG, Rogers SO. Commentary: Cancer Care and Control—the role of surgery. *Global Surgery and Anesthesia*, 2010. <http://www.ghdonline.org/surgery/discussion/cancer-care-and-control-the-role-of-surgery/>.

Table 49-8

Prioritization of surgical conditions

PRIORITY*	PUBLIC HEALTH BURDEN	SURGICAL PROCEDURE SUCCESSFUL	COST-EFFECTIVE AND FEASIBLE TO PROMOTE GLOBALLY
1	High	Highly	Highly
2	Moderate	Moderately	Moderately
3	Low	Neither highly or moderately	Low

*Priority one implies that all three conditions must be met. The priority should be shifted to 2 or 3 if any of the conditions are moderate or low. Data from Mock C, Cherian M, Juillard C, et al: Developing priorities for addressing surgical conditions globally: furthering the link between surgery and public health policy, *World J Surg*. 2010 Mar;34(3):381-385.

trauma care; obstetrical emergencies; acute-surgical emergencies; and nonacute surgical conditions that significantly affect the quality of life (Table 49-9).¹⁰

Trauma Care. The Essential Trauma Care Project (EsTC) begun in 2001 is a collaboration effort between the International Association for Trauma Surgery and Intensive Care, an integrated society within the International Society of Surgery-Societe-Internationale Chirurgie (ISS-SIC) and the World Health Organization (WHO), specifically the Violence and Injury Prevention unit. The project culminated in a document that identified 11 core essential trauma care services (“the rights of the injured patient”) that ought to be available at all levels of healthcare facilities (Table 49-10).¹¹² In addition, the document delineated 260 human and physical resources that should be available based on the type of facility (Table 49-11).

Table 49-9

The role of surgery for public health strategies

Trauma care	Prevention of death and chronic disability by the provision of timely, expert, and complete surgical care
Obstetrical emergencies	Timely surgical intervention in obstructed labor, in pre- and post-partum hemorrhage, and other obstetrical complications
Acute surgical emergencies	Provision of competent surgery to treat a wide range of emergency abdominal and nonabdominal conditions
Nonacute surgical conditions	Surgical care for several elective conditions that have a significant effect on the quality of life such as cataract, otitis media, clubfoot, and hernias

Data from Jamison DT, Breman JG, Measham AR et al: *Disease Control Priorities in Developing Countries*, 2nd ed. New York, NY: Oxford University Press for the World Bank; 2006.

Table 49-10

Essential trauma care services

1. Obstructed airway appropriately maintained
2. Impaired breathing supported
3. Pneumothorax and hemothorax promptly diagnosed and treated
4. Bleeding promptly stopped (internal or external)
5. Shock recognized and treated appropriately (I.V. fluids)
6. Timely decompression of space occupying lesions to prevent secondary brain injury
7. Abdominal injuries diagnosed and promptly repaired (intestinal injuries and others)
8. Disabling extremity injuries corrected
9. Potentially unstable spine injuries identified and managed (early immobilization)
10. Minimize consequences of injuries by appropriate rehabilitative services
11. Medication to provide above services and relieve pain readily available

Data from Mock C, Joshipura M, Goosen J, et al: Overview of the Essential Trauma Care Project, *World J Surg.* 2006 Jun;30(6):919-929.

The EsTC recommendations provide a cost-effective framework for LMICs to improve their trauma care. These recommendations have been used as a planning guide and as an advocacy statement. To catalyze strengthening trauma and emergency care in low- and middle-income countries, in 2007, the WHA adopted a resolution on emergency care systems (resolution WHA 60.22).^{113,114} This first-ever WHA resolution dedicated specifically to trauma care highlights the importance accorded by world governments in caring for their injured.

Quality improvement programs provide inexpensive tools to strengthen trauma systems. National trauma registries,

Figure 49-22. Case fatality rates for severely injured people, 1998. Note: ISS = injury severity score. Income classifications are based on status at the time of the study. Ghana is now a lower-middle income country, and Mexico is an upper-middle-income country. (Reproduced with permission from Intermountain Healthcare.)

integral for trauma research, can be used to monitor and improve patient outcomes.^{115,116} Yet very few trauma registries exist in LMICs.^{117,118} The World Bank stated, “It is critical for LMICs to create or strengthen existing trauma systems to improve outcomes.”^{119,120} Trauma systems exist in varying states of development in different countries, and even within countries. Initiatives to strengthen trauma systems target the full spectrum of services: prevention, prehospital and definitive hospital care, rehabilitation, and process improvement and patient safety initiatives. Nearly 2 million lives could be saved each year if LMICs could design and implement simple trauma care initiatives that reduced the case fatality rates among seriously injured patients to equal those in HICs (Fig. 49-22).^{119,120} In one Canadian province, introducing simple prehospital

Figure 49-23. Improvement in mortality among severely injured patients in Canada through evolving interventions. Note: Inclusion criteria specified death as a result of injury or an injury severity score (ISS) exceeding 12, a prehospital index exceeding 3, two or more injuries with an abbreviated injury scale score of 3 or higher, or a hospital stay exceeding 3 days. (Adapted with permission from Liberman M, Mulder D, Lavoie A et al. *Implementation of a Trauma Care System: Evolution through Evaluation, J Trauma.* 2004 Jun;56(6):1330-1335.)

interventions and improving the focus on trauma at the policy level demonstrated consistent improvement in trauma-related morbidity and mortality, over a relatively short time period (Fig. 49-23).¹²¹

Obstetrical and Other Acute Surgical Emergencies.

Reduction of maternal deaths and long-term disability are high priorities for the international community.¹²² Despite the 44% reduction in maternal deaths from 1990 to 2015, approximately 830 women—mostly in LMICs—still die daily from preventable causes related to pregnancy and childbirth.¹²³ For every maternal death, 30 women are incapacitated by chronic problems that reduce their quality of life and ability to care for their families. High priority surgical procedures to improve maternal health include cesarean section, hysterectomy for postpartum bleeding and uterine rupture, management of ectopic pregnancy, and dilatation and curettage.¹¹¹ In 2015, the LCGS reported that maternal mortality was closely related to density of surgical, anesthetic, and obstetrical providers (SAOPs). They showed that maternal mortality throughout the world appeared to decrease—by 13.1% on average—for every 10 unit increase in SAOPs per 100,000 persons, a strong argument for addressing maldistribution of providers related to surgical disease.¹⁶

In terms of nonobstetrical acute surgical emergencies, about 90% could be addressed by developing the capability to care for the 10 most common acute surgical conditions in any local region. While a few types of disease processes vary by geographical location, there are many that are universal, including

appendicitis, strangulated hernia, small bowel obstruction, perforated peptic ulcer, fractures, lacerations, and wounds.

Nonacute Surgical Conditions. Even common nonacute conditions can have significant impact on the quality of life. Hernias can prevent otherwise healthy individuals from working, especially in societies where the economy relies heavily on manual labor. Cleft lip and cleft palate deformities interfere with the ability to speak or eat properly and predispose affected individuals to chronic ear infections leading to hearing loss. Many live in isolation because social ostracism prevents them from attending school, marrying, or holding jobs.¹²⁴ Plastic surgeons who pioneered global outreach for reconstructive procedures for cleft lip and palate opened the door for subsequent outreach by other specialties, including ophthalmology, orthopedics, general surgery, urology, and dentistry.¹²⁵⁻¹²⁷

The most common form of blindness is caused by cataracts. Cataracts decrease the quality of life and the socioeconomic status for both the blind person and his or her family. The fact that 90% of blind people no longer work reveals the extra burdens carried by the family members who care for them.¹²⁸ The Himalayan Cataract Project (HCP) is a highly successful initiative focusing on cataracts in Asia and Africa. HCP priorities and measurable outcomes illustrate how combining key public health concepts with a comprehensive approach to surgical care creates a model for curing disease, building economies, and delivering hope in resource-poor areas⁹ (**Box:** The Himalayan Cataract Project: A Sustainable Public Health Approach for Curing Blindness).

The Himalayan Cataract Project (HCP): A Sustainable Public Health Approach for Curing Blindness

According to the WHO criteria, 285 million people worldwide are visually disabled. Of that population, 39 million are classified as bilaterally blind; 90% live in the developing world where poor water quality, lack of sanitation, malnutrition, and inadequate services cause a higher incidence of eye disease.¹²⁸ The most common cause of avoidable blindness in LMICs is cataract (43%). Nepal has one of the highest incidences of cataracts partially due to increased exposure to ultraviolet sunlight encountered at its higher elevations; 62% of total blindness in Nepal is due to cataracts.¹²⁹

In 1995, Sanduk Ruit joined forces with Geoffrey Tabin to establish the Himalayan Cataract Project (HCP). In the early 1990s, difficult geography with inadequate transportation, the high cost of intraocular lenses, and a lack of trained ophthalmologists, assistants, and nurses limited access to cataract surgery for the poor.

HCP developed and defined six priorities, each with an associated public health principle and outcome measurement that provided the basis for assessing success and for implementing change (Fig. 49-24). HCP's care model targeted the entire population of blind people with cataracts regardless of the ability to pay. Since most of the potential patients lived in remote areas, HCP found it imperative to take cataract surgery to the local communities. The Tilganga Institute of Ophthalmology (TIO) in Katmandu, Nepal, has served as a base from which 493 doctors and over 19,000 ophthalmic personnel of all levels have received training since 1994. Through the TIO and its outreach programs, over 4,657,748 people have been screened, and more than 307,611 eye surgeries have been performed since 1994 (Fig. 49-25).¹³⁰

The TIO developed an ophthalmology residency training program implementing standards set forth by the American Academy of Ophthalmology. In addition to the formal residency program for ophthalmologists, HCP established training programs for community eye care workers in a three-year Ophthalmic Assistant Training Program.

Ruit developed an innovative sutureless technique for cataract surgery yielding equivalent results to those in developed countries but also reproducible in resource-constrained areas. By redesigning the intraocular lens implant and mass producing it locally in Nepal for U.S. \$4, Ruit and Tabin provided a low-cost alternative to the higher-priced lens produced in developed countries. A local business—the Fred Hollows Intraocular Lens Factory—mass produces the lenses and supports the local economy by creating a new sustainable business.¹³¹

HCP also designed a compassion-driven, culturally acceptable method for cost-recovery that involves a sliding scale for payment: 45% of patients pay U.S. \$120; 20% pay a smaller amount based on their economic situation; and 35% receive cataract surgery for free.

With the rapidity and scale of success experienced in Nepal, HCP and TIO began expanding their efforts globally. HCP is now actively working to replicate and proliferate their model in countries throughout South Asia and Africa by developing high-quality eye care systems, supporting local institutions, and training local doctors and ophthalmic personnel. Since 2005, HCP has trained over 300 ophthalmic personnel from 19 countries.

HCP priorities	Public health principles	Implementation
Humanitarian	Accessible	Entire population Care at local level
High quality	Appropriate	Care comparable to western standards Disease with high incidence/prevalence
Innovation	Disruptive technology	Designed \$4 lens Local business
Direct impact	Sustainable growth	Skills transfer Building infrastructure
Affordability	Affordable	Delivery model \$20 cost/cataract
Replication	Sustainability	Meet needs of current population Culturally and economically acceptable

Cancer Initiatives

Surgery for cancer in public health plays a role not only for curative surgery, but also for early diagnosis, prevention, and palliation.^{52,110,132,133} Solid tumors, in their early stages, presents insidiously as a nonacute surgical problem. Due to cancer's recent recognition as a leading cause of death, cancer has been identified as a health priority in LMICs. Most solid tumors are incurable without surgery and at a minimum require surgical excision of the primary lesion.¹¹⁰

It is often not appreciated that surgeons provide a significant amount of primary care and are the principle providers involved in endoscopic screening and treatment of gastrointestinal tumors in LMICs. In countries without specialized services, low-cost and effective treatment options combining early prevention and treatment with off-patent drug use have led to coverage of cancer treatment in several middle-income countries' national health insurance plans.⁵² Cancer care provides significant opportunity for including surgery in community-wide public health programs as a high priority according to the prioritization model (see Table 49-6); cancer has a high public health burden, is treated with highly successful procedures, and can be cost-effective and feasible globally. In 2009, a coalition of leaders in cancer care and public health organized the Global Task Force on Expanded Access to Cancer Care and Control in Developing Countries (GTFCCC).¹³⁴ GTFCCC's mission is to expand access to cancer prevention, detection, and care in LMICs. Successful partnerships have already been entered into Haiti, Rwanda, Mexico, Malawi, and Jordan.

Cost-Effectiveness of Surgical Care. Funders in healthcare look for measurable return on their investments. While comparison of outcomes and objective measures would be ideal, reality demonstrates that healthcare budgets more commonly are dictated by politics rather than actual need. Nevertheless, in a world of limited resources and tightening budgets for healthcare, cost-effective analyses of various options for intervention are critical for policy makers. Comparing various options that have different outcomes is an approach called *cost-utility analysis (CUA)*. Surgical interventions can be evaluated by specific diseases or

conditions, or by systems or services required to support the delivery of surgical care. In 1990, the World Bank defined the Disability Adjusted Life Year (DALY) as the sum of Years of Life Lost (YLL) due to premature mortality in the population and the Years Lost due to Disability (YLD) for people living with the health condition or its consequences ($DALY = YLL + YLD$). Evaluating the cost per DALY averted is one approach for comparing the cost-utility between medical and surgical interventions. Recent surgical cost/DALY studies identifying the cost-effectiveness of various types of surgical care have allowed surgical initiatives to be considered when prioritizing public health initiatives.

The World Bank arbitrarily defined U.S. \$100 per DALY averted per day in low-income countries as highly cost-effective. Compared to other public health initiatives, developing basic and emergency surgical care at the district level hospital is as cost-effective as, or more so, than typical public health programs such as retroviral treatments for HIV/AIDS or immunization for measles (Fig. 49-26).¹³⁵⁻¹³⁹

Using the WHO's cost-effectiveness standards, investing in emergency obstetrical systems, including timely caesarean delivery, can also be considered "highly cost-effective" for 48 of 49 countries in which there are currently inadequate numbers of cesarean deliveries.^{140,141} The median cost per DALY averted by cesarean-section was \$304. In addition, the cost-benefit ratio in 46 of 49 countries was >1 , suggesting that investment in caesarean delivery is a viable economic proposition.

Inguinal hernia repair is one of the most common operations performed worldwide. Tension-free inguinal hernia repairs performed with mosquito netting or polypropylene mesh were cost-effective in Western Ecuador and Western Ghana (\$78.18 per DALY and \$12.88 per DALY averted, respectively).^{136,142} Using mosquito netting in India was 3700 times cheaper than using traditional polypropylene mesh.¹⁴³

Using "value of lost output" (VLO) data representing 90% of the world's population, it is estimated that U.S. \$20.7 trillion would be lost between 2015 and 2030 due to unmet surgical needs and their inherent morbidity and mortality.¹⁴⁴ Projected

Figure 49-26. Cost-effectiveness of surgical interventions, compared to two key medical interventions. Note: DALY = disability-adjusted life year. (Reproduced with permission from Intermountain Healthcare.)

economic losses of such magnitude have underlined the importance of prioritizing surgical infrastructure and the cost-effective nature of many interventions within the surgical realm.

Factors Affecting Utilization and Outcome for Surgical Care. There are three major factors that severely limit utilization of surgical services:

1. Socioeconomic and cultural factors
2. Accessibility of facilities
3. Quality of care (Fig. 49-27)¹⁴⁵

The decision to seek timely care is affected by the costs associated with time off from work and inability to support the family during the absence, transportation and lodging, and the surgical services themselves. Cultural and religious traditions may define acceptability of various treatment options. For example, many people in Mongolia refuse to have surgery on Tuesdays as this is viewed as a “bad luck” day. Understanding local customs and cultural concerns can improve utilization of surgical services.

At the intersection of cost and culture are “willingness to pay” (WTP) models, which predict how a society’s perceived

costs of obtaining care versus tolerating a medical condition will lead to or prevent them from seeking care. Such calculations can inform which policies are most likely to yield improved health for a country or region, and they rely heavily on per capita gross domestic product (GDP) and DALYs averted. It is vital to understand that these models, and the policies they inform, are context-dependent. What is perceived as socially valuable in Tanzania may be seen as overpriced or unnecessary in Haiti. As global surgical advocates work with public health experts to strengthen surgical systems, it will be important to remember that context, culture, and cost are indivisible from one another.¹⁴⁶

Austere environments, difficult terrain, and long distances from health care facilities significantly delay or prevent access to surgical care. Triage and transfer guidelines along with telemedicine have the potential to mitigate the limitations of geography. However, without adequately trained care providers and support staff, the risk for poor outcomes is increased.

Recognizing these three important factors for increasing utilization and outcomes, Mongolia initiated a public health approach for the management of gallbladder disease incorporating minimally invasive surgery (**Box:** The Public Health Approach to Management of Gallbladder Disease in Mongolia).

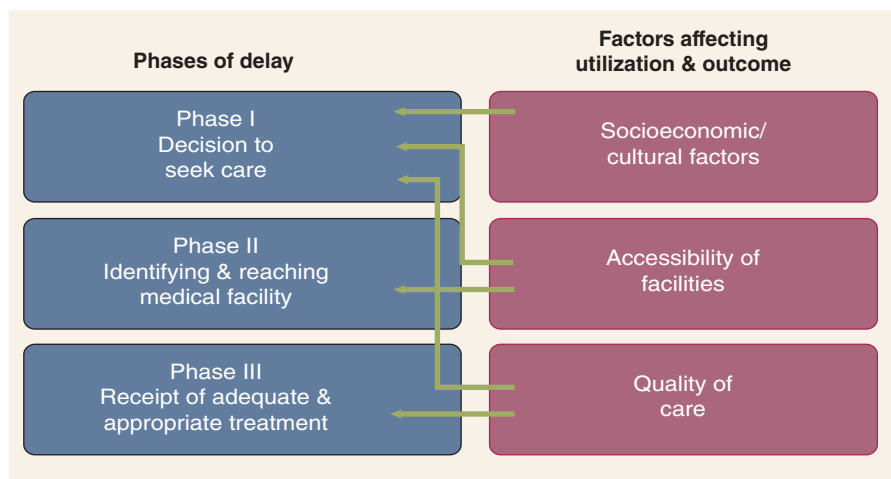

Figure 49-27. Factors affecting utilization and outcome of surgical care. (Adapted with permission from UNFPA United Nations Population Fund (UNFPA); Setting standards for emergency obstetric and newborn care; Available from: <https://www.unfpa.org/resources/setting-standards-emergency-obstetric-and-newborn-care>. Illustration reproduced with permission from Intermountain Healthcare.)

The Public Health Approach to Management of Gallbladder Disease in Mongolia

Mongolia, the most sparsely populated country in the world, covers a large geographic area nestled between China and Siberia.¹⁴⁷ The austere environment with extremes of weather, dry deserts, and high mountains present significant obstacles for road building limiting transportation for patients in the vast rural areas (Fig. 49-28). Significant deficiencies in infrastructure, supplies, equipment, and human resources at primary healthcare facilities exist: sporadic electricity, no fully qualified surgeons or anesthesiologists, and less than half the facilities with running water.³ In 2006, Healthcare expenditures reached only U.S. \$23.2 per capita.^{148,149}

The second most common cause of inpatient morbidity in Mongolia has transitioned to gastrointestinal diseases with liver disease, appendicitis, and gallbladder disease the top three causes.¹⁵⁰ While laparoscopic cholecystectomy was introduced in Mongolia in 1994, by 2005 only 2% of gallbladders were removed laparoscopically, and then, only in the capital city.¹⁵¹ A cohort study in 2005 comparing open with laparoscopic cholecystectomy by Dr. Sergelen, the chief of surgery at the Health Sciences University of Mongolia (HSUM), found the wound infection rate to be significantly lower, hospital stays shorter, and hospital expenditures 50% less with laparoscopy compared to open cholecystectomy.¹⁵²

Dr. Sergelen formulated a plan to expand access to laparoscopic surgery throughout Mongolia. This plan targeted the three main areas affecting utilization and outcome:

1. Quality of Care:
 - a. Develop a laparoscopic training didactic and practical course to train surgical teams and transfer skills safely.
 - b. Improve the surgical infrastructure for each facility.
 - c. Expand the surgical residency to include laparoscopic training.
2. Accessibility of Quality Care:
 - a. Begin training surgical teams in the capital city, but then expand them to four carefully selected regional diagnostic treatment and referral centers (RDTRCs) in all four quadrants of the country.
 - b. Invite industry to offer cost-affordable supplies and replacement parts to sustain the laparoscopic equipment in Mongolia.
3. Socioeconomic/Cultural Factors:
 - a. Educate the public on the increased benefits of laparoscopic surgery so they would initiate lobbying efforts demanding the government increase funding for these services.
 - b. Educate government leaders about the need and benefit of laparoscopic cholecystectomy for the Mongolian people.

The strategic initiative that began by expanding laparoscopic cholecystectomy within the capital city and then to the four key Regional Diagnostic and Treatment Referral Centers (RDTRCs) created the foundation for countrywide access to high-quality modern surgery for a regionally prevalent disease (Fig. 49-29).^{147,153}

In 2011, through a multinational partnership (HSUM, the Dr. WC Swanson Family Foundation (SFF), the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), and the University of Utah Department of Surgery), Mongolia experienced a

Figure 49-28. Rural Ger. (Used with permission from Michelle K. Price.)

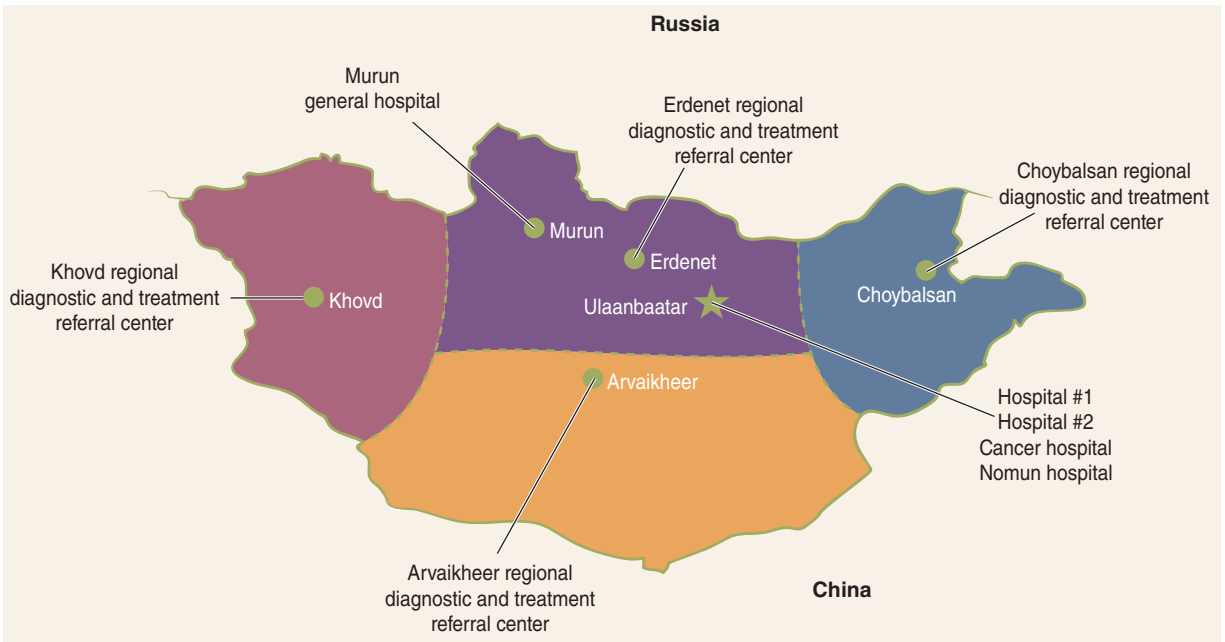

Figure 49-29. The public health approach to expanding laparoscopy to the regional diagnostic treatment and referral centers of Mongolia (RDTRCs). (Reproduced with permission from Intermountain Healthcare.)

dramatic transformation from open to laparoscopic cholecystectomy; laparoscopic replaced open cholecystectomy and became the primary method to remove the gallbladder in Mongolia (Fig. 49-30).¹⁵⁴

As people began to see their neighbors return to functional ability faster with the laparoscopic approach, the Mongolian people developed increased trust in their healthcare providers and the quality of care they could receive. The Ministry of Health committed increased funding for laparoscopic surgery and changed existing laws making it easier for hospitals to purchase the needed equipment and supplies solidifying the needed financial and business models to support laparoscopic surgery in Mongolia.

By 2016, with the introduction of laparoscopic training into the surgical residency program and development of laparoscopic fellowship training for surgical teams from outlying provinces, 17 of 21 provinces now provide laparoscopic cholecystectomy allowing patients the benefits of less pain, smaller incisions, fewer wound infections, and more rapid return to work (Fig. 49-31).

Figure 49-30. Transition from open to laparoscopic cholecystectomy in Mongolia. (Reproduced with permission from Wells KM, Lee YJ, Erdene S, et al: Building operative care capacity in a resource limited setting: The Mongolian model of the expansion of sustainable laparoscopic cholecystectomy, Surgery. 2016 Aug;160(2):509-517.)

Integrating Value into Global Surgery

Another topic closely related to quality is the concept of value in healthcare, often described in terms of the *value equation*. The value equation states that value equals quality plus service, divided by cost. In this model, systems that generate high-quality care, at lower costs, produce greater value for stakeholders in that system (i.e., patients, physicians, insurers, and hospitals). This discussion is most pertinent in high-income countries such as the United States, where rising healthcare expenditures are cause for worry. It is also relevant in LMICs, where proposed interventions to improve quality must also control cost. A bidirectional exchange of information related to surgical systems between HICs and LMICs may provide one strategy for reduction of cost in HICs and maximization of quality in LMICs.

Advanced Surgical Care for Resource-Poor Areas

Limited financial, physical, and human resources, political and social conflicts, and austere environments cause many to believe that advanced surgical care is inappropriate in resource-poor countries.^{111,155-157} Misconception of the needs and abilities of people in LMICs cause some policymakers to discount the desire of people worldwide for advanced surgical care.¹⁴⁴ Developing these capabilities in resource-poor countries has the potential to decrease overall cost and actually develop the infrastructure necessary to entice physicians and other healthcare workers to remain in their own countries. Establishing advanced surgical care requires expertise and services that symbiotically support and improve general medical care. Therefore, many developing countries are actively building capacity and capability to provide the full spectrum of modern surgical care locally.¹⁵⁸

As economies improve and the benefits of laparoscopic surgery for resource-poor areas become better delineated, patients and doctors, surgical societies, ministries of health, and industries are demanding the benefits of minimally invasive surgery for patients and communities.^{150,159-165} The economic impact of laparoscopy may be even greater in LMICs than in developed countries.¹⁶⁶ Worldwide, surgeons have identified laparoscopic training as one of their greatest needs. In a 2010 survey, developing laparoscopic and endoscopic skills were identified as the most important skills desired by surgeons from the West Africa College of Surgeons (WACS) (Fig. 49-32).¹⁶⁷

Transplantation is another area of great interest to people in poor countries partly because of the high prevalence of kidney failure and because chronic dialysis facilities are limited. Hepatoma and liver failure are very common in countries with a strong prevalence of hepatitis B and C. Transplantation has become the treatment of choice for end-stage kidney disease in developed countries as it dramatically improves the quality of life and increases survival rates compared to medical management.¹⁶⁸ Yet, transplantation eludes most of the developing world. Initial attempts to transport critically ill patients from LMICs to developed countries for kidney transplantation were cost-prohibitive.¹⁶⁹ With the alarming increase in the rate at which young people have been presenting with kidney disease in developing countries, the increased utilization placed on the few dialysis machines has been overwhelming.¹⁷⁰ Dialysis units which previously were utilized three times a week, now operate 24 hours a day, 7 days a week, and cannot begin to provide the needed services to the multitudes needing treatment. Even programs to develop peritoneal dialysis cannot fully ease the demand.

Figure 49-32. West African College of Surgeons: most desired skills. CT = computed tomography; MRI = magnetic resonance imaging. (Adapted with permission from Akporiaye L. Trigen survey: West African College of Surgeons. Trigen, Lagos, Nigeria. Unpublished data. 2010. Illustration reproduced with permission from Intermountain Healthcare.)

The majority of kidney transplants in developing countries are from living related donation because of cultural and legal prohibitions precluding cadaveric transplantation. Laparoscopic living related donation has the potential to increase the voluntary donor pool as patients have less postoperative pain, return to work and activities quicker, and have much better cosmesis than open surgery.¹⁷¹ Ethical concerns exist for nonrelated donations, however, because of concern for coercion in some countries. Adapting to the limited resources, surgeons have described various cost-saving techniques to facilitate the laparoscopic approach in resource poor areas, such as using endoclips instead of staplers for vascular control, modifications to the surgical approach, and suprapubic extraction of the kidney rather than endocatch removal.¹⁷¹⁻¹⁷³

Academic Global Surgery

There has been a paradigm shift from traditional reliance on intermittent short-term volunteerism toward a strengthening of the education and research pillars for surgical healthcare in developing regions, a role ideally suited for academic surgery. Global surgery is emerging as a new academic field of endeavor (Table 49-12). Academic institutions have historically pioneered discovery in disease causation and treatment. As globalization expands, academic surgical programs are beginning to respond by broadening their vision and mission. This vision and mission includes interdisciplinary and collaborative approaches to designing innovative, affordable surgical care that is accessible to all through research, education, development, and advocacy.^{174,175}

Responding to the challenges of disparities, new generations of students, faculty, philanthropists, private industry leaders, and policymakers have demonstrated a growing passion to address global surgery as part of global health.^{176,177} Prior

to 1984, only 0.32% of physicians and 0.12% of nurses were involved in international health (either paid or volunteer).¹⁷⁸ Recently, interest in global health has exploded among medical students, residents, and faculty in the United States.^{179,180}

Table 49-12

Examples of academic global surgery programs

INSTITUTION	NAME OF GLOBAL SURGERY CENTER
Brigham and Women's Hospital	Center for Surgery and Public Health
Emory University School of Medicine	Global Surgery Program
Harvard Medical School	Program in Global Surgery and Social Change
King's College London	King's Center for Global Health and Health Partnerships
McGill University	Centre of Global Surgery
Oregon Health and Sciences University	Global Health Advocacy Program in Surgery
University of British Columbia	Branch for International Surgical Care
University of California San Francisco	Center for Global Surgical Studies
University of Chicago	Global Surgery Program
University of Utah	Center for Global Surgery

Academic involvement in global surgery provides training for the next generation of surgical leaders where they can learn the necessary skills to develop systems for quality and affordable surgical care, both locally and internationally. Leaders for the 21st century will need to know how to provide outstanding cost-effective clinical care for all environments.

Global Surgery programs use a variety of methods to engage faculty, residents, and students to foster an environment of creativity and innovation necessary to generate new ideas for solving some of the most vexing problems in global health. For example, some academic collaborative programs introduce medical, engineering, and business students to the fascinating world of medical device innovation focusing on a variety of communities with very limited resources.^{181,182} Other academic endeavors include global surgery resident rotations, fellowships, journal clubs, classes (locally and online), certificates, Masters of Public Health, bilateral exchange programs, and a variety of educational, research, and entrepreneurial meetings (local, national, and international). Many of these activities provide opportunities for collaborative scholarly work (journal publications, books, book chapters, films, grants, research trials) that present new avenues for academic advancement supporting both colleagues from abroad as well as the home institution. More importantly, Ministries of Health are responding to results of these scholarly works by designing policies that include surgical care in their countrywide health plans.

Partnering academic programs from high-income countries with LMICs and/or with NGOs provides opportunities for collaboration¹⁸³ (**Box:** Academic Global Surgery

Figure 49-33. Training outcomes from NGO/academic partnership. (Reproduced with permission from *IVUmed and Intermountain Healthcare*.)

Partnerships). Global surgery engagements exist along a continuum from simple associations, to alliances, collaborations, or formal partnerships (Fig. 49-33). A true partnership usually involves specified and joint rights and responsibilities. The other engagements vary depending on the amount of integration between the institutions and organizations. Successful sustainable progress for global surgery can occur within any of the different levels of engagement. Many partnerships begin with a simple association or alliance before growing into a formal partnership.

Academic Global Surgery helped progress the foundational knowledge in defining the burden of surgical disease, clarifying the cost-effectiveness of surgical care, and establishing baseline values of surgical capacity.¹⁸⁴ Further work is necessary to move beyond data collection and to use this foundational knowledge to now develop interventional strategies and stimulate sustainable solutions for accessible, affordable, appropriate surgical care for all.¹⁸⁵

Academic Global Surgery Partnerships

A. Rwanda Human Resources for Health (HRH) Program

The Rwanda Human Resources for Health (HRH) program is an ambitious 7-year long program of the Ministry of Health (MOH) of Rwanda, funded by the U.S. Government and the Global Fund to Fight AIDS, Tuberculosis, and Malaria. The HRH Program seeks to greatly expand and improve Rwanda's health care workforce by strengthening national training programs of specialized physicians, nurses, oral health providers, and health managers. The HRH Program is also designed to strengthen the capacity of academic institutions in Rwanda to sustain the training programs initiated and supported by the HRH Program through (a) recruitment and retention of Rwandan faculty, (b) transfer of knowledge and skills to Rwandan faculty, (c) establishment of additional academic partnerships and collaborations between Rwandan academic institutions and U.S. academic institutions. Currently, 22 U.S. academic medical centers and universities are participating in this program, in collaboration with the University of Rwanda—College of Medicine and Health Sciences (UR-CMHS) training faculty. Since the launch of the program in 2012, U.S. institutions have deployed about 100 faculty members per year across these four health-related professions. The recruited U.S. faculty are twinned with UR faculty and senior trainees, paired along common goals and interests, and together they engage in a diversity of activities—including teaching, training, research, clinical care, and care delivery improvement projects.

The program is currently in its fifth year (August 2016–July 2017). Focusing our discussion on the surgical disciplines, the annual intake of postgraduate students (residents) has dramatically increased. The anesthesiology residency, whose annual matriculation ranged from zero to three residents, now routinely admits 10 new residents yearly. The surgery residency has divided into the four specialties of general surgery, orthopedics, urology, and neurosurgery. Annual matriculation across all for programs now ranges from 15 to 20 compared to 3 to 6, prior to the HRH program's support of the surgery department. In July 2016, UR graduated eight new general surgeons and one new urologist, the largest output to date. Similar training output is noted across the other disciplines and specialties as well. As a result, Rwanda is now on track to achieve most of its targets for the health workforce. Most graduates are deployed across provincial hospitals to provide specialty level care in a decentralized fashion, while a portion are maintained at the teaching hospitals to be recruited as new faculty. The HRH Program also aims to strengthen the quality of the training programs through competency-based training and pedagogic innovation, improvements in infrastructure and equipment within the schools at the CMHS and the teaching hospitals, and stronger administration of the training programs. As the HRH program comes into its final years, efforts are underway towards faculty professional development program that will both ensure that the UR-CMHS is able to

continue making the aforementioned human resource gains independent of this large foreign aid grant, and that the relationships and collaborations forged between academic institutions may continue to grow and find new avenues for productive work together.¹⁸⁶

—Robert Riviello, MD, MPH, FACS

B. Coordinating Nongovernmental Organizations (NGO) and Academic Organizations: IVUmed

Nonprofit organizations (NGO) have filled a niche in establishing surgical care in countries where training centers and healthcare systems are historically nonexistent or understaffed. More recently, professional organizations have developed a focus on specific diseases or patient groups and have become a resource for education and training in poor countries.

For more than 20 years, the IVUmed NGO has focused on urological education and hands-on training in Africa, Asia, and Latin America. IVUmed evolved from a need identified by plastic surgeons that had seen many children with hypospadias and other urological anomalies, such as exstrophy, when providing care for children with cleft lip and palate. Adult surgeons were not trained in the delicate reconstruction of pediatric genitourinary anomalies, and pediatric surgeons were not trained in endoscopic or reconstructive urological surgery. The program has expanded to support training in all aspects of urological care, including adult reconstruction, oncology, and endoscopic management of stones and prostatic disease.

As a nonprofit organization, IVUmed is a partnership between surgeons, anesthesiologists and nurses, academic medical centers, urological professional associations, industry, and the public with urologic surgery training in more than 20 countries. It also provides North American trainees scholarships to travel to low-resource countries to learn and to share knowledge gained in their own programs. Many former scholars become mentors for other residents when they complete their training. The sites with the longest collaborations have developed their own educational programs in general urology or subspecialty areas and are now providing advanced training and care locally (see Fig. 49-33).

C. Cancer Disparities Consortium in West Africa

Noncommunicable diseases, such as cancer, are a major public health problem in low- and middle-income countries (LMIC). In many LMIC, surgeons, due to the lack of medical oncologists, treat all stages of noninfectious related cancers, such as breast and colorectal cancer (CRC). In 2011, to address the disparity in outcomes for patients with cancer in West Africa compared to the United States, a research and training collaboration was formed between the Obafemi Awolowo University Teaching Hospital in Nigeria and Memorial Sloan Kettering Cancer Center (MSK) in New York. This relationship has now grown to become a consortium of five Nigerian hospitals and the Global Cancer Disparity Initiative Team at MSK.

The consortium began by focusing on important questions regarding CRC: how can early stage patients be identified; what are the demographics of CRC patients in Nigeria; and is the biology of CRC different in Nigeria compared to the USA? These questions are being answered, with the support of two NIH grants, by creating a robust prospective database with a matching biobank. With over 250 patients, the consortium can now describe the metastatic patterns, stages of presentation, and risk factors for CRC in West Africa. Given that over 65% of patients present with stage IV disease, the development of a risk model to identify patients with early stage disease is a priority. This is being accomplished with a 400-patient prospective trial of colonoscopy in patients over 45 years of age with rectal bleeding in three Nigerian cities. Future projects include studying new technologies for CRC and breast cancer screening.

—Peter Kingham, MD, FACS

Ethics

The ethics involved in working outside one's own country are complex. While a practitioner's scope of practice is usually constrained by regulation in America and Europe, in many countries the limits of what one can do are neither regulated nor enforced. Guidelines for what should be done, where, and under what circumstances are beyond the expertise of some ministries of health. Some problems are so episodic that they are not anticipated, and few guidelines exist. For example, in natural disasters and emergencies, should any willing provider from any country be granted permission to provide care? Should specific disaster-related training be encouraged or required?^{187,188} In the nonacute setting, should practitioners not licensed or credentialed in their home environments be allowed to perform volunteer surgery in other countries? What entity should oversee the flow of volunteer practitioners? Can a standard set of guidelines meet the needs of most countries? Currently, there is little cross-national agreement between state entities, like ministries of health and independent

organizations and individuals. While many countries require at least temporary licensure, some do not. In many cases enforcement is inconsistent.

With respect to research, the poor historically have not received benefit from research performed on them. In international studies, even local collaborators have been left out of study design and publication.¹⁸⁹ As internet communications have improved, these lapses are no longer tolerated.¹⁹⁰ Informed consent for surgical procedures, in the appropriate language and respectful of local customs, is becoming the norm. Few hospitals outside academic medical centers have institutional review boards (IRBs) to oversee the implementation and review of clinical research. In recent years, peer reviewed journals have become more mindful of attribution of credit, and authors are strongly encouraged to design and report studies with local input at all levels.

With regard to transplantation, many countries have laws against cadaveric transplants because of the very real concern for illegal marketing of organs. Even living-donor

transplantation has seen effects of coercion in some regions and for some populations such as prisoners. Nevertheless, the need and popular desire for transplantation is accelerating acquisition of skills and technology to make transplantation available worldwide.¹⁹¹

Finally, what is considered ethical in one country or community might be considered highly unethical in another. Consent for surgery may in one setting rest with the patient, but in another, with the community or family. Values about privacy vary markedly from region to region. Health information in many cultures is considered to be a community concern, not the personal property of an individual patient.

Innovation in Global Surgery

The pressing need for surgical care at all levels and the shortage of fully trained surgeons, anesthesiologists, and support personnel as well as equipment and supplies means that opportunities abound for innovation. Innovations in education, including simulation, can shorten the time necessary for learning technical skills. Gaming technology can teach algorithms for interpretation of X-rays and ultrasounds. Telemedicine/telehealth is transforming education through combinations of clinical case-based learning and massively open online courses (MOOC) (**Box: Telemedicine**). The potential for education innovation in surgery beyond the apprenticeship system championed by Halsted in 1904 is vast.

Telementoring in Global Surgery

One excellent example of successful telementoring in surgery is a program started by Allan Okrainec, MD, a minimally invasive surgeon at the University of Toronto, and Georges Azzie, MD, a pediatric surgeon at Toronto's Hospital for Sick Children. In the mid-2000s, the two imagined utilizing laparoscopic box trainers and videoconferencing technology via Skype to teach minimally invasive techniques to surgeons in LMICs.¹⁹² As part of the "Go Global" Initiative of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), Dr. Okrainec's team traveled to Botswana in 2007 to teach a 3-day Fundamentals of Laparoscopic Surgery (FLS) course in person. Although only two of twenty surgeons achieved certification, average posttest scores showed promising improvement.

Realizing that continued mentorship promotes success, Dr. Okrainec's team reconfigured their teaching model to include telesimulation. In 2009, they carried out an 8-week course in FLS, with weekly meetings via videoconference and real-time simulation demonstration and feedback between Botswana and Toronto. This time, 100% of participants in the tele-simulation group attained certification.¹⁹³ Subsequently, the team expanded its program to Colombia, with similar success in skill acquisition.¹⁹⁴ Since 2009, the program has expanded to 15 countries, with satellite telesimulation sites in Colombia and Ukraine. They have trained more than 300 individuals in FLS skills around the world.

Innovation that radically changes the way we do things and that changes a paradigm of a service or system is called "disruptive"; it abruptly changes an older and more expensive system in favor of a less expensive, more widely available

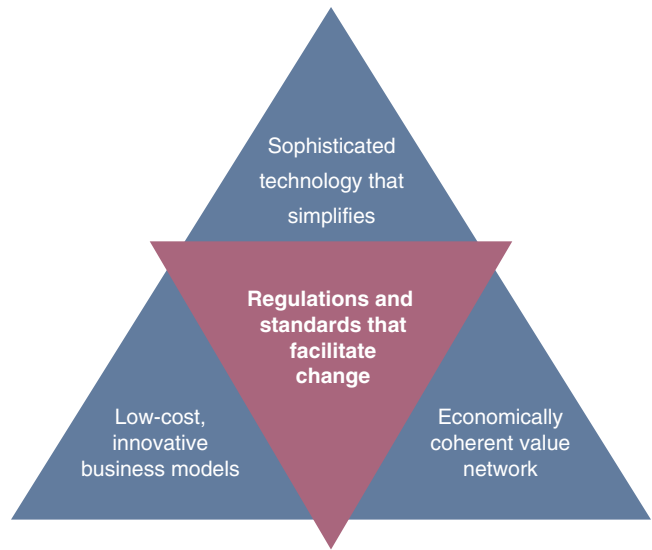

Figure 49-34. Elements of disruptive innovation. (Reproduced with permission from Intermountain Healthcare.)

technology or process. The ability for disruptive innovations to transform products and services into affordable realities requires three main factors: a sophisticated technology that simplifies, a low-cost business model, and an economically coherent value network (Fig. 49-34).¹⁹⁵

Regulations and standards that vary between countries and locales can facilitate or impede disruptive change. While disruptions often are not qualitatively superior to the status quo, they make the process both less expensive and more accessible, and through multiple iterations, ultimately improve quality as they cycle through the transformative process.

Decentralizing education, laboratory testing, and medical records have been made possible through free and open-source software, apps, and devices such as smart phones, tablets, and laptop computers. Monitoring and imaging devices and laparoscopic instruments designed for low resource environments have the potential to not only improve accessibility in poor countries but also to radically reduce surgical costs in wealthy ones.¹⁹⁶

THE FUTURE FOR GLOBAL SURGERY

Surgeons of the future will need to educate themselves in areas that have not historically been taught in surgical curricula. Beyond the technical aspects of surgical practice, there is a complex ecosystem that supports surgical care. Surgeons must become more aware of the complexities of cost in order to be able to shape the environment in which they work. They must understand better what patients are seeking from the surgical experience, rather than focusing primarily on a narrow view of what surgery might have to offer. Surgeons must engage in policy development and advocate for affordable and accessible surgical care without sacrificing quality. Thoughtful technology design can focus on improving quality and on decreasing cost, both in poor and wealthy countries. Building surgical capacity through a health systems-focused approach, with robust data collection, and establishment of global surgery centers of

excellence will stimulate improvements in the provision of surgical and anesthesia services.¹⁹⁷ Further integration of surgical care into national health plans of governments should encourage increased investments and political will necessary to create capacity, leading to timely, quality surgical care to all without risk of financial ruin.^{16,91} Our colleagues in public health and the World Bank, Paul Farmer and Jim Kim, have challenged us: “We need our surgical colleagues to speak fluently about rebuilding infrastructure, training, personnel, and delivering high-quality care to the very poorest.”¹⁰⁶

ENHANCED RECOVERY AFTER SURGERY

History and Overview of Enhanced Recovery

As anesthetic techniques, antibiotics, and minimally invasive surgery have improved surgical care over the centuries, further strategies to continue to improve patient outcomes have emerged. A novel perioperative regimen for patients following colon surgery using early oral nutrition, early mobilization, and epidural analgesia was first described in 1995 by Professor Henrik Kehlet from Copenhagen, Denmark in a small group of nine patients.¹ He subsequently outlined a more detailed multimodal approach to perioperative care in 1997, reducing length of stay to a median of 2 days following sigmoid resection, and thus, has been described as the founder of enhanced recovery after surgery (ERAS).^{2,3} Soon thereafter, several others duplicated that applying standard perioperative care protocols could reduce length of stay following colon surgery.⁴

The ERAS Study Group was founded in 2001 by Professor Ken Fearon and Professor Olle Ljungqvist to further expand on the ideas proposed by Professor Kehlet. As there was a great discrepancy between actual practices and evidence-based best practices, as well as geographical and practitioner variations in care, the group desired to create a consensus on best practices with guidelines that could be employed in the clinical arena. The primary goal of ERAS is to treat the surgical patient in a multidisciplinary team approach throughout the perioperative course with the unified goal of accelerating functional recovery and optimizing patient outcomes based on evidence-based medicine (Fig. 50-1).

In order to develop the key tenets of ERAS, the details of preoperative care, intraoperative surgical and anesthetic technique, and postoperative care were scrutinized and standards for each facet of care were developed (Fig. 50-2).

ERAS and its associated principles truly represented a paradigm shift in perioperative care, breaking from the classical teaching of prolonged fasting postoperatively until signs of bowel function, excessive fluid administration, and delayed postoperative mobilization. Instead, mitigating the metabolic and stress responses to surgery through multimodal care and utilizing evidenced based medicine allows for “fast-track” recovery and improved outcomes.

Each facet of perioperative care may have modest benefit to the patient when applied alone, but when an integrated, multimodal enhanced recovery pathway (ERP) is used, the beneficial effects become synergistic. Patients return to presurgical functional states faster, spend less time in the hospital, and experience less morbidity.⁵ Furthermore, resource utilization is reduced, healthcare system cost is less, and societal cost is lower with faster return to work and reduced homecare needs.⁶ Though initial studies of ERP were primarily performed for colorectal surgery, ERP can be applied to a wide variety of specialties in

1► the inpatient and outpatient setting including urology, orthopedics, and gynecology.

Preoperative Optimization

First proposed in 1949 by the anesthesiologist, Dr. J. Albert Lee, a preanesthetic and presurgical evaluation by an anesthesiologist is associated with improved outcomes for the efficiency of the operating room, the hospital, and most importantly, the patient.⁷ The use of a preoperative evaluation results in identifying patients at elevated respiratory risk, a 55% decrease in preoperative testing, an 88% reduction in case cancellations, reduction in day of surgery delays, reduced total length of stay, a positive impact on hospital finances with cost reduction, and lower in-hospital mortality.⁸⁻¹³ Therefore, while it is very important for the surgeon to see the patient prior to a surgery, it is also

Key Points

- 1 Enhanced recovery after surgery (ERAS) is a paradigm shift in the surgical care of patients. As a multimodal, integrated, evidence-based care pathway, ERAS optimizes patient care in the preoperative, intraoperative, and postoperative setting in order to achieve best patient outcomes. Patients recover faster, experience less physiological stress, enjoy shorter stays in the hospital, and have fewer complications.
- 2▶ Setting appropriate expectations, optimizing nutritional and physical status through prehabilitation, and treating medical comorbidities optimizes patients before surgery.
- 3▶ Achieving normovolemia both intraoperatively and postoperatively is important in order to maintain perfusion without volume overload, as hypervolemia and hypovolemia are both associated with significant complications. Goal-directed therapy approaches maintain normovolemia with zero fluid balance.
- 4▶ Intravenous normal saline administration results in hyperchloremia, which has been associated with increased mortality and morbidity.
- 5▶ As pain is a subjective response and cannot therefore be experienced while unconscious, the use of opioids intraoperatively should generally be avoided in order to minimize the multiorgan system side effects of these medications. Additionally, avoiding intraoperative opioids actually improves postoperative pain scores and reduces the need for postoperative opioids.
- 6▶ Multimodal analgesia, which includes oral or IV nonopioid analgesia and regional analgesic techniques, can reduce postoperative physiological stress and decrease complications associated with surgery as part of a pain management regimen. Multimodal analgesia has been shown to reduce the number of opioids required for analgesia.
- 7▶ The strategies for avoiding postoperative nausea and vomiting include the avoidance of general anesthesia, the use of totally intravenous anesthesia, avoidance of nitrous oxide and volatile agents, minimizing intraoperative and postoperative opioids, and adequate hydration.
- 8▶ Enhanced recovery after surgery care pathways can be applied to numerous types of surgery including colorectal, liver, pancreas, bariatric, gynecologic, and urologic surgery with success.
- 9▶ Traditional Chinese medicine has been practiced for thousands of years and serves as a distinct cultural heritage of China. Its unique theories and methods are still applied widely in the practice of modern medicine, including disease prevention, disease treatment, and perioperative management.
- 10▶ Acupuncture and transcutaneous electroacupuncture can reduce the number of opioids utilized in the perioperative setting. Additionally, acupuncture, transcutaneous electroacupuncture, and some Chinese herb decoctions are effective in the prevention and treatment of postoperative nausea and vomiting.

highly important for the patient to have an opportunity to discuss the upcoming perisurgical and perianesthetic experience with a physician that is trained in the realm of perioperative optimization.

Setting Expectations and Patient Education. Setting expectations in the preoperative clinic helps to orient patients regarding the entire surgical experience, from what they are expected to do at home before the surgery to the entire length of the recovery both in the hospital and at home. Information on the procedure and typical recovery should be clear, well defined, and consistently reinforced from all healthcare personnel that interact with the patient. Clear expectations of goals prior to surgery, in the hospital, and after discharge should be communicated long before the surgery. Expected length of stay and disposition should also be clearly communicated in order to

optimize timely discharge. The preoperative clinic helps in this role and to establish the patient as the leader in his or her own care. The patient must understand that his or her active participation throughout the perioperative experience will facilitate the recovery. A surgeon can do an operation. An anesthesiologist can keep a patient alive while the patient asleep. However, in reality, it is up to the patient to make his or her own care a priority. If individuals train for a race, should they not also prepare for their procedure so that the recovery is swift? The optimization for success at surgery begins preoperatively with smoking cessation, exercise, and nutrition, but it also continues in the hospital and after discharge with pain control, physical activity, discharge planning, and returning to daily activities. Clear expectations at each point in the perioperative continuum, which are communicated to the patient, will improve the perioperative experience for the patient and the provider.

According to Costa, “Evidence shows that patients suffer needlessly due to inadequate preoperative preparation and lack of information regarding their postoperative course as indicated by reports of unexpected pain, fatigue, and the inability to care for oneself.”¹⁴ Patients enter physician offices and procedures with a great deal of fear and anxiety related to the identification of a disease, the consequences of treatment of this disease, and/or the fear of death. Eliciting the patient’s concerns and providing optimal communication and education can allay much of this fear and anxiety. There is a substantial perioperative culture change that is brought about by the elements of ERAS, and many patients have personally had or have had a close relative that has experienced surgery that likely did not include many

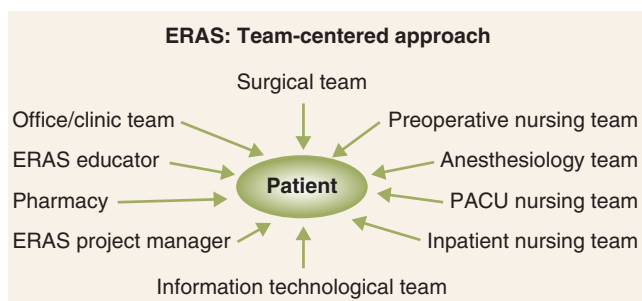

Figure 50-1. Enhanced recovery multidisciplinary team. ERAS = enhanced recovery after surgery; PACU = postanesthesia care unit.

Preoperative phase	Intraoperative phase	Postoperative phase
Patient education & set expectations	Pain blocks	Goal-directed fluid therapy
Smoking & alcohol cessation	Minimally invasive surgery	Prevention of PONV
Prehabilitation with diet & exercise	Goal-directed fluid therapy	Early ambulation
Shortened fasting	Multimodal pain relief	Early feeding
Antimicrobial prophylaxis	Prevention of PONV	Multimodal pain relief
VTE prophylaxis	Avoidance of tubes, drains, lines	Early urinary catheter removal
Minimize bowel preparation	Normothermia	Defined discharge criteria

Figure 50-2. Phases and components of an enhanced recovery after surgery pathway. VTE = venous thromboembolism; PONV = postoperative nausea and vomiting.

components of ERAS. Therefore, this culture change must be clearly disseminated to the patients and include new fasting guidelines, analgesic management, and patient participation in preoperative optimization. Patients can then anticipate and plan for certain events and sensations, such as what and when to eat and drink, how to exercise, what medications will be used, what tubes or lines will be present, and what criteria are used for discharge and return to daily activities. This kind of teaching has been defined as a therapeutic communication to help the patient face and cope with the surgical procedure in a calm manner.¹⁵

Approximately 90 million people have difficulty understanding and subsequently acting upon health information distributed to them.¹⁶ Further, the ability of patients to process and understand basic information to make appropriate health decisions is directly related to socioeconomic status and to Caucasian race; furthermore, the readability of patient-directed healthcare material may be too advanced for comprehension by much of the surgical population.^{17,18} Thus, it is appropriate for patient information material to be at no higher than a sixth grade reading level, friendly, clear, concise, and simply designed. The employment of audiovisual aids may assist some patients as well.

Nutrition. Surgery results in a significant catabolic stress response on the body, triggering inflammation and nutrient depletion. This stress response results in downstream effects on numerous organ systems and can lead to a higher risk of postoperative complications. Ensuring preoperative adequate nutrition is imperative before a large surgical procedure in order to mitigate adverse outcomes.

While enteral or parenteral nutritional supplementation can be considered for the most nutritionally compromised patient, the enteral route is always preferred if clinically appropriate and can be adequately achieved in a timely fashion. Two main approaches to preoperative enteral nutrition include standard oral nutrition supplements and immunonutrition supplements, each providing extra protein and calories to supplement the diet. There is no statistical difference in infections, complications, and length of hospital stay between patients given standard oral versus immunonutrition supplements.¹⁹

Standard oral nutrition products are high in protein, contain vitamins and minerals, and are widely available.

Immunonutrition supplements usually similarly contain high protein, vitamins, and minerals, but they also have the addition of arginine to improve immunity and tissue repair and omega-3 fatty acids to mediate the inflammatory response.¹⁹ The exact dosage of arginine and omega-3 fatty acids that contribute to improved outcomes is not known. Standard oral nutrition products may contain no or lesser quantities of arginine and omega-3 fatty acids when compared to immunonutrition supplements. The exact duration and frequency of supplementation have not been established; however, it is clear that the use of standard oral nutrition products has a positive impact on surgical outcomes by reducing postsurgical complications.¹⁹

Exercise and Prehabilitation. Prehabilitation is defined as “the process of enhancing the functional capacity of the individual to enable him or her to withstand a stressful event.”^{20,21} Both exercise and prehabilitation, which have, heretofore, focused on cardiopulmonary rehabilitation prior to surgery, are very important to optimization of patient outcomes. Perioperative cardiopulmonary exercise testing and prehabilitation in relation to ERAS programs around the world have been analyzed, and it is noted that a reduction in fitness prior to surgery is associated with increased mortality and morbidity in the postoperative arena.²² Patients who actively exercise even when suffering from documented coronary artery disease, heart failure, hypertension, diabetes, chronic obstructive pulmonary disease, depression, dementia, cancer, and stroke have better outcomes.²³⁻³⁶ Furthermore, other literature supports the significant merits of exercise therapy and cardiopulmonary exercise therapy before and after major surgery, with the ability to reduce infection, hospital-associated complications, length of stay, and postoperative mortality.³⁷

There is a significant amount of evidence indicating that exercise training is feasible and safe in patients with a spectrum of severe cardiac and pulmonary diseases as many of these patients require surgery to manage other disease processes. A randomized controlled trial involving 246 low-risk patients undergoing cardiac surgery reported a 1-day reduction in ICU stay and a reduced hospital length of stay in the intervention group.³⁸ Cardiopulmonary fitness was found to be a strong independent predictor of survival after lung surgery, especially for non-small cell lung cancer.³⁹ Preliminary nonrandomized

data from patients undergoing elective rectal cancer surgery within an ERAS program have shown the feasibility of providing a cardiopulmonary exercise interval training program that is delivered three times per week for 6 weeks in a hospital setting after neoadjuvant chemoradiotherapy and before surgery.⁴⁰ The interval following neoadjuvant therapy offers a unique window of time to improve the fitness and nutrition of many oncologic patients, which is especially important as these patients can often be some of the most debilitated.

The addition of physical fitness and activity to a preoperative regimen for elderly patients undergoing major abdominal surgery significantly improved mortality, discharge to home versus a care facility, and length of stay.⁴¹ While this study showed that patients benefited from 60-minute sessions 2 to 4 weeks prior to surgery, even brief therapy before surgery, have been associated with a significant decrease in postoperative complications.^{42,43} Therefore, some oncologic or semiurgent patients may actually benefit from preoperative cardiopulmonary exercise programs.

Smoking Cessation. Clearly tobacco use, especially smoking, has been well documented across all surgical specialties to increase postoperative mortality, as well as increase postoperative complications including prolonged ventilation, pneumonia, deep venous thrombosis, wound infection, delayed wound healing, and reduced bone fusion.⁴⁴⁻⁴⁷ Physiologically, the carbon monoxide and nicotine from tobacco products increase heart rate and blood pressure and the body's demand for oxygen. Nicotine also causes vasoconstriction, reducing perfusion to many tissue beds. Obviously, it is advantageous for patients to cease

smoking preoperatively. There is debate about the duration of the nicotine free days needed preoperatively to offer best outcomes, though the literature suggests that the longer duration of smoking cessation prior to surgery portends better outcomes.⁴⁸ This is likely to allow for bronchiolar and collagen remodeling and the several weeks following last exposure that are needed to achieve blood free of nicotine and its derivatives.

Metabolic Stress Response to Surgery

Multiple organ systems interact in numerous metabolic and inflammatory cascades following the stress response to surgery leading to insulin resistance and protein catabolism (Fig. 50-3). Neuroendocrine responses, stress hormones cascades, activation of cytokine, and immune reactions all occur, leading to a catabolic state.⁴⁹ Central to this metabolic and inflammatory cascade is the development of insulin resistance, whereby a normal insulin concentration results in a subnormal biologic response. As insulin is the main anabolic hormone involved in glucose control, fat metabolism, and protein balance, insulin resistance disrupts many metabolic pathways.

Hyperglycemia from insulin resistance results from an increase in glucose production and a decrease in glucose uptake by the periphery. In a fed state, insulin levels surge to 6 to 8 times basal levels, which stops glucose production and increases peripheral glucose uptake three- to fourfold.⁵⁰ When fasting, insulin levels remain in a relative steady state with minimal effects on glucose and protein metabolism. Even when insulin levels increase to three times basal levels, there is no increase in peripheral glucose uptake. Therefore, in the postoperative fasting state, without the assistance of exogenous insulin, peripheral

Figure 50-3. Metabolic stress response to surgery results in insulin resistance. (Reproduced with permission from McGill University Health Center Patient Education Office, Montreal, Quebec, Canada.)

glucose uptake is reduced. The resulting hyperglycemia can be corrected, however, with the use of exogenous insulin, and when normoglycemia is achieved in the perioperative period, the main components of metabolism also normalize.⁵¹

The preoperative and postoperative fasting state triggers insulin resistance resulting in a catabolic state with gluconeogenesis and protein breakdown. Following prolonged fasting states with stress such as following surgery, protein catabolism can be increased several fold over baseline. As less glycogen is stored in the muscle and loss of lean body mass occurs, there is less muscle function and therefore less capacity to mobilize.

In addition to the typical metabolic effects of surgery, pain has been demonstrated to increase insulin resistance. In healthy male volunteers undergoing painful stimulation, glucose uptake was reduced as a direct result of decreased insulin sensitivity.⁵² In addition, serum cortisol, epinephrine, and free fatty acids were all increased following painful stimulation.

Elective surgery results in a state of insulin resistance, with the magnitude of surgery corresponding to a decrease in insulin sensitivity.⁵³ For example, the difference in insulin sensitivity following laparoscopic cholecystectomy versus open cholecystectomy is 2.5-fold. More complex abdominal surgery such as an open colorectal resection results in a 3.5-fold increase in insulin resistance over laparoscopic cholecystectomy. As levels of insulin resistance increase, complications also increase.⁵⁴ In addition to an association with complications, insulin resistance has been shown to be an independent predictor of length of stay.⁵³

The increased postoperative complications associated with insulin resistance may be not only from the direct metabolic effects of insulin on glucose but also from free radical formation. In peripheral tissues that are independent of insulin metabolism, and therefore do not store glycogen, the increased plasma glucose levels result in greater glycolysis and oxygen free radical formation. This leads to alterations in gene expression, which in turn propagates a cycle of increased inflammation causing even more insulin resistance.⁵⁵ Elective surgery has been implicated in increased inflammatory gene pathways and changes in insulin signaling genes in both adipose and skeletal muscle tissues.^{56,57}

Components of an ERP may offset the metabolic and stress responses of surgery. Preoperative carbohydrate supplementation has been shown to counter the catabolic effects of the fasted state by stimulating glucose uptake and transitioning metabolism to a more anabolic state with improved insulin sensitivity.⁵⁸ Preoperative carbohydrate supplementation also reduces protein loss and improves muscle strength postoperatively.⁵⁹⁻⁶¹ When preoperative carbohydrate supplementation is added to epidural analgesia, there is even greater improvement in insulin resistance.⁶²

Preoperative Fasting and Preoperative Carbohydrate Loading

Traditionally, patients have been instructed to fast for 6 to 12 hours before surgery to reduce the risk of aspiration of gastric contents during the induction of anesthesia. This fasting state results in a prolonged period without nutrients or hydration prior to and during surgery, and it can lead to insulin resistance, hyperglycemia, failure to achieve a postsurgical anabolic state, and sometimes, the need for insulin. Both European and American Societies of Anesthesiology guidelines have supported the use of clear liquid oral intake up to 2 hours prior to surgery with the

exception of patients with gastroparesis, intestinal obstruction, or dysphagia.⁶³⁻⁶⁵ Carbohydrate oral intake up to 2 hours prior to surgery does not increase aspiration in healthy adults undergoing elective surgery and in fact reduces preoperative hunger, thirst, anxiety, and nausea.^{66,67} In addition, a fasting time of 2 to 4 hours versus more than 4 hours actually results in smaller gastric volume and a higher gastric pH value.⁶⁸⁻⁷⁵ Nevertheless, prior to the introduction of ERAS, the dogma of prolonged nothing-by-mouth status widely adopted many decades ago had little advocacy to change, despite evidence supporting more liberal fasting parameters. Current guidelines support fasting from clear liquids for 2 hours and solid food for 6 hours.

Preoperative carbohydrate loading prior to surgery in the form of a carbohydrate rich clear liquid improves patient nausea and discomfort over preoperative water hydration or a prolonged fasting state.⁷⁶ It may also have further benefits over low carbohydrate clear liquid beverages or fasting by changing the overnight fasting state to a fed state and thus altering glucose, protein, and fat metabolism by increasing postoperative insulin sensitivity.⁷⁷⁻⁷⁹ Furthermore, in patients whose expected length of stay is greater than 2 days, there is a significant length of stay reduction in patients that receive preoperative carbohydrate loading.⁸⁰ The best carbohydrate loading drink is unclear as studies are heterogeneous and the carbohydrate content is variable. Nevertheless, the carbohydrate drink should be hypo-osmolar for faster gastric emptying, result in a fed state with full glycogen stores, and reduce postoperative insulin resistance. The most commonly studied carbohydrate loading drink includes 100 g of carbohydrate the evening prior and 50 g of carbohydrate 2 to 3 hours prior to surgery.

Intraoperative Considerations

Surgical Considerations. Prevention of surgical site infection consists of the use of mechanical, chemical, and/or antimicrobial modalities. Mechanical and chemical methods include the use of patient bathing preoperatively and skin preparation with betadine, chlorhexidine, or similar chemical in order to limit the microbial content of the skin. Additionally, the appropriate use of antimicrobial prophylaxis should be employed and follow guidelines specific to the type of surgery and for duration of antibiotic prophylactic administration.

Minimally invasive surgical approaches should be considered as minimally invasive techniques have demonstrated improved outcomes across surgical specialties, including reductions in length of stay and postoperative complications. Additionally, the use of catheters or drains should be limited unless necessary, as these hinder the patient's perceived ability for ambulation.⁸¹⁻⁸⁴

Hypothermia Prevention. Hypothermia is a common perioperative problem. Up to 90% of all patients undergoing elective surgery suffer from inadvertent postoperative hypothermia.^{85,86} Those at highest risk include patients over the age of 60 years, and/or patients that have malnourishment, preexisting hypothermia, preexisting medical comorbidities that impair body temperature regulation (including advanced diabetes with neuropathy and hypothyroidism), who are undergoing general anesthesia, and who are undergoing a major long surgery. Further, in patients who experience hypothermia, surgical complications are increased, including impaired wound healing, wound infection, pressure ulcers, cardiac disorders including arrhythmia and infarction, as well as increased bleeding requiring blood transfusion (Table 50-1).

Table 50-1

Relative risk of elective surgical complications secondary to hypothermia⁸⁶

	RELATIVE RISK	95% CONFIDENCE INTERVALS
Impaired wound healing	3.25	1.35–7.84
Cardiac disorders	4.49	1–20.16
Blood transfusion	1.33	1.06–1.66

The reasons for hypothermia are multifactorial. Radiation, the transfer of heat by electromagnetic waves through space without a medium, accounts for 50% to 70% of heat loss. Convection, the loss of heat through ambient air stream, accounts for 15% to 25% of heat loss. Evaporation accounts for 5% to 20%, and conduction accounts for 3% to 5%.⁸⁵ Temperature reduction can also be accelerated by cold intravenous fluids, low operating room temperatures, and a decreased thermoregulatory threshold, which occurs during the administration of general anesthesia. Further, the ability to compensate for reduction in body temperature is also compromised by muscle relaxation and anesthesia in general, as these processes impair shivering and thermoregulatory vasoconstriction.⁸⁷ There are steps to take to prevent this hypothermia including active, convective heating using clean, filtered, forced-air warming blankets in patients in the preoperative area (prewarming) and also during anesthesia; thermal insulation; warmer ambient operating room temperatures, warmed irrigation solutions during surgery; and warmed infusions and blood products.⁸⁸⁻⁹⁹

Venous Thromboembolism Prophylaxis. Venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE), is the number one cause of potentially preventable death in common but preventable causes of morbidity and mortality in the perioperative patient. Several national quality improvement organizations have cited VTE prophylaxis for patients at risk as a priority for individual physicians and for hospitals because this intervention reduces adverse patient outcomes and hospital costs.

Surgical patients have increased risk for VTE due to advanced age, multiple medical comorbidities, prolonged procedure times, the inflammatory and hypercoagulable state of surgery, and immobility. Specific risk factors include major general, vascular, or orthopedic surgery; lower extremity paralysis due to spinal cord injury; fracture of the pelvis, hip, or long bones; multiple trauma; cancer; prior VTE; age 40 years and higher; obesity; immobility; oral contraceptive use; hyperviscosity syndromes; and severe cardiopulmonary disease (prior myocardial infarction, congestive heart failure, chronic obstructive pulmonary disease).

Postoperative DVT is usually asymptomatic, and fatal PE can often be the first sign of VTE. DVT occurs after approximately 25% of all major surgeries without prophylaxis, and PE occurs after 7%. Since screening modalities (such as venous duplex imaging) in asymptomatic patients have low sensitivity to detect clot, the best approach is to systematically apply prevention strategies to all patients undergoing surgery, with treatment choices based on patient-related and procedure-related risks.

VTE prophylaxis is therefore an important component in optimal perioperative care and current surgical practice and should be included in all practice guidelines. Appropriate VTE prophylaxis should be given preoperatively, intraoperatively, and postoperatively based upon current guidelines for the surgery type.¹⁰⁰ Examples of nonpharmacologic methods include early ambulation, graduated compression stockings, and intermittent pneumatic compression devices. Pharmacologic methods include the use of low dose unfractionated heparin, low molecular weight heparin, and in some case, factor Xa inhibitors.

Perioperative Fluid Management. Current and traditional fluid management strategies, which are based on a fixed fluid requirement per patient per case, have failed to improve outcomes. More modern goal-directed therapy (GDT) intravenous fluid approaches rely on the use of advanced medical devices, including esophageal Doppler monitors and other noninvasive cardiac output or bioimpedance models to determine whether or not patients are “fluid responsive” during surgery.¹⁰¹ In the setting of a normal ejection fraction, fluid is only administered when the expectation is that cardiac output will increase, and vasopressors are utilized if the aforementioned devices show fluid will not increase cardiac output. Excess fluid in certain general surgical cases can cause ileus and bowel edema, and in cardiac cases, it can cause hemodilution. Patients randomized to restricted and liberal fluid resuscitation strategies found a clear linear relationship between total fluids administered (and weight gain) and complications following colorectal surgery including pulmonary edema and tissue-healing complications.¹⁰² Further multiple studies exist demonstrating fewer complications with normovolemia than with liberal strategies of fluid resuscitation.¹⁰²⁻¹⁰⁸

It must be understood that goal-directed therapy does, in no way, mean reduction in fluid administration. For some procedures, it may be necessary to administer more than anticipated fluid volumes (orthopedics), while for others, the opposite may be true (abdominal). Normovolemia is important to maintain perfusion without volume overload. Thus, the idea behind goal-directed therapy is to maintain zero fluid balance coupled with minimal weight gain or loss. Hypovolemia is associated with reduced circulating blood volume, decreased renal perfusion, altered coagulation, microcirculation compromise, and endothelial dysfunction, among other processes. Hypervolemia is associated with splanchnic edema, decreased pulmonary gas exchange secondary to pulmonary edema, impaired wound healing, anastomotic dehiscence, decreased mobility, altered coagulation, and endothelial dysfunction, amidst others

3▶ processes¹⁰⁹ (Fig. 50-4).

Esophageal Doppler is a mode by which ultrasound is used to monitor and guide intraoperative fluid management has been used quite frequently. The use of this device for fluid optimization has been studied in several randomized controlled trials or meta-analyses, all of which showed a significant reduction in length of stay of up to 4 days.^{110,111} Reductions in length of stay have been seen in gastrointestinal surgery, trauma surgery, urologic surgery, and also the orthopedic population.¹¹²⁻¹¹⁶ Alternative devices such as arterial waveform analyzers and pulse oximeter waveform analyzers have been studied and may be promising with the added advantage of lower cost over esophageal Doppler.

Postoperatively, once the patient is adequately tolerating at least a liquid diet and maintaining adequate hydration,

Figure 50-4. Volume status affects postoperative morbidity. (Reproduced with permission from Francis N, Kennedy RH, Ljungqvist O, et al: *Manual of Fast Track Recovery for Colorectal Surgery*. London: Springer-Verlag; 2012.)

supplemental intravenous fluids should be minimized or terminated. The use of Dopplers or other volume status wave form analyzers have not been studied in the nonventilated postoperative patient and therefore cannot be used to reliably assess volume status. Clinical judgment based on patient factors, surgery type, and the clinical findings should be considered in the decision to continue intravenous fluids. However, once the patient is able to maintain adequate hydration, supplemental fluids should be used judiciously to limit fluid overload, tissue and lower extremity edema, and the constraints that the intravenous medication pole has upon patient-initiated ambulation.

It is not enough to have normovolemia, but one must also consider the type of fluid that should be used for resuscitation. From a recent Cochrane review, there is no evidence that colloids are superior to crystalloid for resuscitation in patients.¹¹⁷ Therefore, crystalloid fluids should generally be the primary intravenous fluid during the perioperative course. In cardiac surgery, the utilization of 0.9% normal saline solution was associated with hyperchloremia and poor postoperative outcomes, including higher length of stay and increased mortality.¹¹⁸ Further, a more balanced crystalloid, such as Plasma-Lyte, was associated with improved outcomes in 22,851 surgical patients.¹¹⁹ In this study, there was a 2.05 odds ratio predictor of mortality with normal saline. Other complications such as acute kidney injury, gastrointestinal complications, major hemorrhage, and major infection were also increased in the group of patients that were hyperchloremic after normal saline administration. Based on such evidence, it would seem prudent to proceed with a more balanced solution, such as PlasmaLyte, to reduce complications.

Perioperative Pain Management

According to the International Association for the Study of Pain (IASP) Taxonomy, the definition of pain is described as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such

damage.”¹²⁰ There are two important implications of this: pain is completely subjective in that it is whatever the patient says it is, and patients cannot experience pain while unconscious.¹²¹ This has some effects on how the anesthesiologist treats sympathetic stimulation in the operating room. Heretofore, elevations in heart rate and blood pressure were treated with opioid medications, as these sympathetic markers were considered surrogates for patients experiencing pain while under general anesthesia. However, other medications can be used to treat the sympathetic response to surgery such as β -blockers and deepening the anesthesia without administering opioid medications while the patient is unable to experience the pain.

The mainstay of alleviating pain has historically relied almost exclusively on opioids, especially with the usage of patient controlled analgesia devices (PCAs). However, limiting opioids in the perioperative setting is of substantial benefit. Opioids, in fact, reduce pain immediately after administration. However, they also worsen pain scores after they wear off, increase postoperative opioid requirements, increase nausea and vomiting, cause respiratory depression, reduce gastrointestinal motility, worsen urinary retention, induce endocrine dysfunction, and suppress the immune system.⁸⁷ There have been a number of randomized controlled trials that have shown that as opioid administration increases, pain scores and postoperative nausea and vomiting increase.¹²¹⁻¹²⁹ Exposure to any fentanyl or opioid in the operating room worsens postoperative pain scores and should therefore be limited or omitted.^{122,123,127,129} Opioid containing PCAs have been the standard for opioid administration because of their safety and efficacy in patients to control the administration of opioids. However, because a PCA only offers opioid medication, there is the possibility that the desired analgesic effect will be associated with the aforementioned complications of opioids.

Despite their disadvantages, opioids are still quite useful in the treatment of pain. However, the ERAS protocols focus on opioids as a single component of a comprehensive pain relief strategy, not as the mainstay for treatment. Instead, multimodal

analgesia should be emphasized by utilizing multiple medications to limit postoperative pain and therefore opioid use. Multimodal analgesia mitigates the side effects of opioids by opioid reduction and enhances pain management. Preoperative and postoperative administration of acetaminophen and celecoxib or other nonsteroidal anti-inflammatory drugs, as well as gabapentin have been shown to be efficacious.¹³⁰⁻¹³⁵ Intraoperatively, the utilization of ketamine, lidocaine, and magnesium, act as adjunctive measures to limit pain and have been utilized to reduce the utilization of opioids in the postoperative period.¹³⁶⁻¹⁴⁰ Administration of lidocaine and ketamine can also be continued in the postoperative setting (Table 50-2).

Neuraxial opioid analgesia, the administration of opioids through either the intrathecal or epidural route, can be accomplished by either a single shot (both spinal and epidural) or catheter-based therapy (epidural). The use of opioids by this route was shown to have improved pain relief when compared to preoperative oral, IV, or intramuscular morphine.¹⁴⁴ Further, neuraxial opioid analgesia is associated with lower postoperative pain scores in adults and children who undergo surgery.¹⁴⁵ Neuraxial analgesia can also be performed with local anesthetic only. Finally, the American Pain Society (APS) recommends the utilization of such postoperative analgesic methods in patients who undergo major surgeries, including thoracic and abdominal

Table 50-2

Analgesic medications

	ADVANTAGES	DISADVANTAGES
Opioids ¹⁴¹	Relieve pain immediately after administration	Worsen pain scores after opioids wear off Increase postoperative opioid requirements Central Nervous System: Euphoria/dysphoria Sedation Respiratory depression Nausea/vomiting Cough suppression Cardiovascular: Bradycardia/tachycardia Arterial/venous dilation Renal: Antidiuretic Increased sodium resorption Urinary retention Gastrointestinal: Decreased motility Constipation Biliary colic Endocrine: Stimulates release of antidiuretic hormone Stimulates release of prolactin Stimulates release of somatotropin Decreases luteinizing hormone Immunologic: Decreased immune system function Cancer growth
NSAIDs ¹⁴²	Reduce inflammation Synergistic effect with opioids	Renal insufficiency Increased bleeding Delay healing Adverse cardiovascular risk
Local anesthetics ¹⁴⁰	Opioid-sparing effect Decrease PONV Reduce ileus Possible anticancer effect	Cardiac toxicity Central nervous system toxicity
Ketamine ^{136,137,143}	Opioid-sparing effect May prevent opioid-induced hyperalgesia and chronic pain syndromes	Dysphoria Hallucinations
Gabapentinoids ¹³⁰⁻¹³⁵	Opioid-sparing effect Reduce opioid side effects Reduce postoperative pain	Visual disturbances

procedures, cesarean sections, and hip and lower-extremity surgeries; this is especially recommended for patients at risk for cardiopulmonary complications or prolonged ileus.¹⁴⁵

Multimodal analgesia can also include regional analgesic techniques such as peripheral nerve blocks, paravertebral blocks, plexus blocks, and local infiltration, which can reduce postoperative physiological stress and decrease complications associated with surgery as part of a regimen.¹⁴⁶ These techniques have been shown to reduce the amount of opioids required for analgesia and also have been shown to reduce the adverse events seen with epidural local anesthetics (such as urinary retention and hypotension) and/or opioid-containing PCAs.

6► Postoperative Nausea and Vomiting Prevention

Postoperative nausea and vomiting (PONV) is very common and can cause significant distress to patients, with the incidence of vomiting at approximately 30%, nausea at 50%, and the combination of PONV as high as 80%. All result in poor patient satisfaction, increased recovery room length of stay, and higher costs to the health-care system.¹⁴⁷⁻¹⁵² This could further increase the time to first feeding, which in turn may prolong ileus and/or hospital stay.

Dr. Gan and colleagues developed a consensus guideline for the management of nausea and vomiting and details the risk and possible choices for the treatment of PONV.¹⁵³ Risk factors include female sex, history of PONV or motion sickness, nonsmoking, younger age, general versus regional anesthesia, use of volatile anesthetics and nitrous oxide, postoperative opioids, duration of anesthesia, and the type of surgery including cholecystectomy, laparoscopy, gynecological, and strabismus. The strategies for avoiding PONV include the avoidance of general anesthesia, the use of totally intravenous anesthesia, avoidance of nitrous oxide and volatile

agents, minimizing intraoperative and postoperative opioids, and adequate hydration.^{150,152,154-159} The medications to prevent, abort, and reduce PONV include perphenazine, aprepitant, dexamethasone, scopolamine, dolasetron, granisetron, and ondansetron, among others.¹⁶⁰⁻¹⁶⁴ PONV should be targeted before it occurs for optimal prevention (Fig. 50-5).

7► Early Nutrition and Postoperative Ileus Prevention

Postoperative ileus is the most common cause of prolonged hospital stay and readmissions following surgery on the digestive tract, occurring in up to 19% of cases.¹⁶⁵ Not only is this adverse to the individual patient clinically, this also results in doubling of the total cost of the index hospital stay and thus carries a tremendous socioeconomic impact globally.¹⁶⁶ Numerous risk factors contribute to postoperative ileus and include open surgery, increased surgery length of time, blood transfusion, fasting, fluid overload, opioids, postoperative nausea and vomiting, and other pharmacological agents. While some risk factors are unavoidable in certain patients, others are modifiable, and therefore minimization of the risk of postoperative ileus is achievable.

Nasogastric tubes (NGTs) were previously used prophylactically to prevent ileus, limit distension on the gastrointestinal anastomosis, as well as to prevent pulmonary complications. However, NGT use actually delays return of gastrointestinal activity and increases pulmonary complications without preventing anastomotic leaks in numerous types of surgery, including gastroduodenal, biliary, trauma, and esophageal.¹⁶⁷⁻¹⁶⁹ Therefore, the routine use of NGTs for prophylaxis should be avoided.

Addressing the numerous risk factors for postoperative ileus has a benefit on the reduction of the incidence of postoperative ileus. For example, mitigating the surgical trauma through

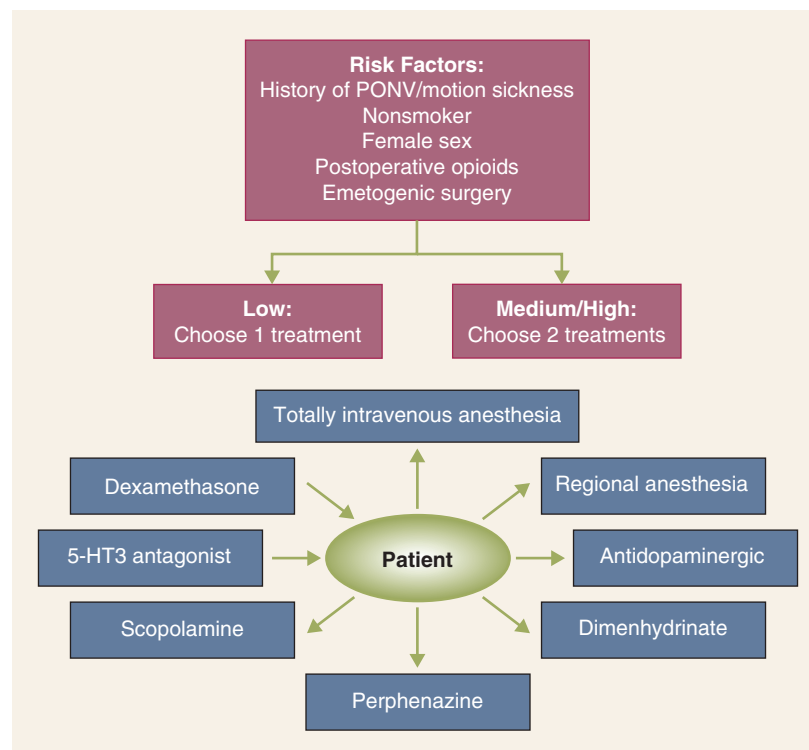

Figure 50-5. Risk factors of and treatment options for postoperative nausea and vomiting. PONV = postoperative nausea and vomiting.

minimally invasive surgery and meticulous surgery with minimal blood loss reduces postoperative ileus, either directly by limiting the inflammatory response with smaller incisions or indirectly through reduced opioid use.¹⁷⁰⁻¹⁷⁴ Anesthetic technique can also aid in prevention of postoperative nausea and vomiting, which in turn reduces the need for parenteral opioids, a known risk factor for postoperative ileus. Multimodal pain strategies and neuraxial blocks reduce opioid use and therefore minimize nausea, improve early enteral nutrition, limit intravenous fluid administration, and improve ambulation. Maintenance of normovolemia in the perioperative setting should be achieved as fluid overload and dehydration both negatively affect return of bowel function, length of stay, and complications.^{105,106,175} Clearly, each facet of the perioperative care process is intricately intertwined to the next and has implications in total body homeostasis.

Other measures may also assist in the prevention of postoperative ileus; however, the role of each in the setting of an ERAS pathway is unclear. Chewing gum is hypothesized to reduce postoperative ileus by stimulating the cephalovagal reflex and is considered a form of sham feeding. Prior to the introduction of ERAS, the use of chewing gum in multiple abdominal surgeries demonstrated faster intestinal recovery with variable impact on length of stay.¹⁷⁶⁻¹⁷⁸ Following the use of ERAS and associated early enteral feeding, the benefit of chewing gum is less clear.^{179,180} Alvimopan is a mu opioid receptor antagonist that is administered prior to surgery and twice daily postoperatively. Pooled analysis of phase III trials demonstrated a reduction in postoperative NGT use, faster return of bowel function, and earlier discharge by 0.7 days.¹⁸¹ However, following ERAS implementation, small studies demonstrate a reduction in ileus and length of stay with the use of alvimopan in open surgeries without a benefit in laparoscopic surgery.¹⁸²⁻¹⁸⁴

Mobilization

Though no metric of mobilization has been clearly defined, early mobilization following surgery is an important component of ERAS that accelerates the return to baseline functional status. Prolonged postoperative bedrest leads to deconditioning, increased deep venous thrombosis risk, and loss of muscle mass. Deterioration of mobility and activities of daily living can be seen in older patients after only 2 days of hospitalization.¹⁸⁵ Therefore, preoperative encouragement of an exercise program and perioperative mobilization can have dramatic impacts on not only the elderly but all patients undergoing surgery. Patients that begin a preoperative exercise program are more active postoperatively and have a faster return to baseline exercise capacity when compared to patients undergoing a postoperative exercise program.¹⁸⁶ As patients in an ERAS program are directed to spend time out of bed and to ambulate, early mobilization is therefore encouraged. Many other facets of ERAS will assist in this early mobilization: postoperative nausea prevention, limiting drain use, and improved pain control. Setting preoperative expectations of mobility through patient education in the clinic setting and postoperative nursing unit engagement in promoting mobility provide the proper setting for improved patient compliance with early and frequent mobilization. However, compliance with this is highly variable and difficult to track and may be hindered if pain is inadequately controlled or if the patient is tethered to devices such as drains, catheters, and IVs. As with other components of ERAS, engagement of all providers of patient care from outpatient nursing, to inpatient nursing,

physicians, and physical therapists, will improve compliance not only with mobility but often with other components as well. Reinforcement of expectations can be achieved with preoperative educational pamphlets, postoperative daily task lists, mobility logs, and pedometers.

ERAS in CRS

As the initial development of ERAS pathways occurred in colon surgery patients, the largest preponderance of data exists in this surgical specialty with the first ERAS guidelines developed in 2012 after many studies demonstrated positive outcomes applying the basic tenets of ERAS surgery.⁸¹ In 1997, Henrik Kehlet published the initial series of patients, applying novel perioperative care strategies to colon resection patients.^{2,3} Following this, several groups also applied these principles to colon resection patients. These studies demonstrated that the principles of early mobilization, early feeding, and optimized intravenous fluid administration resulted in patients tolerating a diet sooner, faster return of bowel function, and earlier discharge.¹⁸⁷⁻¹⁸⁹ Furthermore, these studies elucidated reduction in complications such as urinary tract infections, ileus, and cardiopulmonary complications. Nygren et al also demonstrated that muscle strength and lung function were less reduced after colon resection within an enhanced recovery protocol compared to traditional perioperative care.¹⁸⁷ Additionally, as ERAS is expected to diminish the metabolic and hormonal stress response to surgery, attenuation of TNF- α , IL-1 β , IL-6, and IFG- γ occurred after ERAS cases when compared to traditional perioperative care, and cortisol levels were not found to increase immediately postoperatively in ERAS, while those with traditional perioperative care experienced immediate and sustained cortisol elevation.¹⁹⁰

Larger series of patients followed with Delaney et al publishing a single institutional experience of 1000 consecutive laparoscopic colectomy patients with short length of stay and low readmission and mortality rates.¹⁹¹ The protocol was further applied to rectal surgery with success.^{187,192} Meta-analyses and systematic reviews demonstrate less opioid use, shorter length of stay, decreased morbidity, and no increase in readmission rates for laparoscopic or open colon or rectal resections when an ERAS protocol is utilized.¹⁹³⁻¹⁹⁷ Several groups have even discharged patients in as little as 24 hours following colon resection, with Gignoux et al even discharging patients on the same day.¹⁹⁸⁻²⁰⁰ ERAS can also be applied to octogenarian patients with compliance to the protocols and with no increased readmission or mortality rates.²⁰¹ Also, patients with diverting stomas can benefit from ERAS protocols, though diverting ileostomy may slightly delay discharge over patients with no ileostomy.²⁰²

Adherence to the numerous tenets of ERAS is inversely related to length of stay postoperatively in colorectal surgery.^{203,204} When compliance with ERAS measures is lower, length of stay is longer. The strongest predictors for shorter duration of stay include preoperative carbohydrate loading, no nasogastric tube, early mobilization, early oral nutrition, totally intravenous anesthesia, early removal of urinary catheter, and the use of nonopioid analgesia. Predictors for deviation from an ERAS program and thus resultant longer length of stay include pathologic diagnosis, intraoperative complications, high blood loss, surgery length, lack of mobilization, emesis, persistent use of intravenous fluids, reinsertion of urinary catheter, and poor pain control.²⁰⁵⁻²⁰⁸ Though readmissions are no higher than traditional perioperative care, several factors have been implicated in readmission, including poor ERAS compliance and

preoperative neoadjuvant chemoradiation.^{209,210} Predictive tools using artificial neural networks may assist in clinical decision-making.²⁰⁹ The most common reasons for readmission include bowel obstruction and skin and soft tissue infection. While patient and quality outcomes are clearly important, the added benefit of cost savings has been demonstrated. Surgery using the tenets of ERAS is both less costly for direct and indirect costs to the hospital and effective.²¹¹ Furthermore, patients in an ERAS program returned to work faster and had less caregiver burden, resulting in huge indirect savings as well.⁶

ERAS in Hepatopancreaticobiliary Surgery

An initial experience applying an ERAS protocol in 61 consecutive patients undergoing liver resection demonstrated 92% of patients tolerating a diet on postoperative day 1, a reduction in length of stay from 8 to 6 days, and no increased readmissions or morbidity.²¹² A subsequent randomized trial in patients undergoing open major liver resection demonstrated a length of stay reduction from 7 to 4 days with a decrease in medically related postoperative complications and no increase in surgical complications or readmission; ERAS patients also reported improved quality of life over controls.²¹³ Several meta-analyses have similarly supported the use of ERAS protocols in liver surgery, citing reduced morbidity, hospital stays, cost, and time to recovery of bowel function without increasing mortality or readmission rates.²¹⁴⁻²¹⁶ When adherence to all elements of an ERAS protocol for liver resection was less, hospital length of stay was longer.²¹⁷

In 2012, the ERAS Society published recommendations for patients undergoing pancreaticoduodenectomy after several studies published early outcomes in this surgical population.⁸² Patients undergoing pancreaticoduodenectomy often have high rates of delayed gastric emptying; the use of ERAS has reduced the incidence of delayed gastric emptying by nearly half, thus allowing earlier feeding in this complex patient population.^{218,219} Additionally, multiple prospective cohort or retrospective studies have shown that ERAS protocols offer significant benefit to patients undergoing both distal pancreatectomy and pancreaticoduodenectomy with reduced hospital stay and complications.²²⁰⁻²²⁶ Several meta-analyses or systematic reviews have confirmed shorter length of stays, decreased complications, and lower cost with ERAS protocols.²²⁷⁻²³⁰ Furthermore, the use of ERAS protocols in elderly patients undergoing pancreaticoduodenectomy continue to show improved outcomes in length of stay and morbidity, showing that ERAS protocols allow this more fragile patient population to recover faster.^{231,232}

ERAS in Gastrectomy and Esophagectomy

Patients undergoing foregut surgery have notoriously been subjected to prolonged periods of nasogastric tube decompression and resultant starvation while surgical dogma dictated this fasting time diminished the risk of complications from anastomotic leak. Nevertheless, more liberal removal of the nasogastric tube and limited fasting, as components of ERAS protocols, have demonstrated improved recovery and outcomes. Randomized controlled trials demonstrate that removal of the nasogastric tube in the operating room and early feeding, as components in an ERAS program, result in shorter length of stay, fewer grade III or higher postoperative complications, and faster return to baseline weight and functional status.^{233,234} Multiple nonrandomized studies and meta-analyses verify reduction in length of stay and no increase in complications.²³⁵⁻²³⁸ In 2014, consensus guidelines for ERAS after gastrectomy were published, and

these include no routine use of nasogastric decompression, early feeding within the first postoperative day, and early consideration for nutritional support if the patient is malnourished or unable to maintain at least 60% of caloric requirements.²³⁹

Esophagectomy surgery is notoriously complicated and fraught with complications secondary to multiple factors including surgical complexity and medical comorbidity. Postoperative management is governed by the idiosyncrasies of the operating surgeon more so than many other specialties and therefore heterogeneous. While studies of ERAS in gastrectomy suggest no routine use of nasogastric tubes and include early feeding, most ERAS programs for esophagectomy encompass all components not related to feeding, but prolonged nasogastric decompression remains.²⁴⁰ Many of these patients, however, do receive early enteral nutrition through the use of jejunostomy tubes commonly placed at the time of resection. When defined protocols are followed in this cohort of patients, length of stay is reduced, and complications and readmissions are, at a minimum, not increased.²⁴¹⁻²⁴³ Systematic reviews demonstrate a reduction in length of stay, anastomotic leak, and pulmonary complications without increased mortality or readmission.^{244,245}

ERAS in Bariatric Surgery

Bariatric surgeons have applied clinical pathways to both the preoperative and postoperative periods for many years, which have resulted in improved outcomes. The adoption of ERAS protocols in these clinical pathways has offered further success for these patients. A randomized trial for laparoscopic sleeve gastrectomy demonstrated a reduced length of stay to 1 day postoperatively in ERAS patients, and others have also discharged patients on postoperative day 1 following Roux-en-Y gastric bypass.²⁴⁶⁻²⁴⁸ Furthermore, earlier discharge of patients on postoperative day 1 has not been demonstrated to increase resource utilization, with no increase in patient phone calls, emergency department visits, or readmissions.²⁴⁹ A meta-analysis confirms success of ERAS in bariatric surgery with reduction of length of stay without increase in complication or complication severity, while a second meta-analysis demonstrates an increase in minor complications without increasing patient morbidity.^{250,251} Following a thorough review of the literature supporting its use, the ERAS Society published guidelines for ERAS bariatric protocols in 2016.⁸⁴

ERAS in Other Surgical Specialties

Though ERAS has been applied more broadly to complex abdominal surgery, there is surprising little data in its use in large ventral hernia repair and other abdominal wall reconstructive techniques. Three studies report experience in open large ventral hernia repair with varying techniques of abdominal wall reconstruction including myofascial release.²⁵²⁻²⁵⁴ Each study cites faster return of gastrointestinal function and reduction in length of stay by up to 2.5 days. Furthermore, there were no increases in readmission, postoperative complications, or reoperation. Though no long-term follow-up, there is no report that early feeding results in intestinal compromise from “tight” closure or early hernia recurrence. In fact, as ERAS reduces the incidence of postoperative vomiting and ileus, it is likely very beneficial for this patient population.

ERAS has been introduced to non-general surgery subspecialties as well. Complex urological procedures such as radical cystectomy have trialed ERAS over the last decade with favorable results. In this patient population, length of stay was reduced, and complications were similar to or reduced when

compared to baseline controls.²⁵⁵⁻²⁵⁷ Similarly, ERAS has been applied to both minimally invasive and open complex cytoreductive gynecological oncology surgery with favorable results for earlier discharge and decreased pain.²⁵⁸⁻²⁶³ Total joint replacement surgery in orthopedics has also used ERAS with improved early mobility, a significant length of stay reduction, and decreased morbidity.^{264,265}

Setting Up an ERAS Program

The successful implementation of an enhanced recovery program depends heavily upon cultural change and excellent organizational behavior. As the ERAS program encompasses so many facets of patient care, the implementation team should not only include surgeons and anesthesiologists but also inpatient and outpatient nurses, pharmacists, information technology specialists, compliance officers, and hospital administration.

Initial strategy for ERAS implementation should define the scope of practice change by identifying the current state and the goal state of care. Protocol content can be discussed in a small group of engaged stakeholders. Once the protocol elements are defined, all stakeholders should review and discuss the protocol in detail in order to identify barriers to implementation, identify solutions to these barriers, and finalize the protocol. This allows for all stakeholders to remain engaged and have ownership in the protocol. Appropriate informational resources for hospital and office staff education are created in order to have a thorough and successful educational campaign. Patient informational resources should also be developed in order to set clear expectations throughout the perioperative process. Additionally, and importantly, standardized order sets are also developed to ensure that all components of an ERAS program have little variation in order to improve compliance. A final implementation date is defined after coordinating that all stakeholders are indeed ready for launch. Appropriate educational campaigns are performed in a timely fashion prior to final implementation to outpatient office staff, inpatient units, preoperative and postoperative care units, operating room personnel and physicians, and midlevel providers and trainees (Fig. 50-6).

Compliance and auditing should be done with relative frequency in the beginning, from weekly to biweekly and then monthly. Team meetings with all stakeholders present allow the team to address any issues in timely fashion with a multidisciplinary approach and thus upholds accountability. The frequency of checkpoint meetings can be reduced over time. Sharing data of successes and failures keeps the team engaged. It is also recommended that a financial team be employed. The financial savings after adoption of an ERAS protocol can be substantial from reduction in length of stay, medication use, and resource utilization. Ideally, a portion of the cost savings should be funneled back into the ERAS program in order to ensure program maintenance and compliance and also to assist with expansion to other service lines or patient care improvement projects.

TRADITIONAL CHINESE MEDICINE IN SURGICAL PATIENTS

History of Traditional Chinese Medicine

Traditional Chinese medicine is one of China's outstanding national cultural heritages and the quintessence of China, sharing a deep history and common homology with the Chinese culture.²⁶⁶ It is derived from the rich experience and theoretical

knowledge that Chinese people have used to combat disease for thousands of years. The achievements of traditional Chinese medicine caught the attention of the world because it examines each function of the human organism and adjusts those functions to achieve ultimate balance.

Traditional Chinese medicine is the oldest medicine in China. It is a medical system with unique theory, style, diagnoses, and treatments, which were gradually formed throughout the historical medical practice of the Chinese nation. Its development not only depended on the practice but also resulted from the systemic mode of thinking and Chinese philosophy of *protecting life shape*. Yet, it is a traditional subject that still stands in the modern world of science.

Traditional Chinese medicine theory mainly resulted from the summary of practice and was continuously enriched and developed in practice. As early as 2000 years ago, Huang Di Nei Jing wrote the earliest existing theory of traditional Chinese medicine in China, and it summarized the treatment experience and medical theory to that time. Combining the achievements of other natural science branches and simple materialism and dialectical thinking of the Chinese culture, Huang Di Nei Jing comprehensively expounded the knowledge of human anatomy, physiology, and pathology and also stated the diagnosis, treatment, and prevention of disease, thus founding the preliminary theoretical basis of traditional Chinese medicine.

Based on herbal remedies of primitive people, *Shen Nong Ben Cao* was the earliest existing monograph on herbal pharmacology in China.²⁶⁷ It summed the study of herbology to date, including 365 kinds of drugs until the Han Dynasty. Long-term clinical practice and modern scientific research show that the effects of the drugs described in the book are mostly correct.

In the third century, the famous physician Zhongjing Zhang of the Eastern Han Dynasty delved into the classical medical books such as *Su Wen*, *Zhen Jing*, and *Nan Jing* and extensively collected the effective prescriptions, combining this with his own clinical experience. He published a famous book about typhoid fever, *Shang Han Bing Za Lun*. This book established the theoretical system and treatment principles that applied dialectical therapy of Chinese medicine and influenced the future of traditional Chinese medicine.

In 610 A.D., Yuanfang Chao et al wrote *Treatise on the Etiology of Various Diseases*, which is the earliest existing monograph on causes of symptomatology in China. This book also recorded the intestinal anastomosis, abortion, tooth extraction, and other operations, indicating the breadth of surgery practiced at that time. Subsequently, the ancient Chinese government in 659 A.D. issued *Tang Xiu Ben Cao*; it was not only the first pharmacopoeia of ancient China but also the first national pharmacopoeia of the world. It was published 883 years earlier than the *Nuremberg Pharmacopoeia*, which was issued by the European Nuremberg government in 1542 A.D.

The Tang Dynasty physician Simiao Sun authored *Bei Ji Qian Jin Yao Fang* and *Qian Jin Yi Fang*. In these two books, clinical subjects, acupuncture, dietary therapy, disease prevention, and life preservation were discussed. These were an outstanding achievement of the time, especially in the prevention and treatment of nutritional deficiency diseases.

Between the 12th and 14th centuries, i.e., the *Jin* and *Yuan* eras of China, several new Chinese medicine theories emerged. There were four representative scholars. Wansu Liu (1120–1200 A.D.) thought the symptoms of *shanghan* (exogenous febrile disease) were related to “excessive internal heat,” so the herbal

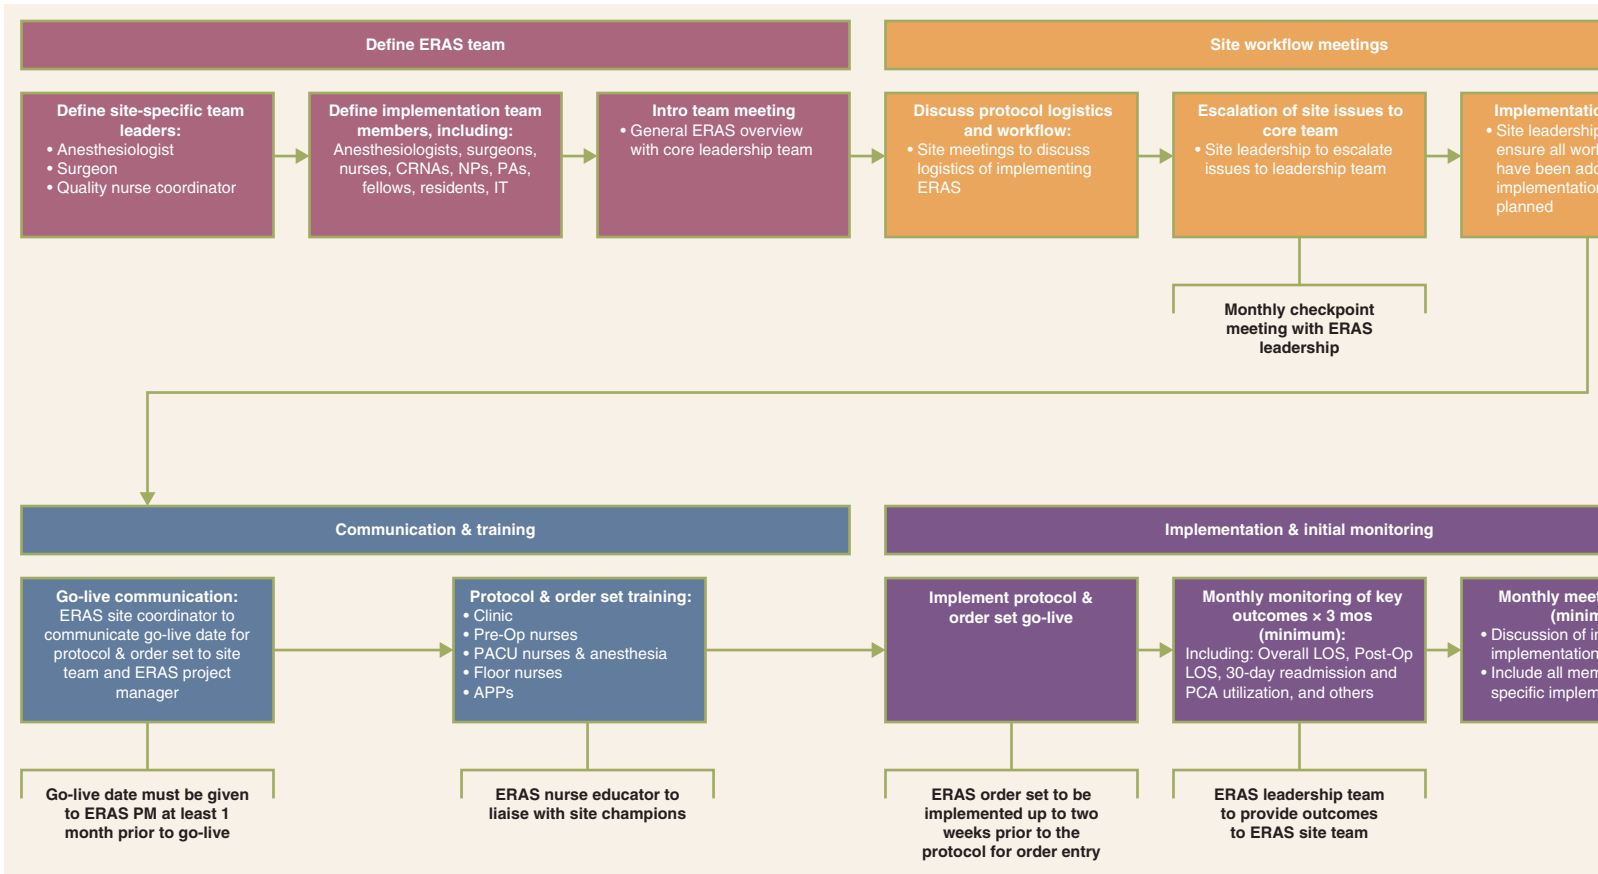

Figure 50-6. Implementation process of an enhanced recovery after surgery pathway. ERAS = enhanced recovery after surgery; CRNA = certified registered nurse; NP = nurse practitioner; PA = physician assistant; IT = information technology; PACU = postanesthesia care unit; APP = advanced practice provider; LOS = length of patient-controlled analgesia.

characteristics of *cold and cool* were used in treatment, and this was known as the “cold and cool” treatment style. Congzheng Zhang (approximately 1156–1228 A.D.) thought the cause of disease was “exogenous evil” (exogenous pathogenic factor) invading the human body; therefore, the treatment focused on “eliminating evil,” through the diaphoresis, emetic, and/or purgative methods, which were known as the “offensive precipitation” style. Dongyuan Li (1180–1251 A.D.) proposed that “internal injury of viscera causes various diseases,” and pyretic tonification of the spleen and stomach was emphasized in the treatment, known as the “invigorating the spleen” style. Zhenheng Zhu (1281–1358 A.D.) thought “*yang* was always excessive, while *yin* was always insufficient” in the body, so the treatment was focused on *nourishing yin and cutting down heat*, which was known as the “nourishing yin” style.

In approximately the 11th century, the Chinese began to use human pox vesicle exposure as vaccination to prevent smallpox and thus pioneered the field of medical immunology and vaccination. In the 17th to 19th centuries, due to the epidemics of infectious diseases, the seasonal febrile disease theory developed. This theory broke the traditional Chinese medicine long-term conception that the pathogens invaded from the surface to the inside of the body. In the mid-17th century when bacteriology had not yet appeared, this was undoubtedly a great pioneering work and laid the groundwork for the epidemiology of the spread of disease.

In the period from the Opium War (1838–1842 A.D.) to the founding of the People’s Republic of China in 1949 A.D., Western medicine was introduced to the continent of China. However, Western medicine and Chinese medicine theories were unique to each other. There was almost no interchange between them, either in theory or in practice; yet together, they formed a unique and relatively mature theoretical system. In the 1920s to 1930s, Western medicine proposed abolishing Chinese medicine. At the same time, Chinese medicine did not deny the merits of Western medicine but thought that Chinese medicine was superior to Western medicine. However, there were several advocates to combine the theories who published such works as “Chinese Medicine for Main, Western Medicine for Use,” “Using Their Respective Strengths, Reaching the Same Goal by Different Means,” and “Chinese Medicine Treat Internal Disease, Western Medicine Treat Surgical Disease.”²⁶⁸ In short, the pervasive opinion was to learn from the other’s strong points to make up for one’s deficiencies. This forged the trail for establishing modern Chinese integrative medicine.

In the past decade, a series of significant progresses and breakthroughs have been made in the modern study of traditional Chinese medicine theory and its application to clinical practice. For example, acupuncture anesthesia can be used for small splint fixation, and the treatment of acute abdomen integrates both traditional Chinese and Western medicine.²⁶⁹ Most lately, Tu Yo Yo’s team found that artemisinin, derived from the wormwood plant, treats malaria, and the team was awarded the Nobel Prize in 2015.

Clearly, integration of traditional Chinese medicine with modern science and technology will advance knowledge and treatment. Modern diagnostic instruments and techniques have become auxiliary methods of clinical diagnosis and treatment of traditional Chinese medicine, making up for the deficiency of the traditional “four ways of diagnosis” methods and improving the accuracy and efficiency of traditional Chinese medicine diagnosis and treatment. Thus, modern science and technology’s

infiltration, transformation, and integration in all aspects of Chinese medicine will be one of the distinctive characteristics of the future development of Chinese medicine.

In summary, traditional Chinese medicine and pharmacy are an important part of the splendid culture of the Chinese nation, making outstanding contributions over thousands of years because of its systemic theory, distinctive treatment methods, significant efficacy, and abundant historical documentation. Modern Chinese medicine includes traditional Chinese medicine and thus offers integrated and superior health service. This integration of Eastern and Western medical ideas and philosophies are important for the future of this modern medical era.²⁷⁰

Preoperative Nutritional Optimization

Many surgical abdominal diseases have a long incubation period before clinical presentation, during which time the patients may develop malnutrition including specific nutrient deficiencies and hypoproteinemia. These comorbidities directly influence the surgical treatment and postoperative effect of the patient undergoing an operation. In this setting, some experts advocate the use of parenteral nutrition and other adjunctive nutritional measures. These measures can often improve the patient’s nutritional status, but they are difficult to popularize because of the high cost of treatment and common complications with parenteral nutrition.

In traditional Chinese medicine theory, it is thought that there are a variety of “asthenic symptoms” in patients who need surgical treatment and that applying the treatment principle of “treating deficiency with tonification” improves conditions throughout the body. On the basis of the traditional Chinese medicine theory of the “concept of holism” and “treatment according to syndrome differentiation,” the *all nourishing decoction* (*Shiquan Dabu* decoction) and *Buzhong Yiqi* decoction are used in patients with the “deficiency of vital energy and blood syndrome” before surgery and have achieved good results.²⁷¹⁻²⁷⁵ Similar success has been shown with the *Shenmai* injection and *Astragalus* injection.^{276,277} For example, when traditional Chinese medicine is used effectively to treat patients with breast cancer before an operation, it enhances the general body status, improves the patient’s energy, and regulates the liver and kidney functions, which ultimately promotes the success of the operation and controls progression of the tumor.^{278,279}

Bowel Preparation for Surgery

In gastrointestinal surgery, the method of “purgation and offensive precipitation” is used in preparation for the operation. Either *Large Chengqi* decoction or *Seasoning Chengqi* decoction significantly increases the gastrointestinal motility and washes the gastrointestinal stagnation to prepare the bowel for surgery. These decoctions also improve visceral blood flow and peritoneal absorption, promote early recovery of postoperative bowel function, and prevent superimposed infection of the intestine and the effect of endotoxin.^{280,281}

Preoperative Optimization During Sepsis and Infection

Due to infection, endotoxemia, blood loss, and other factors, many critically ill patients will deteriorate or progress to shock. Initial surgery during profound shock may be counterproductive until adequate resuscitation is achieved. In addition to resuscitation, blood transfusion, and antimicrobial treatment if indicated for sepsis, the traditional Chinese medicine treatment based on dialectics can help to create a favorable condition for surgery, if indicated.

For traumatic shock and anaphylactic shock patients, the use of flavored *pure ginseng* decoction supplemented by blood transfusion and other comprehensive antishock measures, can rapidly raise blood pressure and provide a more optimal setting for surgical treatment.²⁸² *Qingdan* decoction and *Qingyi* decoction, which are composed of herbs to clear away heat and toxins, remove stasis, purge the bowel, and are used to treat acute obstructive suppurative cholangitis and hemorrhagic and/or necrotizing pancreatitis.²⁸³⁻²⁸⁵

Perioperative Pain Management

The application of traditional Chinese medicine in perioperative pain management is has become more prevalent in recent years. Research of acupuncture for analgesia began in the 1950s in China and has developed into a combined acupuncture and medicine anesthesia that is currently recognized by the medical field.²⁸⁶ During surgery, the combined anesthesia is composed of acupuncture and opioid drugs. Experimental data show that the combined acupuncture anesthesia could reduce the dose of opioid by 50%.²⁸⁷ Acupuncture also helps the management of postoperative pain by enhancing the level of the endogenous opioid, enkephalin. Enkephalin restrains the pain signal from being transmitted to the central nervous system, blocks the body's reaction to pain, and increases the pain threshold accordingly.²⁸⁸ In several clinical trials, the needed doses of opioid at 8, 24, and 72 hours postoperatively were reduced in acupuncture groups compared to control groups.²⁸⁹ In addition, electroacupuncture has been demonstrated to be effective at alleviating postoperative pain and assisting in recovery. One randomized controlled trial shows electroacupuncture significantly reduced the dose of fentanyl used, improved the quality of recovery and decreased the incidence of anesthesia related side effects for patients undergoing surgery.²⁹⁰

10► Postoperative Nausea and Vomiting Prevention

PONV is a common complication after surgery. Acupuncture and herbs can be applied to prevent and treat PONV. Acupuncture or transcutaneous electroacupuncture improves stress-induced impairment in gastric motility functions, significantly inhibits the frequency of transient lower esophageal sphincter relaxations in response to gastric distention, and suppresses retrograde peristaltic contraction.²⁹¹⁻²⁹³ In clinical trials, intraoperative P6 acupuncture point (*Neiguan* acupoint) stimulation during surgery significantly reduces the incidence of PONV over 24 hours, and the efficacy of P6 stimulation is similar to that of commonly used antiemetic drugs in the prevention of PONV.²⁹⁴ Furthermore, electroacupuncture restrains the release of gastrointestinal peptides and consequently relieves PONV with an efficacy comparable to ondansetron.²⁹⁵ Moreover, a randomized, prospective, double-blinded clinical trial shows that auricular acupressure within 24 hours postoperatively has a similar effect to prevent PONV.²⁹⁶

Additionally, some Chinese herb decoctions, such as *Liu Jun Zi* decoction and *Cheng Qi* decoction, administered perioperatively, show possible effectiveness to reduce the severity of PONV and to relieve abdominal distension.^{297,298}

Early Nutrition and Postoperative Ileus Prevention

In traditional Chinese medicine, acupuncture and decoctions have a role in the prevention of postoperative ileus. For example, early acupuncture on *Zusanli*, *Shangjuxu*, and *Xijuxu* acupoints,

combined with early enteral nutrition, can effectively improve gastrointestinal function and shorten the length of stay after surgery.²⁹⁹ In addition, *Dachengqi* decoction applied to patients after laparotomy improves gastric dysrhythmia, promotes intestinal peristalsis, and enhances gastrointestinal motility.^{300,301} Furthermore, in one randomized trial, the combination of *Simo* decoction and acupuncture reduces the incidence of postoperative ileus and shortens hospital stay for patient undergoing abdominal surgery when compared to the perioperative use of chewing gum.³⁰² Other traditional Chinese medicine methods such as electroacupuncture combined with Evodia hot compress, confers benefit in postoperative recovery of gastrointestinal function of patients who have undergone abdominal surgery.³⁰³

Traditional Chinese Medicine in Common Surgical Conditions

Colon Surgery. Several traditional Chinese medicine decoctions can assist in bowel preparation prior to surgery. For example, during the bowel cleansing before surgery, *Dachengqi* decoction can be used to promote bowel peristalsis and evacuation, thus preventing contamination during surgery and reducing the risk of postoperative complications of infection. Additionally, after colon surgery, traditional Chinese medicine therapies such as acupuncture and decoctions prevent postoperative ileus, reduce the incidence of PONV, and promote the recovery of colon function. As a result, traditional Chinese medicine can shorten the hospital stay after colon surgery.

Appendicitis. In general, patients suffering from acute appendicitis will undergo appendectomy. Exceptionally, when a case of acute simple appendicitis or a periappendiceal abscess is encountered, Chinese herbs together with antibiotics can serve as an alternative treatment. In early acute simple appendicitis, oral *Qinghua* decoction can help the appendix infection resolve without surgical management.³⁰⁴ This nonsurgical treatment also can be applied to patients with periappendiceal abscess that is unsuitable for surgery. These Chinese medicine herbs activate blood flow, dissolve stasis, clear heat, and remove toxicity.

Biliary Disease. Cholelithiasis is a common disease of the biliary tract that can result in cholecystitis and the possible need for cholecystectomy. Several traditional Chinese medicine herbs can relieve the symptoms of acute cholecystitis and delay the progression of the disease, possibly preventing the need for cholecystectomy. These Chinese medicine herbs are composed of herbs for clearing heat and secreting bile (*Qing Re Li Dan*), herbs for promoting circulation of Qi and relieving pain (*Xing Qi Zhi Tong*), and herbs for clearing heat and promoting diuresis (*Qing Re Li Shi*). According to different Chinese medicine therapies, the use of these herbs can also be applied to patients postoperatively from abdominal or biliary surgery to adjust biliary excretion and/or prevent cholestasis.

Unfortunately, severe cholecystitis or cholangitis may progress to liver abscess. When a liver abscess develops, percutaneous catheter drainage and Chinese medicine herbs are applied in Chinese medicine practice.³⁰⁵ Generally, in the early stage of abscess, Chinese medicine herbs are used for clearing heat and removing toxicity (*Qing Re Jie Du*) and for promoting blood circulation and removing blood stasis (*Huo Xue Hua Yu*). When abscess is evident, Chinese medicine herbs for clearing heat and cooling blood are added.³⁰⁵ The main function of these Chinese medicine herbs is to relieve infection, reduce inflammation, and activate intestinal motility in order to evacuate the

toxicity, reduce the inflammatory response, and thus hasten recovery.

Pancreas Surgery. In recent years, the early use of traditional Chinese medicine and enteral nutrition treatment in patients after pancreaticoduodenectomy, can help to hasten recovery in gastrointestinal function, improve nutritional status and immune function, and also reduce postoperative complications. The combined use of total parenteral nutrition and *Astragalus* injection can improve the nutrition status of patients with obstructive jaundice and improve the immune function of these patients.³⁰⁶ *All Nourishing (Shiquan Dabu)* decoction has the role of increasing the level of plasma albumin and hemoglobin, which can be used as a recipe in surgical nutrition therapy.³⁰⁷

Intestinal Obstruction. Adhesive ileus is the most common type of small intestinal obstruction and also is the kind to which traditional Chinese medicine therapies apply widely. The methods of traditional Chinese medicine treatment include acupuncture, Chinese herbal enema, and gastrointestinal intubation. Acupuncture or transcutaneous electroacupuncture applied to acupoints such as *Zusanli* point, *Neiguan* point, *Zhongwan* point, and *Tianshu* point has remarkable regulatory effects on gastrointestinal function and can promote relief of obstruction.³⁰⁸ *Dachengqi* decoction combined with the Chinese medicine herbs for clearing heat and removing toxicity (*Qing Re Jie Du*), and for promoting blood circulation and removing blood stasis (*Huo Xue Hua Yu*), can enhance gastrointestinal motility, improve blood circulation of the intestine, reduce intestinal capillary permeability, protect the barrier function of the intestinal mucosa, and help inflammatory edema to resolve.³⁰⁹ Additionally, acupuncture, Chinese herbal enema, and gastrointestinal intubation can shorten the time of the obstructive event and reduce the length of stay in patients suffering from adhesive intestinal obstruction.³¹⁰ These methods of traditional Chinese medicine treatment can also be applied to the treatment of postoperative ileus.

INTRODUCTION

The singular importance of this chapter rests on the following chain of reasoning:

1. The state of surgical science and knowledge is constantly changing.
2. The education of a surgeon is a continuous process.
3. Surgeons need to know how to evaluate new surgical knowledge to maintain their education in order to best serve their patients.
4. This chapter provides guidance as to how surgeons might navigate, interpret and apply this new knowledge.

Notably, this reasoning also applies to the process of acquisition of new knowledge itself, which explains why this inaugural chapter on evidence-based medicine is occurring in the 11th edition of this book. Recognizing the impermanence and fluidity of knowledge is a critical insight for the responsible surgeon, but so too is realizing that “good practice” cannot occur without reference points as to what should be done given the current imperfect state of knowledge. These dual recognitions inform the organization of this chapter, which introduces and describes the currently accepted approach to evidence-based medicine, and then follows by noting a series of current issues that anticipate the likelihood that what is meant by “evidence-based medicine” will evolve over the coming years. Also note that this chapter is not intended to be a primer on statistics and clinical trial design; there are entire textbooks devoted to those subjects. Rather, this chapter will focus on how those tools are aggregated and presented in order to inform a surgeon how to keep abreast with current developments in practice.

WHAT IS EVIDENCE-BASED MEDICINE?

For centuries, the practice of medicine was guided primarily by anecdotal experience, often based on rationales that did not arise from a rigorous scientific process and sustained by the fundamental barriers associated with being able to learn from one’s experience (e.g., cognitive bias). For example, treatments such as bloodletting and purging were based on ostensible principles of bodily humors originating from the Ancient Greeks, and persisted well into the 18th century despite repeated disastrous outcomes. To a great degree, the goal of the Scientific Method, through its emphasis on skepticism and falsifiability, is predicated upon overriding observational/experiential bias by the application of rigorous methodology statistical analysis. The dangers of bias were recognized at the dawn of the Scientific Era, and continue to manifest today (**Box:** The History and Sources of Bias in Biomedical Literature).

The History and Sources of Bias in Biomedical Literature

In Sir Francis Bacon’s initial description of the scientific method in his *Novum Organum*¹ he notes what he terms the “idols of the mind,” in essence recognizing and classifying the sources of cognitive bias that limit the reliability of subjective observation and interpretation. These “idols” are:

- Idols of the tribe (*Idola tribus*): A humans’ tendency to perceive more order and regularity in systems than truly exists, and arises from their preconceived ideas about things
- Idols of the cave (*Idola specus*): Arising from an individual’s personal limitations in reasoning due to particular personalities, subjective likes and dislikes

Key Points

- 1▶ Cognitive bias is inescapable, and limits the ability of both individual practitioners and the surgical field in general, to advance and improve in a scientific fashion. Evidence Based Medicine is an attempt to codify the process of interpreting experience, assessing the literature and translating it into practice.
- 2▶ Dealing with and interpreting the vast amount of surgical literature available on the Internet can be daunting, and this task can be aided by the application of identified formats for executing online search. The PICO (Patient/Population, Intervention, Comparison and Outcome) format is a commonly used method for codifying online search.
- 3▶ Not all literature or evidence is created equal. There exist various approaches, such as the Oxford Center for Evidence Based Medicine (CEBM) Levels of Evidence or the GRADE (Grading and Recommendations, Assessment, Development and Evaluation) system, that have been developed to provide guidance in assessing and reifying scientific literature.
- 4▶ The conversion of evidence into clinical practice often manifests in the creation of clinical guidelines. As with all things

related to evidence based medicine, not all guidelines are created equal, and therefore there are certain characteristics that can be used to evaluate the quality of a particular clinical guideline.

- 5▶ There are specific challenges in the application of evidence based medicine to surgery, not least of which is the difficulty in performing a truly randomized clinical trial. The CONSORT (Consolidated Standard of Reporting Clinical Trials) guidelines were developed to serve as minimal recommendations for reporting randomized clinical trials.
- 6▶ The well-known saying “There are lies, damn lies and then statistics” points to the recognition that statistical tools can be prone to misuse, and emphasizes the need to understand the appropriate application, limits of and interpretation of reported statistics.
- 7▶ Evidence based medicine has not thus far been held to its own standards of evidence. Recognizing that available “evidence” is a constantly shifting landscape should warn one against the dangers of epistemic certainty, and further emphasizes the fact that surgical education is an ongoing and perpetual process.

- Idols of the marketplace (*Idola fori*): Arising from the confusion in the use of language and taking some words in science to have a different meaning than their common usage
- Idols of the theatre (*Idola theatri*): Arising from the following of academic dogma and not asking questions about the world

These descriptions still resonate today, illustrating just how long the dangers of cognitive bias have been recognized, and just how embedded those tendencies may be. For instance, the following are sources of bias in biomedical literature:

- Publication bias: publishers incentivized to accept positive results
- Prevailing field bias: supporting entrenched opinions
- Citation bias: tendency to cite positive studies
- Time-lag bias: delay the reporting of negative results
- Reporting bias: emphasizing positive over negative results

In the medical field, the transition from accumulated anecdote to true statistical analysis can be seen in the emergence of clinical epidemiology as a field in 1938, which began to shift the focus from descriptions of individual patients to trends affecting entire populations. This shift, however, was accompanied by new challenges, as different means of turning anecdotal experience into statistics (e.g., case series, observational studies, retrospective studies, prospective studies) meant that now practitioners needed to be able to compare these “scientific” presentations against each other in order to best establish their practices. The processes and methods of aggregating, comparing, and translating these different types of data from the medical literature into clinical practice were explicitly established in the latter part of the 20th century, particularly arising from efforts at McMaster University, which eventually led to a fundamental framework for literature-informed medical decision-making known as evidence-based medicine (EBM).

EBM is defined as the “conscientious, explicit and judicious use of current best evidence in making decisions about treating individual patients.”^{2,3} This term was coined by Gordon Guyatt in 1991, focusing on assessing the credibility of the medical literature, understanding the presented results, and applying the information to individual practice. EBM is defined by three epistemological principles⁴:

- 1▶ Principle 1: Not all evidence is created equal, and the practice of medicine should be based on the best available evidence
- 2▶ Principle 2: The pursuit of truth is best accomplished by evaluation of the totality of the evidence, and not selecting evidence that favors a particular claim
- 3▶ Principle 3: Clinical decision-making requires consideration of patients’ values and preference

The adoption of EBM in the discipline of surgery has lagged compared to nonsurgical specialties. To a great extent, this is due to the challenges of achieving the highest level of evidence noted in principle 1: definitive conclusions from a randomized controlled trial (RCT). A literature analysis of MEDLINE from 1966 to 2000 demonstrated that only 15.1% of the 134,689 RCTs evaluated a surgical topic.⁵ In the early days of EBM during the 1990s, surgical RCTs accounted for only 7% of published articles in surgical journals; most of the articles were retrospective studies and case series,⁶ which are essentially aggregated anecdotes. Over the next decade, the relative frequency of RCTs in surgery further decreased, accounting for 3.4% of all publications in 2003.⁵ As a result, most of the available evidence to guide surgical practice today remains based on retrospective reviews, nonrandomized trials, and expert opinion. The barriers to performing prospective RCTs in surgery remain substantial: standardization of clinical presentation and, of course, accounting for variations in operative technique and the ability to blind studies to reduce experimental bias. The relative paucity in RCTs in surgery make it even more

important that surgeons understand the best-practice methods to critically appraise available evidence, while recognizing the limitations and potential pitfalls of those methods, in order to optimize their practice and decision-making regarding patient care when high quality evidence may not be available. Herein we present the steps of such a workflow, starting with an initial search for information, identification of the classes of information that such a search can return, and then guidelines by which that information is evaluated, compared, and aggregated.

Searching for Information: Patient/Population, Intervention, Comparison, and Outcome

Technology has substantively changed how information can be sought and retrieved. Online search engines such as MEDLINE via PubMed, which contains over 26 million citations, have dramatically enhanced the ability to access biomedical literature.⁷ However, there is a very real potential for such access to become overwhelming. Effective and efficient use of search engines can be enhanced by framing the clinical question in a format designed to improve the relevancy of search results. PICO is one such format, where the acronym stands for Patient/Population, Intervention, Comparison, and Outcome.⁸

- **Patient or population** is the specific group of individuals for which the questions is being asked.
- **Intervention** is the treatment or technique of interest for the defined patient or population. Intervention might be a procedure, such as “laparoscopic appendectomy” or be defined as an exposure of interest, such as “smoking.”
- **Comparison** is the alternative treatment or technique to which you are comparing the intervention. Terms might include, for example, “open appendectomy” or “observation.”
- **Outcome of interest** is the final step of the PICO format. Examples include “mortality,” “operative time,” and “wound infection.”

As with all online search strategies, there is a trade-off between the specificity of the search and the breadth of the returned items. When using PICO to inform clinical decision-making, it is generally advantageous to be as precise and specific as possible when initiating a search: this increases the likelihood the search will return information most germane to the particular clinical scenario. This is accomplished by the use of “AND” in the framing of the search to encompass the set of questions of interest. For example, one could construct a query consisting of a particular procedure, with a particular method, with a particular outcome metric, such as “(distal pancreatectomy) AND splenectomy AND (splenic preservation) AND morbidity” to frame a PICO question.

Types of Studies

Principle 1 of EBM states that not all evidence is created equal; therefore, evaluating the evidentiary quality of the results of an online search requires classifying the returned search items by type of study. As noted earlier, acknowledging that the “gold standard” level of evidence, RCTs, are rare in the surgical literature, the application of EBM to surgery requires increased familiarity with the types of alternative studies available, with their relative strengths and weaknesses. These types are listed below:

- **Meta-analysis:** A meta-analysis is a technique to combine similarly published data in order to increase the overall

statistical power compared to each study individually. The amount of interstudy heterogeneity (methods, study population, endpoints, etc.) should be limited to allow for the generation of informative conclusions. The pooling of similar studies enables researchers to generate a new statistical conclusion based on a substantially larger sample size. These approaches, though useful, have their limitations: the inclusion of inappropriate studies and the mislabeling of a meta-analysis leading to inaccurate conclusions. Attention should be directed toward this type of evidence when clinical guidelines do not exist.

- **Systematic Review:** Like meta-analyses, systematic reviews use standardized methods to search for and appraise studies in order to attempt to reduce bias. However, systematic reviews do not utilize quantitative methods to summarize the results. For this reason, systematic reviews are often not considered to provide the same strength of evidence as a meta-analysis.
- **Cross-Sectional Studies:** In a cross-sectional study, exposures and outcomes are measured at a single point in time. The prevalence of the outcome is then compared in patients who did and did not have the exposure. Multiple exposures and outcomes can be measured at the same time, which is an advantage; however, there are important limitations. One significant limitation is that a temporal relationship cannot be determined between exposure and outcome because they are measured simultaneously. These studies will often form the foundation for more definitive studies.
- **Case Control Study:** In a case-control study, cohorts are determined by the presence or absence of a particular outcome of interest. This is in contrast to a cross-sectional study where samples are determined by the presence or absence of an exposure. Once the samples have been identified based upon outcome, then possible prior exposures are identified, and the odds of those exposures are compared between cohorts.
- **Case Series:** A Case Series involves a report of a small group of patients that share specified clinical features; this generally does not include description of a control group. Case series are prevalent in the field of surgery, and some of the most famous eponymous procedures originated from case series, including the Whipple procedure⁹ and Nissen fundoplication.¹⁰ This type of study provides weak evidence due to issues with patient selection, biases, and confounding factors. However, the findings from a case series can be used to generate hypotheses for a randomized control trial.
- **Expert Opinion:** Expert opinions represent the lowest level of evidence and is representative of a clinician’s individual experience and anecdotes. Prior to evidence-based medicine, expert opinion was the primary means of teaching medicine and shaping the field. However, the opinions of clinicians can vary substantially leading to a wide range of potential unproven treatments for a medical issue. Thus, expert opinion should only be solicited in the complete absence of evidence in the literature.

It should also be noted that irrespective of the type of study or recommendation, there are additional factors that can contribute to bias in publication. To a great degree these are extrapolations of the sources of individual cognitive bias, but writ large across an entire community (see **Box:** The History and Sources of Bias in Biomedical Literature).

Hierarchies of Evidence

The original architects of EBM codified the notion that certain types of evidence are superior to others based on characteristics of study design, depicting this concept as a “pyramid,” with expert opinion comprising the base of the pyramid and randomized controlled trials at the peak (Fig. 51-1). Although conceptually appealing, this initial attempt to “rank” the evidence was relatively simplistic and rested on unproven assumptions that RCT were inherently superior to observational studies. While RCTs theoretically provide higher quality evidence compared to observational studies, RCTs can also have significant limitations and biases (see later section, “The Challenges of Applying EBM to Surgery”). Furthermore, translating the results from well-crafted RCTs can be challenging, where the specific restrictive criteria for executing a high-quality RCT can inherently limit its applicability to clinical scenarios not specifically noted or tested in the RCT. Therefore, one could find oneself in the situation of trying to compare an RCT on a related but clearly distinct use case with a well performed observational study that more closely approximated the clinical scenario in question. This led to the subsequent development of more refined frameworks to assess the quality of evidence in order to try and address these issues, although there is currently no consensus on a single framework. The current situation is that while many newer systems have devised ways in which studies can move up and down the pyramid, for well-designed studies, the pyramid largely remains intact.

The initial hierarchies of evidence were limited because they entangled the method of evidence collection with underlying study design. They failed to recognize principle 2 of EBM: “the pursuit of truth is best accomplished by evaluation of the totality of evidence” and the principle that “health claims be based upon systematic reviews which summarize the best available evidence.”¹⁴ The earliest hierarchies positioned systematic reviews at the top of the pyramid followed by RCTs; however, this classification failed to acknowledge that systematic reviews can summarize any type of evidence. Cohort studies, case-control studies, and even case reports can be the subject of systematic review. The importance of systematic review in EBM cannot be understated: systematic reviews are the most

Figure 51-1. Evidence-based hierarchy.

cited type of study, and these studies are essential for the development of clinical guidelines and influencing the direction of future studies.^{2,11} When applied in a timely manner, systematic reviews have resulted in major practice changes, for example, encouraging early postoperative enteral feeding compared to parenteral nutrition to prevent sepsis.¹²

Tools to Evaluate a Body of Evidence

By 2002, over 100 unique evidence rating systems existed,² and the differences among them may be nontrivial. Depending upon the specific criteria used, the “strength” of evidence might differ widely from system to system. For example, the American Association of Orthopedic Surgeons (AAOS) published guidelines in 2009 for prevention of venous thromboembolism (VTE) in patients undergoing hip or knee surgery that conflicted with the widely used American College of Chest Physician (ACCP) guidelines, despite having access to the same data. While the ACCP considered VTE prophylaxis to be a grade 1 recommendation with level A evidence, the AAOS recommendation varied based upon risk of pulmonary embolism and bleeding, with no recommendation being greater than B and all recommendations being based upon level III evidence.¹³ In the following section we present a few of the most widely accepted tools for assessing the quality of evidence.

CEBM Levels of Evidence. One of the most widely adopted systems for grading evidence is the Oxford Center for Evidence Based Medicine (CEBM) Levels of Evidence. The original CEBM system was released in 2000 and was subsequently updated in 2011. Earlier systems of evidence ranking were criticized because they categorically placed randomized trials above observational studies, although observational studies and even anecdotes can occasionally give the “best” evidence in certain clinical situations. CEBM was therefore developed to not only improve the ranking of evidence but also to aid clinicians in quickly searching for the best evidence available for a given clinical question (Table 51-1). It is designed as both a tool for traditional critical appraisal as well as a pragmatic system that clinicians can use to answer clinical questions in real time. It can be used as a heuristic that clinicians and patients can utilize to answer clinical questions quickly and without resorting to preappraised sources.¹⁴ The CEBM Levels of Evidence system begins with choosing a clinical question from the first column of the table provided by the creators (see Table 51-1) (for example, “How common is the problem?”, “Does this intervention help?”, or “Is this test worthwhile?”). Therefore, each row of the CEBM Levels of Evidence represents a series of steps one should follow to find the best evidence for the question chosen. Strong evidence is likely to be found in columns to the left of the table, while weak evidence will be found in columns to the right. After completing a clinical query using the table, a final “level” of evidence is assigned on a scale from 1 to 5 based upon the types of studies found to answer the initial question (1 = highest rated evidence; 5 = lowest rated evidence). However, the levels are not intended to provide one with a definitive judgment regarding the quality of evidence. There may be cases where “lower level” evidence—for example, an observational study with a large treatment effect—provides stronger evidence than a “higher level” study, such as a systematic review with an inconclusive result.

CEBM should be thought of as a hierarchy of the *likely* best evidence. An advantage of CEBM is that it allows the potential of resorting to individual studies for the best evidence, while other systems generally assume that there is a systematic

Table 51-1

Oxford center for evidence-based medicine 2011 levels of evidence

QUESTION	STEP 1 (LEVEL 1*)	STEP 2 (LEVEL 2*)	STEP 3 (LEVEL 3*)	STEP 4 (LEVEL 4*)	STEP 5 (LEVEL 5)
How common is the problem?	Local and current random sample surveys (or censuses)	Systematic review of surveys that allow matching to local circumstances**	Local non-random sample**	Case-series**	n/a
Is this diagnostic or monitoring test accurate? (Diagnosis)	Systematic review of cross-sectional studies with consistently applied reference standard and blinding	Individual cross-sectional studies with consistently applied reference standard and blinding	Non-consecutive studies, or studies without consistently applied reference standards**	Case-control studies, or “poor or non-independent reference standard**	Mechanism-based reasoning
What will happen if we do not add a therapy? (Prognosis)	Systematic review of inception cohort studies	Inception cohort studies	Cohort study or control arm of randomized trial*	Case-series or case-control studies, or poor quality prognostic cohort study**	n/a
Does this intervention help? (Treatment Benefits)	Systematic review of randomized trials or <i>n</i> -of-1 trials	Randomized trial or observational study with dramatic effect	Non-randomized controlled cohort/follow-up study**	Case-series, case-control studies, or historically controlled studies**	Mechanism-based reasoning
What are the COMMON harms? (Treatment Harms)	Systematic review of randomized trials, systematic review of nested case-control studies <i>n</i> -of-1 trial with the patient you are raising the question about, or observational study with dramatic effect	Individual randomized trial or (exceptionally) observational study with dramatic effect	Non-randomized controlled cohort/follow-up study (post-marketing surveillance) provided there are sufficient numbers to rule out a common harm. (For long-term harms the duration of follow-up must be sufficient.)**	Case-series, case-control, or historically controlled studies**	Mechanism-based reasoning
What are the RARE harms? (Treatment Harms)	Systematic review of randomized trials or <i>n</i> -of-1 trial	Randomized trial or (exceptionally) observational study with dramatic effect			
Is this (early detection) test worthwhile? (Screening)	Systematic review of randomized trials	Randomized trial	Non-randomized controlled cohort/follow-up study**	Case-series, case-control, or historically controlled studies**	Mechanism-based reasoning

*Level may be graded down on the basis of study quality, Imprecision, Indirectness (study PICO does not match questions PICO), because of inconsistency between studies, or because the absolute effect size is very small; Level may be graded up if there is a large or very large effect size.

**As always, a systematic review is generally better than an individual study.

How to cite the Levels of Evidence Table

OCEBM Levels of Evidence Working Group*. “The Oxford 2011 Levels of Evidence”.

Oxford Centre for Evidence-Based Medicine. <http://www.cebm.net/index.aspx?o=5653>

*OCEBM Table of Evidence Working Group = Jeremy Howick, Iain Chalmers (James Lind Library), Paul Glasziou, Trish Greenhaigh, Carl Heneghan, Alessandro Liberati, Ivan Moschetti, Bob Phillips, Hazel Thornton, Olive Goddard, and Mary Hodgkinsan

Definitions of GRADE Evidence Quality

High quality – Further research is very unlikely to change confidence in the estimate of effect.

Moderate quality – Further research is likely to have an important impact confidence in the estimate of effect and may change the estimate.

Low quality – Further research is very likely to have an important impact on confidence in the estimate of effect and is likely to change the estimate.

Very low quality – Any estimate of effect is very uncertain.

review available. Additionally, other systems are built around considering the strength of evidence for therapeutic effects and harms, while CEBM allows appraisal of evidence for prevalence of disease, accuracy of diagnostic tests, prognosis, therapeutic effects, rare harms, common harms, and usefulness of screening.

Grading and Recommendations, Assessment, Development, and Evaluation. Alternatively, the Grading and Recommendations, Assessment, Development and Evaluation (GRADE) system classifies the quality of evidence into one of four levels: high, moderate, low, and very low¹⁵ (**Box:** Definitions of GRADE Evidence Quality). Evidence quality in the GRADE system is not assigned solely on study design. For example, a randomized controlled trial begins at “high quality,” but may be demoted due to one or more of the following: study limitations, inconsistent results, indirectness of evidence, imprecision, or reporting bias. Alternatively, observational studies (cohort or case-control studies) start as “low quality” but may be upgraded if there is a large magnitude of the treatment effect, evidence of a dose-response relationship, or if all plausible biases would decrease the magnitude of a treatment effect. Thus, the GRADE system of evaluating the quality of evidence provides more granularity than the traditional hierarchy system, which assigns quality based upon study design alone. Although the GRADE system has significant advantages, it is more complex and has a steeper learning curve than traditional systems. Finally, GRADE is intended for appraising a body of evidence, such as in a systematic review.

In addition to providing a transparent approach to grading evidence quality, the GRADE system outlines an approach to the development and assignment of strength to clinical recommendations. GRADE’s sophisticated hierarchy of evidence allows the system to protect against both superficial assessment and unwarranted confidence in all classes of study design. Since its development, the increasing use of GRADE has resulted in higher quality and rigor of systematic reviews due to standards outlined by the system.¹⁵ In creating a recommendation regarding a body of evidence, GRADE allows experts to account for limitations in bodies of evidence comprising of RCTs, while also allowing for the rating of observational studies as high quality in cases where RCTs are not feasible (i.e., an RCT cannot ethically be performed). GRADE therefore potentially allows for observational studies to provide definitive evidence of causal association (e.g., alcohol causing cirrhosis or asbestos causing mesothelioma) where RCTs may not be ethical or necessary.

One of the major advantages of GRADE is that it specifically addresses the process of moving from evidence to recommendations. The process begins with the creation of a summary

of findings table. A summary of findings table consists of a presentation not only of evidence quality but also estimates of the relative and absolute effects of patient-centered outcomes (Fig. 51-2). The summary of findings format was created to minimize framing effects, where different raters may come to varied conclusions based upon identical information due to the information having a contrasting presentation in terms of gain versus loss.¹⁶ GRADE and similar EBM systems specifically takes into consideration judgement of risk versus benefit, resource use, feasibility, and equity to attempt to make decision-making as consistent as possible across a range of reviewers.² Despite all of the aforementioned considerations when constructing a guideline, it is important to realize that patient values or preferences may immediately invalidate any recommendation. Evidence is often constructed based upon measurement of outcomes such as morbidity, mortality, or survival; however, patients may be more concerned with quality of life or avoiding invasive interventions. GRADE attempts to acknowledge this intrinsic variability within its system of grading.

In terms of the overall strength of a recommendation that GRADE can assign, two grades are possible: “strong” and “weak.” A strong recommendation is one where positive effects of an intervention clearly outweigh the negative effects or vice versa. A weak recommendation is one where the association is less clear, either because of low quality evidence or because the evidence clearly suggests that the positive and negative effects are similar. However, quality of evidence is not the only factor that affects the strength of a recommendation (Table 51-2). Factors such as uncertainty of patient values or whether an intervention is an appropriate use of resources can play a role in the strength of a recommendation as well. Therefore, it is important to note that a “strong” or “weak” recommendation may be given regardless of the classification of the evidence. For example, there is a strong recommendation that patients with Zollinger-Ellison syndrome be treated with PPI. This recommendation is made despite weak evidence to support this practice because the potential benefits far outweigh the potential risks.¹⁷

Although the systems for grading evidence are well developed, it is important to remember that the studies used for evidence are judged based on their internal validity, or the extent to which a causal conclusion is warranted based upon application of the results to the study population. This means that care must be exercised when applying a recommendation to a given patient, as the external validity of a recommendation, or generalizability of a causal conclusion to populations outside of the scope of the original studies, may not be appropriate. Therefore, all evidence must be applied within the context of the patient in front of you.

Synthesis of Evidence—Clinical Guidelines

The Institute of Medicine defines a clinical guideline as “statements that include recommendations, intended to optimize patient care, that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options.”¹⁸ Clinical guidelines may reflect previous published studies of varying design and quality, as well as expert opinion, and often represent the highest level of applied clinical evidence. Numerous guidelines have been published; however, like individual studies, even guidelines can vary in quality. The highest quality and most clinically useful guidelines tend to have the following qualities:

Summary of findings:

Compression stockings compared with no compression stockings for people taking long flights						
Patients or population: Anyone taking a long flight (lasting more than 6 hours)						
Settings: International air travel						
Intervention: Compression stockings ¹						
Comparison: Without stockings						
Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	Number of participants (studies)	Quality of the evidence (GRADE)	Comments
	Assumed risk	Corresponding risk				
	Without stockings	With stockings				
Symptomatic deep vein thrombosis (DVT)	See comment	See comment	Not estimable	2821 (9 studies)	See comment	0 participants developed symptomatic DVT in these studies.
Symptom-less deep vein thrombosis	Low risk population²		RR 0.10 (0.04 to 0.26)	2637 (9 studies)	++++ High	
	10 per 1000	1 per 1000 (0 to 3)				
	High risk population²					
	30 per 1000	3 per 1000 (1 to 8)				
Superficial vein thrombosis	13 per 1000	6 per 1000 (2 to 15)	RR 0.45 (0.18 to 1.13)	1804 (8 studies)	+++O Moderate³	
Oedema Post-flight values measured on a scale from 0, no oedema, to 10, maximum oedema.	The mean oedema score ranged across control groups from 6 to 9 .	The mean oedema score in the intervention groups was on average 4.7 lower (95% CI -4.9 to -4.5).		1246 (6 studies)	++OO Low⁴	
Pulmonary embolus	See comment	See comment	Not estimable	2821 (9 studies)	See comment	0 participants developed pulmonary embolus in these studies. ⁵
Death	See comment	See comment	Not estimable	2821 (9 studies)	See comment	0 participants died in these studies.
Adverse effects	See comment	See comment	Not estimable	1182 (4 studies)	See comment	The tolerability of the stockings was described as very good with no complaints of side effects in 4 studies. ⁶
*The basis for the assumed risk is provided in footnotes. The corresponding risk (and its 95% confidence interval) is based on the assumed risk in the intervention group and the relative effect of the intervention (and its 95% CI).						
CI: Confidence interval; RR: Risk ratio GRADE: GRADE Working Group grades of evidence (see explanations)						
¹ All the stockings in the 9 trials included in this review were below-knee compression stockings. In four trials the compression strength was 20–30 mmHg at the ankle. It was 10–20 mmHg in the other four trials. Stockings come in different sizes. If a stocking is too tight around the knee it can prevent essential venous return causing the blood to pool around the knee. Compression stockings should be fitted properly. A stocking that is too tight could cut into the skin on a long flight and potentially cause ulceration and increased risk of DVT. Some stockings can be slightly thicker than normal leg covering and can be potentially restrictive with tight foot wear. It is a good idea to wear stockings around the house prior to travel to ensure a good, comfortable fitting. Stockings were put on 2 to 3 hours before the flight in most of the trials. The availability and cost of stockings can vary.						
² Two trials recruited high risk participants defined as those with previous episodes of DVT, coagulation disorders, severe obesity, limited mobility due to bone or joint problems, neoplastic disease within the previous two years, large varicose veins or, in one of the studies, participants taller than 190 cm and heavier than 90 kg. The incidence for 7 trials that excluded high risk participants was 1.45% and the incidence for the 2 trials that recruited high-risk participants (with at least one risk factor) was 2.43%. We have rounded these off to 10 and 30 per 1000 respectively.						
³ The confidence interval crosses no difference and does not rule out a small increase.						
⁴ The measurement of oedema was not validated or blinded to the intervention. All of these studies were conducted by the same investigators.						
⁵ If there are very few or no events and the number of participants is large, judgement about the quality of evidence (particularly judgements about precision) may be based on the absolute effect. Here the quality rating may be considered “high” if the outcome was appropriately assessed and the event, in fact, did not occur in 2821 studied participants.						
⁶ None of the other trials reported adverse effects, apart from 4 cases of superficial vein thrombosis in varicose veins in the knee region that were compressed by the upper edge of the stocking in one trial.						

Figure 51-2. Example of a “summary of findings” table.

Table 51-2

Factors that affect the strength of a recommendation

FACTOR	EXAMPLES OF STRONG RECOMMENDATIONS	EXAMPLES OF WEAK RECOMMENDATIONS
Quality of evidence	Many high quality randomized trials have shown the benefit of inhaled steroids in asthma	Only case series have examined the utility of pleurodesis in pneumothorax
Uncertainty about the balance between desirable and undesirable effects	Aspirin in myocardial infarction reduces mortality with minimal toxicity, inconvenience, and cost	Warfarin in low risk patients with atrial fibrillation results in small stroke reduction but increased bleeding risk and substantial inconvenience
Uncertainty or variability in values and preferences	Young patients with lymphoma will invariably place a high value on the life prolonging effects of chemotherapy than on treatment toxicity	Older patients with lymphoma may not place a higher value on the life prolonging effects of chemotherapy than on treatment toxicity
Uncertainty about whether the intervention represents a wise use of resources	The low cost of aspirin as prophylaxis against stroke in patients with transient ischemic attacks	The high cost of clopidogrel and of combination dipyridamole and aspirin as prophylaxis against stroke in patients with transient ischaemic attacks

1. An explicit description of development and funding processes that is publicly available.
2. A transparent process that minimizes bias, distortion, and conflicts of interest.
3. Developed by a multidisciplinary panel composed of: clinicians, methodological experts, and representatives, including a patient or consumer, of populations expected to be affected by the guideline.
4. Utilizes rigorous systematic evidence review and considers quality, quantity, and consistency of the aggregate of available evidence.
5. Summarizes evidence about potential benefits and harms relevant to each recommendation.
6. Explains the parts that values, opinion, theory, and clinical experience play in deriving recommendations.
7. Provides a rating of the level of confidence in the evidence underpinning each recommendation and a rating of the strength of each recommendation.
8. Undergoes extensive external review that includes an open period for public comment.
9. Has a mechanism for revision when new evidence becomes available.

Depending upon the clinical question, such guidelines are often interpreted as the standard of care. However, multiple clinical guidelines may be applicable with respect to various aspects of a given clinical situation and must not be followed blindly without considering specific situational issues through the lens of an experienced clinician. Moreover, guidelines do not (and probably cannot) exist for all clinical situations. Clinicians often must resort to other resources to enrich the context in which decisions are made, and, as with all evidence, care must be taken not to extrapolate the application of a clinical guideline beyond its specific conditions.

THE CHALLENGES OF APPLYING EBM TO SURGERY

As noted earlier, the application of EBM to surgery has lagged behind other fields of medicine, and this has been attributed to the difficulty in establishing a sufficient mass of evidence

with the “gold standard” RCT. Here we describe the process of evaluating the quality of a RCT and note the challenges related to the execution of a high-quality RCT in a surgical context.

Analysis of a Surgical Randomized Control Trial

Sufficient knowledge of the trial’s methodological accuracy and results are essential for critical appraisal. However, less than half of journal articles adequately report the study design.¹⁹ This deficiency led to the development of the Consolidated Standards of Reporting Trials (CONSORT) guidelines in 1992, which was subsequently revised in 2010.²⁰ These guidelines are a minimal set of recommendations for reporting RCTs (blinding, randomization, etc) to facilitate critical appraisal. Many of the surgical journals now require completion of a CONSORT checklist prior to submission of the RCT manuscript (Fig. 51-3). Establishing this requirement has standardized the way articles are presented and analyzed. The two key aspects to focus on when assessing a RCT are *internal* and *external validity*.

Internal Validity

Determining the degree that the results of the RCT are accurate and consistent for the sample patients is called internal validity. Without internal validity, a study cannot be properly appraised, as the study was not constructed properly to answer the hypothesis without avoiding bias or confounding factors.²¹ The internal validity of a RCT requires the evaluation of several properties: randomization, blinding, equivalence among groups, completeness of follow-up, and accuracy of analysis. These properties are discussed in the following section.

Randomization. Randomization is the creation of participant groups with similar known and unknown prognostic factors to achieve the goal of eliminating selection bias. For example, if the investigator can decide which treatment the patient receives, he or she may assign a participant to a study arm that is more favorable for that specific patient. On outcomes analysis, certain groups may have an overestimated treatment effect due to patient selection and not necessarily the intervention itself. The methodology

Section	Item No	Checklist item
Title and Abstract	1a	Identification as a randomized trial in the title
	1b	Structured summary of trial design, methods, results, and conclusions
Background and Objectives	2a	Scientific background and explanation of rationale
	2b	Specific objectives or hypotheses
Trial Design	3a	Description of trial design (such as parallel, factorial) including allocation ratio
	3b	Important changes to methods after trial commencement with reasons
Participants	4a	Eligibility criteria for participants
	4b	Settings and locations where the data were collected
Interventions	5	The interventions for each group with sufficient details to allow replication, including how and when they were administered
Outcomes	6a	Completely defined pre-specified primary and secondary outcome measures, including how and when they were assessed
	6b	Any changes to trial outcomes after the trial commenced, with reasons
Sample size	7a	How sample size was determined
	7b	When applicable, explanation of any interim analyses and stopping guidelines
Randomization:		
Sequence Generation	8a	Method used to generate the random allocation sequence
	8b	Type of randomization; details of any restriction (such as blocking and block size)
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned interventions
Blinding	11a	If done, who was blinded after assignment to interventions and how
	11b	If relevant, description of the similarity of interventions
Results		
Participant flow	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analyzed for the primary outcome
	13b	For each group, losses and exclusions after randomization, together with reasons
Recruitment	14a	Dates defining the periods of recruitment and follow-up
	14b	Why the trial ended or was stopped
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group
Numbers analyzed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing pre-specified from exploratory
Harms	19	All important harms or unintended effects in each group
Discussion		
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses
Generalizability	21	Generalizability (external validity, applicability) of the trial findings
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence
Other Information		
Registration	23	Registration number and name of trial registry
Protocol	24	Where the full trial protocol can be accessed, if available
Funding	25	Sources of funding and other support (such as supply of drugs), role of funders

Figure 51-3. CONSORT checklist. (Reproduced with permission from Schulz KF, Altman DG, Moher D, et al: CONSORT 2010 statement: updated guidelines for reporting parallel group randomised trials, *Int J Surg.* 2011;9(8):672-677.)

of randomization should always be reported and carefully analyzed by the reader. Certain approaches of randomization called quasi-random allocation (date of birth, day of week, participant number, etc.) are not truly random and cannot be fully concealed from study personnel. Additionally, the concept of randomization eliminating bias is only theoretical. To truly ensure the probability of confounders being equally balanced between groups, a trial must be repeated indefinitely. Understanding this impracticality, we accept that randomization will suffice.

Blinding. Blinding aims to reduce certain biases that can affect the outcome of the study. A subject's knowledge of the group that they were randomized can lead to a performance bias, which can influence subjective outcomes (placebo effect). Importantly, authors should be explicitly clear regarding which groups (subjects, clinicians, assessors) are blinded and avoid using non-specific phrases such as "double-blinded" or "triple-blinded." Achieving blinding and minimizing bias is a major hurdle in the execution of surgical RCTs, where there are the ethical dilemmas surrounding "sham" or placebo surgery²² (though for a counterargument, see reference no. 23). Moreover, blinding is impossible when comparing an operative versus a nonoperative intervention.

Equivalence Among Groups. During accrual, randomization helps to ensure that each group in the study shares equivalent baseline demographics and unmeasured biases. However, throughout the study, each group should be treated equally (excluding the actual intervention) with respect to the number of clinical visits, diagnostic tests, etc. Enforcing the same protocol to each study participant further decreases sources of bias and provides increased validity when performing final analysis.

Completeness of Follow-Up. Attrition bias is the differences that occur between the groups when participants withdraw from the study. A pattern can usually be identified (the treatment, side effects of treatment, long follow-up time, or other factors) that leads to withdrawal from the study. These events can hinder the ability to interpret the results of the study, and researchers should consider these implications during trial design. Furthermore, the mechanism of attrition may manifest in a bias; patients who elect to remain in a study may in fact select for characteristics that affect or determine efficacy (see the following section).

Accuracy of Analysis. Analyzing the results of only participants who completed all follow-up visits throughout the study can lead to skewed and inaccurate conclusions. Thus, most RCTs follow the principle of intention-to-treat (ITT) analysis. ITT analysis includes study participants who underwent initial randomization assignment regardless of events that transpired after randomization; thus ITT analysis is often described as "once randomized, always analyzed." Removal of noncompliers from statistical analysis may overestimate the effect size of the intervention. Furthermore, in clinical practice, a portion of patients will be noncompliant, and thus ITT analysis will more accurately represent the overall population.

External Validity

The goal of an RCT is to show a causative relationship between an intervention and an outcome. However, to change clinical practice, the results of the RCT must be both relevant and generalizable to the clinical population; this assessment is called *external validity*.

Number Needed to Treat. The number needed to treat (NNT) is defined as the number of patients that undergo the intervention before a single patient benefits compared to the control

group in the trial. It is computed as the inverse of the risk difference between two groups. The smaller the NNT, the more efficacious a treatment. For example, in an RCT comparing laparoscopic cholecystectomy to observation to prevent recurrent idiopathic acute pancreatitis, the number needed to treat was five patients.²⁴ The NNT should also be weighed against the adverse effects of the intervention.

Number Needed to Harm. While NNT reports the number of patients who undergo the intervention before a single patient benefits, number needed to harm (NNH) describes how many patients undergo the intervention for one person to have an adverse event. The higher the NNH, the safer a treatment is. In general, interventions with a low NNT and high NNH are preferred. However, NNT and NNH should not be used in isolation when determining the appropriateness of intervention as neither number takes into account the degree of benefit to harm.

Generalizability of Results. RCTs have specific exclusion and inclusion criteria to recruit a study population that is homogenous with the goal of limiting sources of bias. While this method is appropriate for RCTs, the results may not directly translate to "real-world" situations with greater heterogeneity within the potential target population (see prior comment in "Hierarchies of Evidence"), leading to a potentially significant discrepancy between trial results and their implementation for day-to-day clinical decisions. In addition, RCTs often come to a conclusion that determines the best treatment for the "average" patient enrolled in the trial. However, most patients are not "average," and therefore the proposed conclusion may not be relevant. Additional studies about the intervention of interest in more heterogeneous populations can help convince physicians to change their clinical practice; these correlate to phase 4 pharmaceutical trials and point to the importance of continued postpractice change data collection and analysis. More importantly, principle 3 of EBM, which states that "clinical decisions should be influenced by patient values and preference," needs to be accounted for, especially with the implementation of a new practice guideline or pattern.

Additional Challenges to Conducting a Surgical RCT

In addition to methodological issues that might limit the reliability of a RCT, there are also considerable logistical barriers to performing a RCT. These are not trivial factors, and they contribute heavily to the number and size of RCTs that can be done, particularly in surgical populations.

Recruitment. One of the most challenging aspects of an RCT is recruiting an adequate number of patients to provide a high and sufficient degree of statistical power to demonstrate a measurable difference between interventions. This becomes exponentially more difficult with the prevalence of certain rare diseases. To help overcome low accrual, many trials expand their study to other hospitals and facilities at the expense of increased heterogeneity. While this may decrease internal validity, the benefit is the increase in external validity.

Learning Curves and Expertise-Based Design. Pharmaceutical-based RCTs normally have higher internal validity compared to surgical trials because of the effect of surgeon experience and technique affecting patient outcomes; this is especially impactful when new surgical procedures are introduced. While the administration of a drug is a straightforward process without measurable deviation, the same cannot be said

regarding surgery. Novel surgical procedures have defined learning curves even for the most experienced surgeons. During this learning process, surgeon inexperience, either in technical features of the procedure or procedure-related decision-making, can lead to adverse patient outcomes. Thus, neglecting the learning curve can lead to an underestimation of the success of the experimental intervention; conversely, accounting for the learning curve can be necessary in assessing how a new procedure can best be disseminated across the community. Furthermore, beyond the evaluation of new procedures, even with established procedures each individual surgeon is likely to have acquired throughout his/her career unique techniques and habits when operating on patients. This heterogeneity of surgeon experience and technique can limit standardization for a trial intervention.

To help solve the issue of surgeon heterogeneity and inexperience, RCTs can employ “expertise-based design.” In this method, patients remain randomized to either the intervention or control, but the operating surgeons are experts in the surgery they are performing. This technique is already followed during cross-specialty RCTs, such as open gastrostomy tube placement versus interventional-radiology (IR) gastrostomy tube placement. However, this does not model every day clinical practice because not all surgeons are considered experts in the procedure described in a particular trial.

All-or-None Situation. Despite continual pressure to prove treatment effect by using a RCT, there are situations when conducting a trial does not make ethical or common sense. A famous example is from the *British Medical Journal* in 2003 that questioned as to why there are no RCTs evaluating the use of parachutes during gravitational free-fall.²⁵ The authors state that the evidence to support the use of parachutes is purely observational yet it is considered a “gold standard” practice. This demonstrates the concept of an *all-or-none* situation, where the study population exposed to a risk experiences the outcome and none of the population experiences the outcome with the intervention. Performing an RCT on this type of situation would be dangerous and unethical, and thus purely observational data can provide a high degree of sufficient evidence.

Noninferiority Trials. As reviewed earlier, trialing a new therapy compared to a placebo or sham raises serious ethical issues, especially when an effective therapy has already been established. Moreover, a portion of randomized control trials today are evaluating secondary endpoints, such as quality of life, safety, and cost efficiency of a new therapy compared to the existing gold standard. These studies are called *noninferiority trials*, with the intent to prove efficacy that is not worse than the existing therapy. For example, a 2004 study compared open versus laparoscopic colectomy for colon cancer. The aim was to show similar oncologic endpoints with improved secondary outcomes (improved cosmesis, decreased postoperative pain, decreased hernia incidence).²⁶ The prevalence of these trials have increased substantially from under 100 in 2005 to nearly 600 in 2015.²⁷ The most important consideration when evaluating this type of trial is the prespecified margin of noninferiority, a value that is largely arbitrary in the literature.²⁸

USE AND MISUSE OF STATISTICAL SIGNIFICANCE

The use of statistical methods is central to the scientific process; it is only through statistics that the problem of induction²⁹ can be addressed. While this chapter is not intended to be

a comprehensive description of statistical methods, understanding the appropriate application of statistical tools is critical to being able to assess the conclusions presented in the literature, and therefore we present a summary of those statistical terms that are most germane to being able to interpret a clinical study.

Type I and Type II Errors

By necessity, statistical testing requires declaration of a null hypothesis, usually corresponding to the “default” state (i.e., no difference or the patient is healthy). The alternative hypothesis would then negate the stated null hypothesis (i.e., there is a difference or the patient is unhealthy). The result of a statistical significance test may either reject or accept the null hypothesis, and this result can correspond with the true state (a correct decision) or not correspond with the true state (an error). Two types of error are possible (Table 51-3).

Type I Error. A type I error occurs when the null hypothesis is rejected but is actually true in the population. This may also be referred to as a *false positive*. The type I error rate, denoted by the Greek letter α (alpha), is the probability that the null hypothesis is rejected given that it is true. The error rate may also be referred to as the significance level, and often a value of 0.05, or 5%, is frequently used in the literature.

Type II Error. A type II error is the failure to reject the null hypothesis when the null hypothesis is false. This error may also be referred to as a *false negative*. The type II error rate is denoted by the Greek letter β (beta), and is related to the power of a study. Power can range from 0 to 1, and as power increases, there is decreasing probability of making a type II error. Power is related to three main factors: (a) the statistical significance criterion of the study, (b) the magnitude of the effect of interest, and (c) the sample size used to detect the effect. Power analysis can be used to calculate the minimum sample size required for a study so that one can be likely to detect an effect of a given size.

P Values

The *P* value was an innovation most closely associated with Sir Ronald Fisher, one of the founders of modern statistics. The definition of a *P* value is the probability of an observed result given the assumption that the null hypothesis is true. The arbitrary value established for a result having statistical significance rather than “pure chance” is less than 1 in 20 defined as a *P* value less than 0.05.³⁰ Put differently, the chance of making a false-positive conclusion is 5% at a *P* value of 0.05 (type I error). This risk of making a false-positive conclusion is called a “type I error.” Importantly, the *P* value reported in the study is specific for that study’s patient sample and may not be generalizable to the overall population. The probability of a false positive report not actually having an association depends not

Table 51-3

Decisions regarding the null hypothesis

TABLE OF ERROR TYPES		NULL HYPOTHESIS (H_0) IS	
		TRUE	FALSE
Decision about null hypothesis (H_0)	Reject	Type I error (false positive)	Correct inference (true positive)
	Fail to reject	Correct inference (true negative)	Type II error (false negative)

only on the associated P value, but also the prior probability that the association is real and the statistical power of the given study.^{31,32} The basis of this is due to perpetual undersampling of all possible relationships in a given scientific domain. This will inherently lead to type I errors with respect to all clinical possibilities. Recently, statisticians have postulated that utilizing a P value of 0.05 will lead to wrong conclusions at least 30% of the time and may be even higher with underpowered studies.³³

The use of P values also categorizes statistical conclusions in a binary format. Should a P value of 0.049 be significant but a 0.051 not be significant? Furthermore, P values provide no insight into the effect size being measured. Simply, an intervention may be statistically significant but lack any clinical significance. Purely utilizing a P value to determine the value of research findings without assessing the effect size, confidence interval, and power of the study can be misleading.

Despite these flaws identified in P values, the frequency of their appearance in modern literature has continued to increase.³⁴ Each reader should be carefully skeptical of P values and await replication with similar significance for confirmation. Fisher did not anticipate or endorse the use of the modern $P < 0.05$ criteria. Rather, he envisioned that experiments would be repeated until the investigator was sure that he or she had learned how to use the experimental intervention to get a predictable result.

Alternative to P Values

One potential alternative to Fisher's approach and the limitation of P values is Bayesian statistics. The common element of Bayesian statistics is to provide a probability of a hypothesis being true by using prior knowledge or empirical data to estimate four probabilities:

1. The probability that the hypothesis is true.
2. The probability that the hypothesis is true given the observed data.
3. The probability that the alternative hypothesis is true.
4. The probability that the data would have been observed if the alternative hypothesis is true.

These parameters are used to calculate a Bayes factor, or a ratio of the likelihood probability of two competing hypotheses. One difficulty for many studies is that there can be very little reliable data that can be used to estimate these probability parameters.

It is important to remember that both P values and Bayes factors are mathematically defined entities, and many of the issues that have arisen with P values are due to how they are interpreted by scientists and clinicians. A false interpretation of a Bayes factor is just as troublesome as a false interpretation of a P value.

HOW DO THE TOOLS OF EBM PERFORM?

As mentioned previously, GRADE has been widely adopted by national and international medical societies, health-related branches of government, healthcare regulatory bodies, and online medical resources such as UpToDate.¹⁶ Widespread use of the system has emphasized consistency in the rating of guidelines and an easy to understand strength assessment based upon evidence quality. However, at the heart of any EBM system is a central paradox: as systems have evolved during the EBM movement, there is no evidence that the systems themselves are reliable.

External Consistency

GRADE is one of several EBM systems that aim to evaluate evidence and create recommendations, but it is unknown how it compares with other previously established systems.

The GRADE Working Group attempted to address this question by comparing six different systems (The American College of Chest Physicians Evidence-Based Guidelines, Australian National Health and Medical Research Council Guidelines, Oxford Centre for Evidence-Based Medicine, Scottish Intercollegiate Guidelines Network, U.S. Preventive Services Task Force Recommendations, U.S. Task Force on Community Preventive Services Recommendations) on 12 criteria to assess the overall usefulness of each approach. The authors found that there was poor agreement about the sensibility of the six systems.³⁵ Given that there is no agreed upon or proven gold standard, one may be concerned about the lack of external consistency among different systems. GRADE was constructed to overcome these issues; however, the system's ability to do so has never been formally assessed.

The example of the Surviving Sepsis Campaign (SSC), an important attempt to produce guidelines to improve the care of patients with sepsis or septic shock, suggests that GRADE has not overcome these problems. The endorsement of the SSC by many influential organizations underscores its importance. Nonetheless, the SSC illustrates some of the important difficulties with grading in general and with the GRADE system (**Box:** Examples of Inconsistent Use of EBM).

Examples of Inconsistent Use of EBM

Surviving Sepsis Campaign

- The Surviving Sepsis Campaign recommended rapid use of intravenous antibiotics in their 2004 guidelines, which was given a grade of "E,"³⁶ corresponding to a recommendation based upon level IV or V evidence, or the lowest levels possible.
- In the 2008 update, the same recommendation was given; however, it was given a grade of 1B/1D (depending on if shock was present), corresponding to a "strong" recommendation.³⁷
- Between 2004 and 2008, three additional studies were published; however, none were randomized controlled trials or came to conclusions that were different than the numerous studies that were published prior to 2004.³⁸⁻⁴⁰

Internal Consistency

In 2005, the GRADE working group published a pilot study of the system which found varied levels of agreement on the quality of evidence for the outcomes in question among 17 assessors (kappa values [**Box:** The Kappa Coefficient] for agreement beyond chance ranged from 0 to 0.82; mean $k = 0.27$; $k < 0$ for four judgements). The authors concluded that "judgements about evidence and recommendations are complex" and stated that with discussion they could resolve most disagreements.⁴¹ No assessment of reliability or proof of usefulness has been presented regarding the GRADE system since these findings.⁴²

System Issues

The GRADE group considers the "strength" of their recommendations to reflect "the degree of confidence that the desirable effects of adherence to a recommendation outweigh the

The Kappa Coefficient

The Kappa coefficient is a statistic that measures inter-rater agreement for qualitative items. It is thought to be a more robust measure than simple percent agreement since κ takes into account the possibility of the agreement occurring by chance. In general, κ values < 0 indicate no agreement, 0 to 0.2 slight agreement, 0.21 to 0.4 fair agreement, 0.41 to 0.60 moderate agreement, 0.61 to 0.80 substantial agreement, and 0.81 to 1 as almost perfect agreement.

undesirable effects.”⁴³ However, at the same time, the GRADE system allows the strength of a given recommendation to exist independent of the quality of evidence that underpins that recommendation. The GRADE Working Group states that “separating the judgements regarding the quality of evidence from judgements about the strength of recommendations is a critical and defining feature of this new grading system.”⁴² However, such a system allows for “high quality” evidence for small effects while “low quality” evidence with a strong recommendation is highly implausible except for certain obvious observations.

Finally, the touted advantage of the leveling process in determining the quality of evidence requires significant individual adjudication. A given study design begins at a level of quality and can be upgraded or downgraded based on several judgments regarding adequacy of blinding, follow-up, consistency, generalizability, and effect size. Graders are supposed to balance the level of quality using these factors, yet each is fundamentally different and cannot be simply added or subtracted, and it is therefore up to individual judgment as to how to weigh each factor.

Validity

The GRADE system is well described in a series of publications; however, none of the publications provide validation, data, or proof of the usefulness of the system. The only publication with data is mentioned earlier, which showed a low kappa for interobserver agreement.⁴¹ Based upon the systematic tenets of EBM and lack of literature-based proof for the effectiveness of GRADE, there would not be a basis for its use in creating recommendations. For example, no RCT assessing the effect of using EBM on patient outcomes has been undertaken. Therefore, EBM does not satisfy its own requirements and is, ironically, a form of systematic expert opinion. There is no data to suggest that systematic EBM approaches are superior to the decision-making capabilities of competent physicians with knowledge of the recent medical literature.

Implications of EBM

The GRADE Working Group suggests that “strong recommendations should require little debate and would be implemented in most circumstances.”⁴² Although most strong recommendations are likely accurate, definitive recommendations may have unintended consequences. For example, a definitive recommendation may have the effect of limiting debate or further research on a topic where the recommendation is misguided, and there are numerous examples where “strong” recommendations were later retracted. High-level EBM recommendations concluded that antibiotic prophylaxis should be used in necrotizing pancreatitis based upon multiple prospective randomized controlled trials, meta-analyses, and systematic reviews.^{14,44,45}

These recommendations were later reversed, as additional trials showed that there was no benefit to antibiotic use in these patients.⁴⁶

A valid concern regarding EBM is that established systems may lead to “strong” recommendations that are hard to challenge. This may even lead to situations where life-saving prospective studies are deemed “unethical” due to the presence of high-level, strong recommendations. As such, some groups have even issued warnings about converting practice guidelines into law.^{47,48}

THE ALTERNATIVES TO EBM

EBM is appealing due to its ability to reduce and cope with uncertainty; however, the ability to mitigate uncertainty is not without drawbacks. The various EBM systems that exist are not always consistent in their evaluation of evidence, and even a single system may assign varying grades based on several subjective factors. Finally, the performance of EBM in improving patient care has never been validated. Therefore, while most certainly a useful tool, the limitations of EBM must be recognized to avoid blind adherence to guidelines and oversimplification of the complex clinical decision making that occurs in daily clinical care.

Although striving for certainty is understandable, it is contrary to the reality of medicine in which decisions regarding individual patients are inherently complex. In fact, as science strives for “precision” and “individualized” medicine, EBM’s focus of creating guidelines to care for the “average” patient will exist as a paradox. The best physicians function on a foundation of scientific theory expressed in a setting of practical knowledge gained in a local context, or tacit knowledge. This is how complex physiology and pathology are combined to make a specific decision for an individual patient. Therefore, although it is tempting to think that EBM makes surgery more scientific, one must remember that EBM itself is not founded in scientific principal.

So, what is the alternative? The alternative is a common-sense application of scientific principals and healthy skepticism for the ongoing use of EBM as a guideline for practice. This allows physicians to use published guidelines, applied within the context of their practice, until a grading system has definitively been shown to positively affect patient outcomes or more precise application of patient data is made possible. Recommendations certainly can be useful information; however, clinicians should also understand that there is a nuance with respect to adherence to guidelines and that much lies outside the reaches of EBM. As such, understanding that daily clinical practice involves hundreds of decisions that require varying proportions of explicit and tacit knowledge is important in devising a system where guidelines are flexible and receptive to continual feedback based upon the experiences of practicing physicians.

WHAT CAN RESEARCHERS DO TO IMPROVE THE VALIDITY OF RESEARCH FINDINGS?

Although it is impossible to know the truth with absolute certainty, researchers can take steps to ensure that the posttest probability is maximized. First, researchers can attempt to obtain better-powered evidence. Although even high-powered, low-bias meta analyses are not perfect, they do approach a theoretical “gold standard” of research, and although increasing power is important in arriving at correct conclusions, even high-powered studies can have significant biases. Additionally, obtaining large-scale evidence may not be possible for many research questions.

“You keep using that word. I do not think it means what you think it means.”

—Inigo Montoya from *The Princess Bride*

This chapter started by noting that the landscape of scientific knowledge is constantly evolving and that this fact impacts how we use and evaluate evidence as well. This 11th edition of *Schwartz's Principles of Surgery* is being produced at a particularly volatile period in biomedical research as basic assumptions as to how scientific literature determines what constitutes “evidence” are being reassessed in a critical fashion. We believe it does a disservice to our readers if we fail to note and describe these trends, as they directly affect the basis of this chapter. The reassessment of biomedical literature and clinical trials can be loosely grouped into two distinct, but related topics: the *crisis of reproducibility* and the issue of *medical reversal*.

The Crisis of Reproducibility

Over the past decade it has become increasingly recognized that certain medical studies, held forth as index publications upon which were based either fundamental precepts of practice or to justify entire directions of drug discovery, could not be reproduced independently. This failure strikes at a fundamental assumption of science: that well performed studies with sufficient statistical significance represented generalizable knowledge that could be built upon. However, estimates of irreproducibility range from 75% to 90% based on mathematical inference, and practical investigations have shown as few as 0 in 52 observational study findings being confirmed by randomized controlled trials (RCTs).⁴⁹ Methodological errors in study design, patient selection, or research practices have been proposed as major contributing factors in the debate over replication of scientific studies. However, despite the importance of replicating research findings, there is increasing concern that in modern research there is an intrinsic bias towards positive results in publication. Biases in study design, data collection, data analysis, or presentation of findings can lead to research findings when they do not truly exist. As bias increases, the positive predictive value (PPV) of a given finding being true decreases considerably. The overall effect of bias again depends on both the power and prestudy odds of a given study. In some fields, it may in fact be the case that research findings are simply a measure of the prevailing bias. Medical research operates in areas with low pre- and poststudy probability for true findings, meaning it may be quite common that observed effect sizes varying around the null hypothesis (what one would expect from chance alone) are simply measuring the prevailing bias of a given field.

In addition to bias, the globalization of research means that at any given time it is almost a certainty that multiple research teams are investigating the same question or topic. Despite this fact, research findings by single teams are often considered in isolation, and the first to report a finding receives significantly more attention than subsequent studies. Suppose multiple research teams are investigating a given question with the null hypothesis being that there is no difference in treatment two treatment strategies. The probability that at least one of the groups will claim a significant research finding increases, and the positive predictive value decreases as the number of research teams increases. Unfortunately, there is little way to control for this phenomenon other than increasing the power of each individual study.

Due to the combination of the aforementioned factors, the current framework of research means it is quite difficult to end up with a PPV >50%. Based on mathematical principles, even a well-constructed, adequately powered RCT with a pretest probability of 50% will arrive at a true conclusion only about 85% of the time.³¹ These findings limit the available literature upon which evidence-based medicine (EBM) relies and place a greater burden on practitioners when they are attempting to analyze and draw conclusions from what they find.

Medical Reversal

A related topic that directly impacts how EBM is carried out is that of medical reversal. This term was introduced by Vinay Prasad and Adam Cifu in 2011^{50,51} to describe the process and pitfalls by which a previously established practice or drug falls out of favor because it is subsequently identified not to work. As such, the issue of medical reversal is impacted by the decision for a particular therapy to become adopted in the first place (ostensibly based on the principles of EBM) and the barriers to how subsequent evidence (either acquired through studies, or, more importantly, upon a more critical reassessment of the basis of its initial adoption) can reverse a prior recommendation. The set of intersecting issues related to medical reversal are highly complex (interested readers are encouraged to delve into the growing list of reports on this topic), but in terms of EBM, central issues addressed in medical reversal pertain to the use of surrogate endpoints in clinical trials, the presentation/misrepresentation of clinical trial effects, the effect of bias (academic and economic) in trial reporting and dissemination, and the strength and reliability of alternatives to RCTs (for all their flaws). As with the crisis of reproducibility, understanding the factors of medical reversal directly impacts what is appropriately considered “evidence” when executing EBM, placing greater responsibility on the surgical practitioner when determining what is appropriate or optimal care.

It should come as no surprise to the attentive reader that many of the issues related to the crisis of reproducibility and medical reversal refer back to the sources of bias and potentially perverse incentives originally noted by Francis Bacon back in 1620 (**Box: The History and Sources of Bias in Biomedical Literature**).

Second, as was noted previously, multiple teams often simultaneously address a given research question, and it is not proper to focus on any one study in isolation. Instead, clinicians should focus on the body of evidence in its entirety. A potential solution would be connecting groups through networking of data. This would allow for more accurate analysis and drawing of conclusions, although it would require a significant change in the culture of academic research practices.

Today, clinicians rely on the statistics provided in a scientific study to provide a summary of the results. We place trust and confidence that the paper's biostatistician accurately and truthfully calculated these statistics without incorporating conscious bias. Each article should completely answer four questions regarding the results of the study:

1. What is the statistical significance of the results?
2. What is the effect size and is this clinically relevant?
3. What is the confidence interval?
4. What is the underlying power of the study to detect a meaningful difference?

Significant progress has been made since the adoption of EBM; however, the current direction of EBM-based guidelines have focused on populations as opposed to the complex, nuanced interactions that occur on a case by case basis. Algorithmic protocols actually serve to steer the focus away from an individual patient, at times leading to a disconnect between patients and physicians when physicians propose treatment based upon guidelines that do not adhere to that patient's goals and values. So what can surgeons do to combat this, and how should they practice? One must ask: "What is the best course of action for this patient, in these circumstances, at this point in their illness or condition?" Therefore, evidence must be synthesized and then *individualized* for each patient encounter by interconnecting it with the ethics, personality, and values associated with the case at hand. Tools such as risk calculators are useful in informing discussion, but they should by no means be definitive evidence to recommend for or against a particular treatment. Judgment remains necessary in the practice of medicine, and therefore guidelines should be thought of as "rules of thumb" that require context as opposed to "rules of law."

INTRODUCTION

Ambulatory Surgery

Ambulatory Surgery is a multidisciplinary field in which surgical procedures are performed on patients who are not expected to be admitted to the hospital. The field includes procedures performed on patients in the setting of hospital outpatient departments (HOPDs), freestanding ambulatory surgery centers (ASCs), and those performed in doctor's offices. The word ambulatory comes from the Latin *ambulare*, which means "to walk," indicating that the patients arrived at the procedure on their own and departed after the procedure to their home environment.¹

Improved anesthesia techniques, the development of minimally invasive procedures, and changes to healthcare policy (particularly healthcare funding) have been the driving factors behind the increase in ambulatory surgery. Prior to these advances, almost all surgery was performed in an inpatient hospital setting. Any outpatient surgeries were minor, performed in physicians' offices, and paid for by Medicare and insurers as part of the physician's office visit reimbursement.²

Since the early 1980s, the volume of ambulatory surgery has increased in the United States.^{2,3} Between 1981 and 2005, the number of outpatient surgeries nationwide grew almost 10-fold to over 32.0 million per year. Outpatient procedures grew from 19% to 60% of all surgical procedures, by volume, in the United States from 1981 to 2011.^{2,4,5} Strong financial incentives exist for hospitals to shift some surgeries to an outpatient setting. The number of Medicare-certified ASCs has also increased steadily, from fewer than 300 in the early 1980s² to 5532 in 2016 (Fig. 52-1).⁵

By definition, procedures at ASCs and physician's offices are performed without the full resources of a hospital. The press has sensationalized a few adverse patient outcomes in these settings and made claims about the overall safety based on these isolated events. However, much of the convenience, high patient

satisfaction rates, and cost-efficiency of ambulatory surgery is lost when performed in a hospital setting. Thus, the challenge underlying ambulatory surgery is performing safe operations on carefully selected patients in a manner that is patient-family-centric and economical.

A majority of large hospitals also have their own outpatient surgery departments that exist within the hospital. ASCs perform procedures faster and more efficiently than HOPDs and at higher volume than both HOPDs and physicians' offices. Additionally, the number of certified, freestanding ASCs nationwide has eclipsed the total number of hospitals by more than 1000 centers.⁵ For these reasons, a plurality of outpatient surgical volume in the United States is now performed in ASCs. It is critical for the modern surgeon to have a grasp of the unique clinical challenges and economic impacts of ambulatory surgery.

Ambulatory Surgery Centers

ASCs are independent healthcare that offer patients the convenience of having surgery performed safely without admission to a hospital. ASCs provide only elective surgical services rather than emergency care. According to the Centers for Medicare & Medicaid Services (CMS), effective May 18, 2009, "ASCs are any distinct entity that operates exclusively for the purpose of providing surgical services to patients not requiring hospitalization and which the expected duration of services would not exceed 24 hours following an admission."⁴ Ambulatory surgery centers should not be confused with office-based surgery practices or with other outpatient centers that provide diagnostic services or primary healthcare, such as urgent care centers, community health centers, mobile diagnostic units, or rural health clinics. ASCs are distinguished from these other healthcare facilities by (a) their use of a referral system for accepting patients and (b) their maintenance of a dedicated operating room. The first feature means that any patient who wants to be treated in an ambulatory surgery center must first consult a

Key Points

- 1▶ Define ambulatory surgery and the unique aspects of ambulatory surgery centers (ASCs).
- 2▶ Understand the history of ambulatory surgery and ASCs in the United States.
- 3▶ Review the most common procedures performed in ASCs compared to those performed in a hospital setting.
- 4▶ Discuss the financial benefits for patients and physicians within the structure of ASCs as they pertain to physician ownership, healthcare systems partnerships, and insurance reimbursement.
- 5▶ Understand the regulatory and accreditation processes that affect ASCs.
- 6▶ Predict how anticipated medical advances, technological development, and an aging population will affect the field of ambulatory surgery.

primary healthcare provider (PCP) and choose to have the condition treated by surgery rather than an alternative approach. The second characteristic means that all ASCs must have at least one dedicated operating room and the equipment needed to perform surgery safely and ensure quality patient care.¹ Patients who choose to have surgery in an ASC arrive on the day of their procedure, have their surgery in a fully equipped operating room, and recover under the care of a highly-skilled anesthesia team, all without hospital admission.

Aspects Leading to Increased Utilization

Technological Developments. Improvements in anesthesia have facilitated the safe practice of outpatient surgery by the use of new medications, improved techniques in regional anesthesia, and better management of postoperative pain. The development of minimally invasive surgical techniques such as fiberoptic endoscopy, arthroscopy, ophthalmologic procedures, and laparoscopic and robotic surgery have made it possible for patients to be discharged the on the same day as the surgery.

Reduced Cost for Patients Without Compromise in Quality of Care. Ambulatory surgery facilities are highly specialized centers originating from a service model rather than the tradition hospital model. This approach allows for streamlined processes and reduced costs. Staffing is the largest cost for most healthcare facilities including ASCs, thus same-day surgery eliminates the need for overnight nursing and support staff.

ASCs Offer Reduced Cost for Healthcare Systems. A review of commercial medical claims data found that annual U.S. healthcare costs are reduced by approximately \$3.8 billion due to the availability of ASCs. Patients save more than \$1.5 billion due to lower deductibles and coinsurance payments. Over the next decade, ASCs are expected to save the U.S. healthcare

system between \$32.5 and \$57.6 billion. This cost reduction is driven by the fact that, in general, ASC prices are significantly lower than HOPD prices for the same procedure in all markets, regardless of payer.⁶ Table 52-1 displays the cost savings compared to hospital outpatient departments for the most commonly performed procedures at ASCs nationwide. While most hospitals offer outpatient surgery, ambulatory surgery centers are regarded as a superior choice for certain procedures because of facility efficiencies and price regulation under the outpatient prospective payment system.⁶

HISTORY OF AMBULATORY SURGERY AND AMBULATORY SURGERY CENTERS

Ambulatory surgical practice traces its history from the early work of itinerant dental surgeons who traveled their circuits by horseback and trains. They frequently operated in hotel rooms and then moved on. In 1909, James Nicoll (Fig. 52-2), a pediatric surgeon in Scotland, wrote of his experiences with ambulatory anesthesia and surgery on nearly 9000 children as outpatients during a 10-year interval at Glasgow Royal Hospital for Sick Children.⁸ Operations included cleft lip and palate repair, correction of pyloric stenosis, mastoidectomy, repair of inguinal and umbilical hernias, and management of spina bifida and depressed skull fractures. Nicoll pleaded with his fellow surgeons to perform more pediatric operations on an outpatient basis, stating that “a large number of the cases at present treated in-door constitutes a waste of the resources of a children’s hospital . . . The results obtained in the out-patient department at a tithe [small part] of the cost are equally good.”⁸

Ralph Waters (Fig. 52-3) was a pioneer in the field of ambulatory surgery. He developed an office-based practice in Sioux City, Iowa in 1919. Waters used nitrous oxide, morphine, and scopolamine. He believed medical conditions had to be well controlled prior to surgery and that certain medical conditions precluded outpatient care. In these ways, Waters’ clinic became the prototype for the modern free-standing ASC. Waters subsequently went on to establish the first academic residency program for training anesthesiologists at the University of Wisconsin.⁹

Prior to the advent of freestanding ASCs, the concept of ambulatory surgery first needed to gain acceptance in the form of HOPDs. In 1959, Eric Webb and Horace Graves advocated outpatient surgery because of a shortage of hospital beds in Vancouver. The first HOPD in the United States was established in 1962 at the University of California, Los Angeles by David Cohen and John Dillon, who also sought to address a shortage of hospital beds. These efforts proved to be safe and cost-effective.⁹

Table 52-1

Comparison of top 10 procedures performed at ASCs vs. hospitals nationwide

TOP 10 PROCEDURES PERFORMED AT AMBULATORY SURGICAL CENTERS BY VOLUME AND CPT CODE	NUMBER PERFORMED	AVG PAY PER CLAIM	SAVINGS AT ASC	TOP 10 PROCEDURES PERFORMED AT HOSPITAL OUTPATIENT DEPARTMENTS (HOPD) BY VOLUME AND CPT CODE	NUMBER PERFORMED	AVG PAY PER CLAIM
1. Cataract surgery with intraocular lens (66984)	1155,283	\$959	\$219	1. Subcutaneous tissue debridement (11042)	841,517	\$213
2. Esophagogastro-duodenoscopy with biopsy (43239)	524,082	\$301	\$110	2. Esophagogastro-duodenoscopy with biopsy (43239)	628,900	\$411
3. Colonoscopy and biopsy (45380)	416,218	\$352	\$172	3. Aspiration/injection of joint (20610)	578,407	\$141
4. Colonoscopy with lesion removal (45385)	331,565	\$401	\$20	4. Cataract surgery with IOL implant (66984)	512,191	\$1,178
5. Spine epidural injection foraminal (64483)	282,962	\$335		5. Colonoscopy and biopsy (45380)	472,886	\$524
6. Postlaser cataract surgery capsulotomy (66821)	275,760	\$227		6. Colonoscopy with lesion removal (45385)	350,001	\$421
7. Spine epidural injection lumbar, sacral (62311)	210,159	\$358	\$120	7. Spine epidural injection lumbar, sacral (62311)	326,956	\$478
8. Injection, paravertebral facet joint (64493)	174,450	\$306		8. Insertion of temporary bladder catheter (51702)	308,614	\$69
9. Diagnostic colonoscopy (45378)	157,951	\$401	\$100	9. Appl. of multilayer compression system (29581)	303,026	\$97
10. Colorectal screening, high-risk individual (G0105)	128,181	\$333		10. Diagnostic colonoscopy (45378)	253,350	\$501

The first truly freestanding ASC, “SurgiCenter,” was opened in Phoenix, Arizona by Wallace A. Reed and John L. Ford in 1970 (Fig. 52-4). Reed and Ford were committed to providing timely, convenient, and comfortable surgical services to

patients in their community, and therefore, avoiding more impersonal venues like regular hospitals. Prior to opening SurgiCenter, Reed and Ford were frustrated with having patients wait 6 weeks or more to get elective surgery, and in some cases, found surgeries canceled because the rooms booked were needed for emergencies.⁹

Figure 52-4. Image of “SurgiCenter” in 1970. (Used with permission from Banner Health.)

In its first 6 months, Surgicenter performed more than 1200 operations by 153 surgeons. No adverse cardiac events occurred during the procedures, and only one patient was hospitalized following surgery (due to poorly controlled diabetes, not because of the operation itself).¹⁰ SurgiCenter’s incredible success resulted in more than 400 visitors touring the facility in the first year in order to learn about the new model for patient care.¹¹ Reed and Ford realized that a tremendous need existed for freestanding, independent ASCs. According to Reed, this propelled the formation of what eventually became the Ambulatory Surgery Center Association (ASCA), a major credentialing body within the field of ambulatory surgery.¹¹

The Orkand Report of 1976, a U.S. government–sponsored study of outpatient surgery, concluded that ambulatory surgical facilities can significantly reduce costs while maintaining the same high quality of surgical and anesthetic care achieved in hospitals.¹²

The Society for Ambulatory Anesthesia (SAMBA) was established in 1984 to further the development of ambulatory anesthesiology as a subspecialty. The field continued to advance with the publication of *Wetchler’s Anesthesia for Ambulatory Surgery* in 1985, the introduction of the journal *Ambulatory Surgery* in 1993, and with the first state requiring accreditation for all outpatient facilities (California in 1996). Many other states have since adopted these high standards and require accreditation of ASCs. CMS now requires certification for all ASCs (Fig. 52-5 and 52-6).⁵

PROCEDURES PERFORMED

By 1982, CMS had approved payments to ASCs for more than 200 procedures. Steady growth in the number of ASCs (Fig. 52-7) and the number of surgical procedures performed in the outpatient setting, including HOPDs, has continued since. Each year physicians perform more than 23 million procedures

Figure 52-5. George Isaac Minimally Invasive Surgery Center at the University of Toledo Medical Center. (Used with permission from University of Toledo.)

in ASCs. This shift toward outpatient procedures has increased due to advancements in medical practice and technology that have reduced the need for overnight hospital stays. Most patients, except those with complicated health conditions, can be served in the outpatient setting. Common ASC procedures include colonoscopies, cataract surgeries, tonsillectomies, and arthroscopic orthopedic surgeries. CMS currently approves and reimburses more than 3500 procedures in the ASC setting.⁵ New developments continue to expand the scope of ASCs.

ASCs may perform surgeries in several specialties or dedicate their services to one specialty, such as eye care or sports medicine. The procedure must not pose a significant safety risk and not require an overnight stay when performed in an ASC. The types of surgical procedures performed in ASCs have undergone significant changes in recent years. Many of the early ASCs were outpatient centers for plastic surgery. Advances in minimally invasive surgical techniques in other specialties, however, led to the establishment of ASCs for orthopedic, dental, and ophthalmologic procedures. See Fig. 52-8 for a recent analysis of specialty services provided by ASCs nationwide.

BENEFITS OF AMBULATORY SURGERY CENTERS

Since their founding over 40 years ago, ASCs have grown exponentially. These distinct entities have provided physicians an avenue to provide specialized, efficient, and quality

Figure 52-6. ProMedica Parkway Surgery Center. (Used with permission from ProMedica Health Systems.)

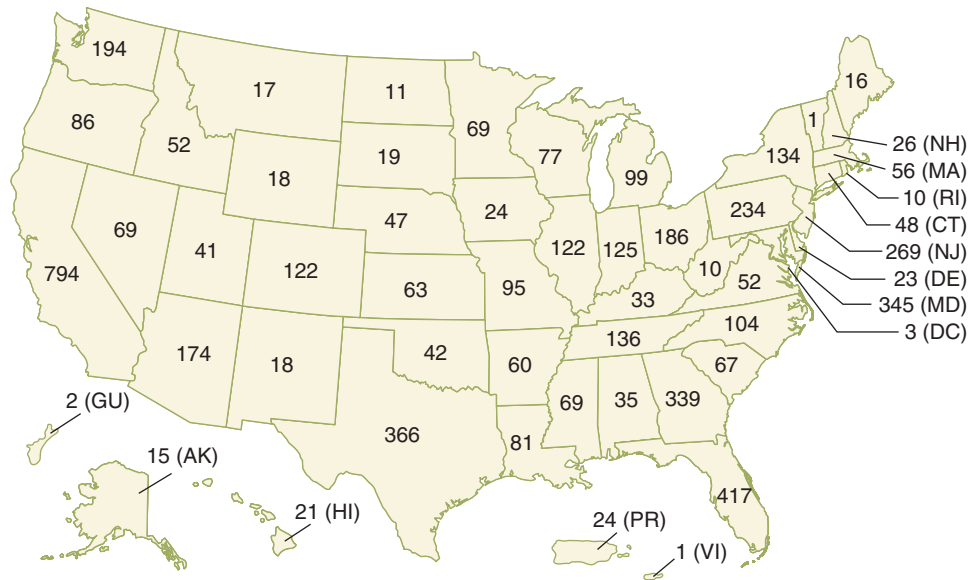

Figure 52-7. As of June 2017, California has 794 ASCs, making it the leading state in terms of number of ASCs. It is followed by Florida with 417 ASCs and Texas with 366 ASCs. Vermont and the U.S. Virgin Islands have the lowest number of ASCs with one each.¹³

care to patients who need surgical procedures. Patient satisfaction with same-day surgery has remained relatively high since ASCs started in 1970. It is important to recognize that patients undergoing generally nonemergent surgery that does not require a hospital stay are relatively satisfied overall. Historically, the field of ambulatory surgery has been associated with very high patient satisfaction.¹⁴⁻¹⁵ In the future, the CMS Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey will report on nationwide patient satisfaction with ASCs and HOPDs.¹⁶

Factors Contributing to Popularization of ASCs

Cost. In many cases an outpatient procedure performed in an ASC is between one-half to one-third the cost as the same procedure performed in a hospital. In large part, ASCs affect cost savings by eliminating overnight hospitalizations and emergency procedures. ASCs perform fewer extensive diagnostic tests and dispense fewer medications. These facilities are not

staffed around the clock and are not encumbered by the need for expensive and highly specialized equipment as are hospitals. For example, the Medicare Payment Advisory Commission found that a cataract operation cost only \$942 at an ambulatory surgery center in 2001 as opposed to \$1334 at a hospital. Figures for an endoscopy and biopsy of the upper digestive tract were \$429 and \$359; for a diagnostic colonoscopy, \$429 and \$401; and for epidural anesthesia, \$320 and \$183, respectively.^{5,7} (see Table 52-1).

Organization, staffing, and specialization may play a large role in the cost differences between ASCs and HOPDs. On average, patients who were treated in ASCs spend 31.8 fewer minutes undergoing procedures than patients who were treated in HOPDs. ASCs could generate savings of \$363 to \$1000 per outpatient case.⁴

Comfort. Whereas most hospitals keep patients recovering from a surgical procedure in separate rooms, in an ASC the patient usually can spend the recovery period after surgery with their loved ones. Limiting the number of delays and disruption of emergent cases allows the surgeon to spend more time with the patient in the preoperative and postoperative areas.¹⁷⁻¹⁹

Convenience. Because ASCs usually schedule routine cases lasting no longer than 2 hours (average 30–45 minutes), and handle no emergency cases, scheduling is typically accurate. By avoiding the logjam, ASCs reduce the waiting time for elective procedures. A study by Hair et al reviewing Medicare patients again showed freestanding ASCs performed surgeries in less time than hospital-based ASCs overall and for procedures on various anatomic systems that resulted in reduced total time spent in facility with earlier discharge.¹⁹ These results corroborate the notion that freestanding ASCs tend to be more efficient than HOPDs.²⁰ One possible advantage for patients would be that they are able to leave an ASC relatively quickly after their surgery, resulting in less time away from work and family. This may be particularly true for pediatric patients or parents.

Efficiency. This advantage is particularly important to surgeons. It takes much less time to prepare an operating room in a specialized ASC for the next patient than in a standard hospital. Improved efficiency allows the surgeon to treat more

Figure 52-8. Specialties served in ASCs. GI = gastroenterology. (Reproduced with permission from Centers for Medicare & Medicaid Services, 2011.)

patients in the same amount of time than he or she would be able to do in a hospital; some surgeons maintain that they can do three times the number of procedures in an ASC as they could in a hospital setting. Many doctors prefer working in an ASC because they can set the standards for staffing, safety precautions, and postoperative care, rather than having these things decided for them by a hospital manager.¹ Trentman and coauthors discuss several factors that affect patient flow and could result in differences in preoperative and recovery times for outpatient procedures between ASCs and hospitals.²⁰ For example, compared to the situation in hospitals, in ASCs surgeons are more likely to be assigned to a single operating room for all cases, which reduces delays; the operating room often is closer to the preoperative and recovery rooms because facilities are smaller; teams of staff have clearer and more consistent roles, with less personnel turnover; and staffing is not done by shifts—that is, staff members go home only after all cases are finished, which creates incentives to work quickly. In addition, hospitals may be more likely to have emergency add-on and bring-back cases for more complex cases that compete with outpatient procedures for operating room time.^{3,5,19} These differences suggest that hospitals would have to adopt a substantially different and highly specialized organizational model to achieve the same efficiencies as ASCs.

REGULATION, COSTS, AND QUALITY

Regulation

Healthcare facilities in the United States are highly regulated by federal and state entities. ASCs are included in this oversight, with both federal and state laws and regulations governing all aspects of them. Independent observers evaluate the safety and quality of care provided in ASCs through three processes: Medicare certification, state licensure, and voluntary accreditation.

To obtain Medicare certification, ASCs must meet the Medicare certification requirements, known as the Conditions for Coverage. These conditions include specifying standards for administration of anesthesia, quality evaluation, operating and recovery rooms, medical staff, nursing services, and other aspects of care. An ASC must have an inspection conducted by a state official or a representative of an organization that the government has authorized to conduct that inspection. These inspectors visit the ASC to verify that it meets established standards. Each state determines the specific requirements ASCs must meet for licensure. An ASC does not have to be certified by Medicare in order to be accredited by JCAHO; however, most ASCs provide care to Medicare beneficiaries, so it is important to meet their requirements in order to be reimbursed appropriately. Medicare inspection and certification of ambulatory surgery centers is a separate process from professional accreditation.

To obtain state licensure, many states have independent rules and regulations as well as associated fees. These third-party bodies can include Accreditation Association for Ambulatory Healthcare (AAAHC), American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF), and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). In states for which accreditation is not mandated, ASCs may undergo voluntary accreditation through these same associations. In 37 states, any party looking to open an ASC must demonstrate a need for the ASC to exist.²¹ State licensure

requirements generally exist for both healthcare facilities and healthcare professionals.¹⁴

There was previously controversy as to whether accreditation status affects safety outcomes. In multivariate analyses that controlled for facility volume and patient characteristics, patients at Joint Commission–accredited facilities were still significantly less likely to be hospitalized after colonoscopy. Specifically, compared with patients treated in nonaccredited ASCs regulated by the state agency, patients treated at accredited facilities were less likely to be hospitalized within 7 to 30 days after surgery.²² All accredited ASCs must meet specific standards that are evaluated during on-site inspections. Patients who visit accredited ASCs can be assured that those medical facilities have rigorous checkpoints to ensure high standards.

The Ambulatory Surgery Center Association (ASCA) or ASC Association has an integral role to ensure top-quality healthcare from the nation's ASCs. The ASCA was established when the two leading national ASC associations—Federated Ambulatory Surgery Association (FASA) and the American Association of Ambulatory Surgery Centers (AAASC)—merged. The ASCA serves as the national membership organization as well as the advocacy group for ASCs.²¹ The ASCA works with legislative and regulatory bodies, liaises with other organizations to improve access, reduce the costs of healthcare, encouraging insurance coverage of outpatient procedures, and works to establish standards for ASCs. ASCA requires all of its facility members to be accredited, licensed, or Medicare certified. The ASCA was instrumental in forming the accrediting body that is now the largest accreditor of ambulatory surgery centers in the country.²²

Costs

Today, more than 5300 Medicare-certified ASCs offer similar services compared to those performed at HOPDs, and do so at a more efficient rate with lower costs. ASCs are able to accomplish this by decreasing administrative and overhead expenses.⁵ Expenses for an ASC include staff wages, insurance, utilities, rent, janitorial services, as well as resources necessary to handle patient records, including technology systems. ASCs are able to schedule procedures without the risk of surgeries getting moved or cancelled due to emergencies. Additionally, ASCs enable patients to go home on the same day, therefore spending less time with staff in postoperative recovery rooms.

Starting in 1982, Medicare has covered surgical procedures provided in ASCs.²¹ There are two primary elements of total cost in a surgical procedure: the cost of physicians' professional services and cost of the facility. Typically, providers bill for professional service separately, whereas facility costs are paid to the ASCs. Currently Medicare provides separate payments for 3500 surgical procedures under the ASC payment system.⁵ The payment system is maintained by CMS, which adjusts fees annually to maintain budget neutrality. Through the Medicare Prescription Drug, Improvement, and Modernization Act of 2003, payments to ASCs are based on the Outpatient Prospective Payment System (OPPS) and capped at no more than 59% of what is paid to hospitals for the same service.⁵

During the period of 2008 to 2011, the growth in number of ASCs plateaued. The system saved an estimated \$7.5 billion for the Medicare program and its beneficiaries.⁵ However,

growth in procedure volume during this time was greater in ASCs than in hospitals.³ This suggests that physicians and patients still preferred using ASCs, possibly due to advantages in cost, convenience, comfort, or the inability for hospitals to meet demand for outpatient surgeries.

Quality

The majority of ambulatory surgery centers ensure safety through maintaining certification and licensing of the facilities and associated staff. There are strict regulations in place at both the state and federal level that ensure quality in ASCs, which have been detailed earlier. ASCs are held to the same high standard of care as all U.S. medical facilities. They have comparable rates of use of perioperative antibiotics, patient falls, wrong-site surgery, and use of safety checklists.²³ Nationwide and among all procedures, from 2014 to 2016 fewer than 2% of all visits to ASCs resulted in an unplanned hospital visit within 7 days.⁵ Of these hospital visits, 1.6% were emergency department or observation stays, and 0.6% were unplanned inpatient admissions.²⁴ CMS is working to develop a new quality measure that will track unplanned hospitalizations after care at an ASC. This would help create increasing data on the quality of ASCs. Due to the isolated nature of ASCs, providers are often unaware when a patient goes to the emergency department or is admitted to an unaffiliated hospital following a procedure. Thus, such a measure from the CMS will help educate providers and allow for continued quality improvement among ASCs.

Looking at the general surgical population, cholecystectomy represents a key procedure to track because it is frequently performed, requires technical skill, and can result in serious complications. Provided appropriate patient selection, outpatient cholecystectomy has been demonstrated to be safely performed in ASCs. ASCs charge significantly less for performing this procedure after controlling for the variety of indications (median of \$6028 for ASCs compared to \$10,876 for HOPDs).²⁵

Ownership

In 2017, 90% of ASCs have partial or complete physician ownership, while 25% to 30% of ASCs are at least partially owned by hospitals, as compared to HOPDs, which are by definition owned and operated exclusively by the hospital. A trend is developing for hospitals to purchase ASC ownership stakes due to their cost efficiency and as a means of diversifying revenue streams.²⁶ Physicians have been a driving force in the development of ASCs through their ownership and building of new facilities. Ownership of an ASC provides many clear advantages to the physician because of the increased control and autonomy over their practice. Some advantages include ease of scheduling, shorter waiting times to get patients in for elective surgery, and the ability to hire specially trained and highly skilled staff. Physicians can also avoid the bureaucracies of a hospital, including having elective surgeries cancelled to make room for emergent surgeries and delays due to more complicated surgeries. They can also ensure that the facility has specialized equipment for their particular specialty and can design the facility to meet their specific needs.²⁶ Furthermore, physicians who perform surgeries in their own ASCs receive a share of the ASC's facility payment in addition to payment for their professional services. This could present a conflict of interest in terms of referring patients and lowering the threshold for surgery, as discussed further in the next section.

Potential for Conflict of Interest

Approximately 90% of ASCs nationwide have at least some physician ownership stake. Many are joint ventures between hospitals and physicians.²⁷ Increasing investment in these centers may be explained in a number of ways, including an attempt by providers to assert greater control over their professional lives, such as by having greater authority in scheduling surgeries and in purchasing equipment. Alternatively, this investment trend may be explained by declining reimbursements for physician services and rising practice costs. These economic pressures have intensified providers' interest in nontraditional revenue sources, such as ASC investment, as a means of generating income.

Ownership entitles physicians to collect a share of the facility's profits from referrals, in addition to their professional fees. One potential conflict of interest is that physician-owners might lower their thresholds for intervention, exposing the patient and healthcare system to the harm and cost associated with unnecessary treatment. After differences between patients and healthcare markets are adjusted for, physicians with ownership in an ASC have been found to perform a higher number of procedures compared with nonowner physicians at the same facilities.²⁷ It has been noted that the increase in outpatient surgery at ASCs was more than double the decline in similar procedures performed in the hospital setting.²⁸⁻²⁹

The other potential conflict in physician ASC ownership is in regard to patient referral. There is some evidence that physicians with an ownership stake may refer well-insured patients to their own facilities while referring Medicare and Medicaid patients to hospital outpatient clinics.³⁰⁻³²

Regardless of the reason for increasing investment in and utilization of ASCs, it is important to note that ASC ownership creates a potential conflict of interest for physicians. In the United States, physician financial interests are heavily regulated by the Stark Law. This can be either a financial investment, employment, or compensation agreement. To avoid conflicts of interest and potential legal violations, physicians should consult with attorneys and advisors knowledgeable in medical law and ethics prior to entering a financial relationship.³³

CHALLENGES

Reimbursement

Savings from use of ASCs are primarily to the patient and healthcare system. Reimbursement to ASCs for services provided is, as a direct result, lower than reimbursement paid to hospitals for the same procedures. It is up to ASCs, which operate as private corporations, to find profit and viability by keeping their costs low through efficiency and staffing. Some steps suggested to improve the financial viability of maintaining an ASC include increasing the variety of procedures offered and grouping surgeries in such a way as to maximize staffing usage.³⁴

Patient Selection

Safe use of ASCs is based on identification of patients who are unlikely to require admission to a hospital after their procedure. Thus far, ASCs do very well in this aspect. Unplanned admissions after ambulatory surgery occur in approximately 0.5% to 2.0% of cases.^{5,35-37} In the future, ASCs will be challenged to reduce this unplanned admission rate even further.

Patients with Medicaid insurance, lower median household income, and a greater preoperative comorbidity burden have the

highest odds of unplanned acute care use. These patients may benefit from interventions that enhance and streamline postoperative follow-up.³⁸ Additionally, the potential costs associated with postoperative acute care following procedures performed in ASCs are not insignificant. Patient specific predictors of unplanned hospital admission include age 65 years or older, anticipated operating time longer than 120 minutes, cardiac comorbidities, peripheral vascular disease, cerebrovascular disease, malignancy, positive for human immunodeficiency virus (HIV), and regional or general anesthesia use.³⁹

The strongest predictor for unplanned inpatient hospital admission was the individual patient's own history of previous hospitalizations, particularly among older adults. African American and Hispanic individuals also have had a markedly elevated risk of inpatient hospital admission, possibly related to cultural or socioeconomic issues of access to care.⁴⁰ These measures may provide a valuable target for quality improvement, cost improvement, and innovation.

ASCs vs. Hospital Outpatient Departments vs. Office-Based Surgical Suites

Competition is increasing among ASCs, HOPDs, and office-based surgical practices. The same improvements in anesthesia and surgical equipment that made outpatient surgery in a freestanding ASCs safe to perform have also led to a growing number of office based surgical suites and HOPDs. Procedures such as dental, ophthalmologic, endoscopy, cosmetic surgery, and liposuction are increasingly being performed in office-based facilities.⁴¹

Physicians' offices are under lower regulatory oversight in comparison to ASCs and HOPDs. This has resulted in the phenomenon of "practice drift," whereby physicians perform procedures outside of their typical scope of practice. Despite several high-profile adverse events in lay media, prospective studies have demonstrated office-based surgical suites to be of similar safety.^{41,42} A recent, large study in the area of cosmetic surgery compared hospital-based procedures with office-based surgical suites and with ASCs and found accredited office-based surgical suites to be a safe alternative to ASCs and hospitals.⁴³

Aging Population

With increased risk of complications from surgery, the older adult population present a unique challenge to ASCs. ASCs must be prepared for complications that may arise from operating on older patients, and they must do so without the same resources as a hospital. The potential benefit of outpatient surgery for elderly patients is substantial, however, as older adults often suffer from postoperative cognitive dysfunction in an inpatient setting, which may be minimized with early discharge.⁴⁴ Additional benefits include lower cost to patients on fixed incomes and increased time and comfort at home.

CONCLUSION

ASCs represent a large benefit to society because of their potential to reduce the financial burden of the healthcare system on the economy. At the same time, ASCs also provide high-quality care which is patient and family centered and convenient for providers. ASCs reduce the length of stay and minimize surgical delays and cancellations. In the future, ASC quality will be rigorously tracked due to more regulatory oversight and data collection. The future of ambulatory surgical centers remains bright. Case numbers are increasing across many specialties,

including general surgery, plastic surgery, vascular, urologic, and orthopedic practices. Surgeons should follow the maturation of ambulatory surgery closely.

BACKGROUND

Introduction

The basic American surgical training model is patterned after that established by William Steward Halsted at the Johns Hopkins Hospital in the late 19th century. By tradition, it has consisted of a regulated apprenticeship system with incremental increases in clinical responsibility for resident surgeons over a specified period of time culminating with the expectation that independent surgical practice will be possible at its conclusion. While this approach has served well throughout the 20th century, the pace of changes in healthcare delivery and society itself has driven the need for new approaches to education and training. Among the important changes that the surgical training community has had to confront are an expanding array of medical and surgical therapies, complex, new and sometimes disruptive technologies advancing at a dizzying pace, and increasing recognition of the opportunities for errors and adverse outcomes because of inadequate preparation for this new world of surgical practice.¹ Appreciation of the scale and insidious consequences of medical errors began to take hold in the 1990s when the groundbreaking Institute of Medicine report “To Err is Human” presented to the public a dire picture of the frequency and implications of medical errors.² Among the proposed new approaches to deal with this problem was the use of simulation training.

Simulation is the imitation of an actual or possible real-world condition or event. The degree to which a simulation resembles its real-world counterpart describes its fidelity. There are innumerable specific applications of simulation to train or assess human performance on anticipated real-world tasks. As such, it is a valuable tool with great potential to increase safety in high-stakes undertakings such as commercial aviation, military

training, and nuclear power generation. These are a few areas where such training has been implemented successfully. With the advent of widely available digital computing, the level of technology applied to simulation and simulators has made near-complete fidelity possible. Moreover, the enormous expense associated with full motion flight simulation, for example, has been made acceptable by safety gains that benefit entire populations. In medicine, there has been gradual acceptance of the role of simulation to achieve these same goals, and this has led to an array of simulation methods and uses that specifically target surgical providers at all levels. The fundamental justification for commitment of resources to simulation is an ethical one: *to reduce patient risk associated with invasive surgical procedures or management of complex clinical problems*. Simulation methods provide opportunities for surgical learners to practice their skills under safe conditions in preparation for clinical experiences and to be assessed and deemed ready for those encounters.

Skills Labs and Skills Training

The history of surgical skills training outside the clinical operating room (OR) is a long one, involving practice of surgical skills and procedures using various models, including animals and cadavers. Newer training practices, including simulation use in a laboratory setting, have emerged that focus on objective assessment of skill and establishment of specific, defined levels of proficiency. These assessment-based approaches are relatively recent educational developments and are being implemented as a means to improve surgeon skill in a safe setting for both learners and patients.³ The use of inanimate benchtop models to test surgical skills required a leap into the world of validation of measurement methodologies. The most important of these pioneering efforts was the implementation of the objective

Key Points

- 1▶ Learning basic skills at the point of care imposes inefficiencies that might very well endanger support for the education mission.
- 2▶ In 2006, the Accreditation Council for Graduate Medical Education Residency Review Committee for Surgery instituted a formal requirement for simulation training in surgical residency.
- 3▶ Procedural skills training in a simulated environment has been shown to transfer to the real-life clinical setting.
- 4▶ Early studies of virtual reality training using both proficiency-based and non-proficiency-based training methods showed it to be an effective means of improving laparoscopic skill both in the lab and in the operating room compared to non-virtual reality trained controls.
- 5▶ Use of proficiency-based training in the context of a larger curriculum appears to be the best way to achieve good training results irrespective of the training platform used.
- 6▶ When assessing simulator validity, researchers have noted that the use of robotic surgery simulators does translate to the clinical environment and the learning curve for initial console training for surgeons is significantly decreased.
- 7▶ Simulation training for communication and other teamwork-pertinent nontechnical skills requires learners to be embedded in realistic scenarios pertinent to a healthcare team's actual clinical responsibilities.
- 8▶ Simulation technology allows trainees the opportunity to execute a variety of tasks and procedures while also experiencing the cognitive demands of surgery, including error correction and surgical planning decisions.
- 9▶ The immediate future of simulation in surgery will likely see expanded use of proficiency-based training given the consistent demonstrations of effectiveness in improving surgeon skills and improved educational outcomes as measured in clinical settings.
- 10▶ Advances in wearables, motion tracking, and sensor technologies allow for a wide variety of hybrid and augmented experiences in simulation as well as extensive opportunities for the development of new performance metrics.

structured assessment of technical skills (OSATS) program by educators at the University of Toronto.^{4,5} Using a series of reproducible physical models of surgical tasks (excision of a skin lesion, bowel anastomosis, insertion of a T tube, and abdominal wall closure) and carefully designed rating instruments, it was possible to show validity of these measurements when compared with skill manifested during surgery in animal models. This demonstration of practical measurement of skill in the lab, where observation for skills rating purposes can be more readily achieved, was seminal in sparking both additional interest in lab-based training and in simulation as a mainstream educational method for surgeons.

The advent of laparoscopic general surgery in the late 1980s and early 1990s, a disruptive technology at that time, was a major driver for the use of surgical simulation to gain unfamiliar and nonintuitive skills needed to safely perform limited-access videoscopic surgery. The recognition that bile duct injury risk is increased by surgeon inexperience stimulated interest in simulation in order to separate a component of the psychomotor learning curve for laparoscopy from the clinical OR and patient by transferring it to the training lab.⁶⁻⁸ At the same time, interest in the science of skills acquisition and measurement made efforts to gain surgical proficiency with simulation more meaningful. The measured performance characteristics of experienced surgeons came to be appreciated as useful learning targets for less experienced surgical learners, and the concept of proficiency-based training began to be implemented successfully not only for research purposes but also for formative education.⁹

As simulation began to be used more extensively and skills labs either evolved or merged with multidisciplinary education centers using simulation as a primary instructional method, recognition of such centers as focal points for surgical education also grew. The American College of Surgeons (ACS) Education Division recognized early on that simulation training was an important educational method that surgeons could take

advantage of and began to explore ways to facilitate growth and implement training centers. In 2006, the ACS began to accredit education centers engaged in simulation training as Level 1 (comprehensive) and Level 2 (focused) Education Institutes.¹⁰ The consortium of 95 institutes, as of early 2017, now spans the globe with centers across the United States and Canada as well as several institutions outside of North America.

In 2007, the American College of Surgeons and the Association of Program Directors in Surgery (APDS) initiated a project to provide a standardized skills curriculum for surgical residents. These efforts produced the modular ACS-APDS skills curricula that represent the first comprehensive and widely available resource that prescribes simulation experiences as the principal means to achieve educational objectives.¹¹ The resources and curricula are readily available to residency programs to address surgical resident learning needs and to facilitate simulation lab use as mandated by the Accreditation Council for Graduate Medical Education (ACGME). The three components of the curriculum are basic technical skills, procedural skills, and team skills. Although these have been acknowledged to be valuable and have been utilized to meet resident training needs, implementation has been limited according to a recent survey of residency programs.¹² Elements of the basic skills curriculum were reported to be used by 36% of respondents while procedural and team training modules were reported to be in use by about half as many programs. Nonetheless, the article notes that simulation methods had permeated surgical education and the various stakeholder organizations had taken steps to either endorse or implement programs for simulation use. The need to explore simulation-based education, as stated by the Surgical Council on Resident Education (SCORE), suggests a pathway by which simulation methods might become fully integrated into standardized cognitive elements of surgical residency curriculum.¹³ Based on current trends, a competency framework can be envisioned that combines advanced forms of

standards-based learning using simulation and measured performance in the OR for purposes of trainee advancement and certification.

Scientific Underpinnings of Simulator Use

The assumption that surgical technical skills can be effectively learned and tested outside the OR serves as the basis for simulation based assessment of skills before, during, and following training. This capability permits the explicit description of understandable surgeon performance characteristics including those that can be characterized as desirable training goals (e.g., “expert”). The effectiveness of specific models of training can also be ascertained by comparative studies examining educational endpoints, such as rate of learning, or testable performance either in simulations or in clinical settings. Simulation-based learning has been described using various pedagogical models to help educators understand and leverage the most effective strategies to achieve educational goals. The most fundamental concept used to justify time spent in skills training is the prospect of achieving progressively higher levels of skill pertinent to clinical care. For medical care providers, this progression is commonly related to the learning model described by Dreyfus and Dreyfus.¹⁴ This model depicts changes in specific mental functions (recollection, recognition, decision, awareness) associated with incremental steps in the progression from novice status to that of expert (Fig. 53-1). The relevance of Anders Ericsson’s description of deliberate practice

to development of clinical skills is also widely accepted.¹⁵ This is predicated on the concept that “expert” performance is fundamentally different than normal performance and results from behaviors that “reflect a life-long period of deliberate effort to improve performance in a specific domain.”¹⁶ The drive to achieve mastery in surgery, provides an aspirational model for the surgeon’s use of simulation because the opportunity for deliberate, repetitive practice of numerous skills in the clinical setting alone is insufficient and in many cases nearly impossible. For this concept to be translated into effective educational results, simulation-based education must be of high quality, and the curricular framework created for its use must be directed toward carefully crafted, attainable, and clinically relevant educational goals.

Simulation in Graduate Medical Education

Surgery residency has been a particular area of focus for simulation use in assessment and training. The need for safe and rapid skills development is especially important in this group of learners whose time in training is limited and for whom every hour spent in education must be prioritized for highest impact. The added direct costs of operative care in training institutions has also provides a strong imperative to conduct training that minimizes negative implications of resident involvement in surgical cases.¹⁷ Learning basic skills at the point of care imposes inefficiencies that might very well endanger support for the education mission.

Figure 53-1. Dreyfus model describing stepwise skills development. In surgery, specific stages of expertise are achieved through cognitive learning, technical practice, and experience and are defined by specific cognitive and behavioral characteristics affecting how we perceive, process, and act in the task environment. (Reproduced with permission from University of South Australia; *Teaching and Learning in Health Sciences*: <https://lo.unisa.edu.au/mod/book/view.php?id=611284&chapterid=104113>.)

Despite early examples of excellence in simulation lab use and fairly wide availability, a survey of residency programs in 2006 suggested the quality of usage for laparoscopic skills training was probably low and that more than half did not use a defined curriculum.¹⁸ Also in 2006, the ACGME Residency

2▶ Review Committee (RRC) for Surgery instituted a formal requirement for simulation training in surgical residency.¹⁹ While the core program requirement did not define any specific educational objectives, performance outcomes, or specific methods to be used, there was a mandate that simulation in surgical education be objectives-based and that it be incorporated into residency curricula within 2 years. As of 2016, the relevant core program requirement indicates that “resources must include simulation and skills laboratories” and that “these facilities must address acquisition and maintenance of skills with a competency-based method of evaluation.”²⁰ Since the original notification of the need to conduct this training, mandated activities have expanded with the pairing of ACGME statements and new American Board of Surgery (ABS) requirements for certifications in Fundamentals of Laparoscopic Surgery (FLS; instituted for 2010 residency graduates) and in Fundamentals of Endoscopic Surgery (FES; instituted for 2018 residency graduates). Both of these certifications demand lab-based practice in order to successfully pass respective technical skill test components.

Both high and low technology and fidelity, off-the-shelf, simulation training solutions have become available for surgery residents’ lab-based training. Curricular content such as the ACS-APDS skills modules are readily available to facilitate a sufficient level of implementation to meet the RRC requirements, although preparation methods have not been specifically prescribed by either the ACGME or the ABS. In 2015, the ABS issued a new requirement for a comprehensive multilevel Flexible Endoscopy Curriculum (FEC) paired with FES certification. This curriculum states explicitly that experiential requirements at the lower levels can be met with simulation methods but it is left to individual programs to decide what preparatory practice in simulation might consist of for their own residents.²¹

Options for simulation use in surgical training are currently numerous and can be implemented with basic facilities and equipment, but the determination to use these methods successfully requires considerable effort that is greatly aided by fully motivated and engaged faculty members with protected time. There are now numerous guides and recommendations for successful surgical simulation lab start-ups.^{18,22-24}

“Bootcamps”

Preparatory training for surgery residency both before and immediately after the start of residency is now a widely used educational practice. The rationale for these programs includes early development of basic skills that would be of obvious use to the new trainee as well as determination of the status of basic skills that would serve as a needs assessment to model curricular efforts expected to be most appropriate for the individual resident.²⁵⁻²⁷ The suggestion that new interns will render safer care has been garnered from results of intensive, short-duration preparatory training that shows higher level of skills measured in simulation are feasible compared to the “control” situation of not using such training.²⁸ However, none of the current reports address whether intensive preparatory training addresses the “July Effect” by improving clinical effectiveness during the earliest months of training.²⁸

Much of the training and assessment during these programs is accomplished using simulation methods. No standardized approach has yet been suggested, and at the present time the impact of specific simulation components is difficult to assess for senior students entering surgical training, or new interns. Sound recommendations on this await further study. A single meta-analysis of postgraduate “boot camp” programs both prior to or at the start of residency found that all programs utilized high and low technology simulation methods as “a key component.”²⁹ Although the analysis included all medical specialties, 93% of the studies were surgical in nature, underscoring the perceived value of this preparatory training for new surgeons. The examined studies were those where pre- and posttraining effects were measured in some way. The compiled data revealed that trainees who completed the programs had uniformly strong increases in skills development, knowledge, and confidence. In 2014 the ABS, ACS, APDS, and Association for Surgical Education, citing the evidence of effectiveness of these now numerous preparatory courses, officially endorsed them as a useful method to position fourth-year students and interns for early success in residency.³⁰ Whether preresidency exposure to surgical simulation can influence a medical student’s decision to pursue a surgical career remains to be determined.

SPECIFIC SIMULATION TRAINING AND ASSESSMENT APPLICATIONS

Training Basic Surgical Skills

The use of the simulation lab to train open, laparoscopic, and flexible endoscopic basic skills in preparation for care and practice clinical constitutes the most accessible and widely adopted set of simulation training practices. In connection with these, the term “proficiency-based” training (sometimes used synonymously with competency-based or objectives-based) is often used, and can be defined as the use of meaningful performance standards as educational goals for training. Implicit in the term is the expectation that if proficiency standards are achieved, a learner will be better positioned to perform to a desirable standard in the clinical setting. Even these most basic skills have been shown to improve with proficiency-based training.³¹ Additional benefits of proficiency-based approaches to basic surgical skills include knowledge of a surgical learner’s specific educational needs and design of a larger skills curriculum roadmap that envisions progression to more advanced skills training.

Educators at Southern Illinois University implemented a program of intensive lab-based practice of basic skills as a preliminary requirement to participate in operative cases. Termed “Verification of Proficiency,” this program targets junior trainees for assessment of skill using OSATS-like rating instruments, but its unique feature is the definition of a minimal level of skill that would permit a resident to assume the role of operator for specific case types.^{32,33}

More recently, the concept of “proficiency-based progression” has been used to describe a formalized process of use of sequenced proficiency standards and a continuum of progressively more advanced and challenging simulation experiences as a potential future model of training.³⁴ Such a model would span whatever period of time was necessary for each learner to progress from basic surgical skills to more advanced ones.

Open Surgical Skills. A variety of benchtop models for practice and assessment of basic open skills are available, the most

Table 53-1**ACS-APDS basic skills curriculum components**

- Knot tying
- Suturing
- Skin flaps
- Skin grafts
- Urethral catheterization
- Airway management
- Chest tube insertion
- Central line insertion
- Surgical biopsy
- Laparotomy opening and closure
- Basic laparoscopy skills
- Advanced laparoscopy skills
- Hand-sewn bowel anastomosis
- Stapled bowel anastomosis
- Arterial anastomosis

well-known of which are the OSATS tasks that remain in use more than 20 years after their inception. The ACS-APDS Basic Skills Curriculum (Table 53-1) is a useful resource for this.

Generally, lower-fidelity models are more cost effective for repetitive training because durability with reuse may be better than high-fidelity physical models and replacement costs can be minimized for many tasks. Examples can include simple models for abdominal wall closure (Fig. 53-2). The use of low-fidelity models in well-formulated curricular training can be very effective in increasing resident skill, although high-quality measurement can be labor intensive. Bowel and vascular anastomosis training has been an especially important point of focus given their prominence and highly technical

nature in clinical practice. In a recent analysis of resident experience with gastrointestinal anastomosis, Nemeth reported that although frequently performed (average 67 per resident), stapled anastomosis experience predominates during training (91% of laparoscopic procedures and 82% of open ones), suggesting a relatively small clinical experience with hand-sewn anastomotic methods, which remain critically relevant.³⁵ Simulated bowel anastomosis models are widely available (Fig. 53-3), and there are numerous reports of successful curriculum-based development of this core technical skill generally utilizing OSATS rating instruments.³⁶⁻³⁸ Although further study is required to demonstrate a clinical effect of this training, other experience strongly suggests that use of proficiency-based anastomosis training should be the next step. In an example of how this could be used for trainee benefit, Palter conducted a randomized trial of use of a proficiency-based technical skills and cognitive curriculum for abdominal wall closure.³⁹ The technical skills component utilized a low-fidelity model for an OSATS assessments of both lab and OR performance. Residents in the intervention arm performed better on both clinical abdominal wall closure and a test of procedural knowledge than controls.

Basic Laparoscopic Manipulative Skills. Current evidence supports the concept that basic laparoscopic skills should be developed in the training lab, avoiding safety concerns as well as the expenditure of time and effort that would result from learning in clinical settings. Specific programs for basic laparoscopic skills development coupled with skills assessment were set forth 20 years ago at a time when this need was newly articulated for surgeons at all levels.^{7,40,41} These utilized videoscopic training “boxes” for two-handed practice using laparoscopic instruments to manipulate box contents. Programs such as the Rosser drills employed various dexterity tasks emphasizing time for task completion as a measure of performance. Later, McGill investigators began to apply greater scientific rigor to the design

Figure 53-2. Abdominal wall closure model made from commonly available materials using instructions in the ACS-APDS Basic Skills Curriculum module for this task.

Figure 53-3. **A.** Hand-sewn GI anastomosis from the ACS-APDS Basic Skills Curriculum module for this task. A full instructional presentation is available with the curriculum along with an assessment instrument for the educator to use. **B.** OSATS stapled bowel anastomosis model. (Reproduced with permission from de Montbrun SL, Macrae H *Simulation in surgical education*, Clin Colon Rectal Surg. 2012 Sep;25(3):156-165.)

and testing of basic skills curricula, with a particular focus on the ability to characterize the skills acquisition process and differences between learner groups based on careful repetitive measurement.⁴² Further study showed that performance, measured using these bench training tasks, correlated with performance measured in vivo animal models.⁴³ In addition to helping learners prepare for basic tissue manipulation, training on basic tasks were found to shorten the learning curves for more complex laparoscopic tasks such as suturing.⁴⁴

Fundamentals of Laparoscopic Surgery

Fundamentals of Laparoscopic Surgery (FLS) was devised by minimally invasive surgical leaders in the Society of American Gastrointestinal and Endoscopic Surgeons as a means to assess laparoscopic surgical knowledge and skills for the purposes of certification of basic ability.⁴⁵ This program represents the first broadly applied effort to demonstrate achievement of a specified level of basic surgical skill with such specific testing. Although most utilized by surgical residents, the resulting skills certification is applicable to a broad range of learners, including surgeons in practice as well as laparoscopic surgeons in specialties other than general surgery. FLS consists of separate tests of knowledge and technical ability. The latter component required integration of simulation tasks with a high degree of validation for both effectiveness in discerning skill and relevance to the respective clinical tasks. The McGill Inanimate System for Training and Evaluation of Laparoscopic Skills (MISTELS) tasks were selected as the technical skills assessment component.⁴⁶ These were developed independently from the FLS program and adapted to the FLS based on the predictive value of a subset of the tasks for clinical skills manifested in the OR. These tasks have remained core features of the certifying examination and have been extensively studied both as training curriculum components and as predictors of clinical performance.^{47,48} Recent work has suggested that specific proficiency-based training can increase pass rates on FLS to 100%, supporting the general suppositions about the benefits of this model of training.⁴⁹

The more recently available FES serves a similar purpose to FLS for flexible endoscopy.⁵⁰ This certification adds the important feature of use of a virtual reality flexible endoscopy simulator as one of the platforms for delivery of the technical skills test.

Bench Models for Training Specific Procedural Skills

Procedure-specific simulation offers a unique opportunity to practice and evaluate wholesome surgical skill. This includes training and evaluating the relationship between basic and complex technical skills and surgical decision-making. While the majority of procedural simulation trainers focus on bedside procedures such as central venous catheter placement, bladder catheterization, and intubation, a number of trainers also have been designed to simulate more complex procedures such as laparoscopic ventral hernia, laparoscopic colectomy, and robotic nephrectomy.⁵¹⁻⁵³ Currently, both virtual reality and physical or hybrid models are used for procedure-specific simulations.⁵⁴ While each technology has specific benefits, there is still a critical need for fabrication and design approaches that are efficient, cost effective, and produce anatomically accurate models with realistic tissue properties.⁵⁵ A number of groups have explored the use of three-dimensional (3D) printing with varying degrees of success.^{56,57} As the printing substrate materials and 3D machines continue to decrease in price and increase in ease of use, there will likely be a significant upsurge in the use of this approach to facilitate development of procedure specific simulations. In addition to full immersion virtual reality, a number of groups are still exploring the benefits of computer-based learning for training procedure-specific surgical skills.⁵⁸

The training and assessment benefits of procedure-specific simulation are numerous. Not only does it allow an opportunity to assess technical skill in the context of a multistep procedure, forced errors and critical decisions can be combined with this technology, allowing for a more in-depth learning experience and skills assessment. By way of example, two multistep bedside procedures were modified: bladder catheterization and central venous catheter insertion. Both simulations had embedded clinical scenarios, which if executed incorrectly in real life might produce patient injury due to incorrect technique or equipment choices. During the implementation of these modified, multistep procedures, it was possible to identify individual cognitive and technical errors that serve as opportunities for additional training.^{59,60} The ACS-APDS Procedural Skills Curriculum was developed to complement the Basic Skills Curriculum and offers detailed learning objectives for a variety of surgical procedures. The goal of this curriculum was to address holistic surgical skills in a context where both technical

Table 53-2

ACS-APDS procedural skills curriculum components

- Laparoscopic ventral hernia repair
- Open colon resection, lap right colon resection
- Laparoscopic sigmoid resection
- Open right colon resection
- Laparoscopic/open bile duct exploration
- Laparoscopic ventral/incisional hernia repair (porcine model)
- Laparoscopic appendectomy
- Laparoscopic Nissen fundoplication
- Sentinel node biopsy and axillary lymph node dissection
- Open inguinal/femoral hernia repair
- Laparoscopic inguinal hernia repair
- Laparoscopic/open splenectomy
- Laparoscopic/open cholecystectomy
- Gastric resection and peptic ulcer disease
- Parathyroidectomy/thyroidectomy

and cognitive performance could be assessed at the same time.¹¹ The simulation scenarios defined for this curriculum are listed in Table 53-2.

Similar to the literature on basic skills training and assessment, procedural skills training and assessment has been shown to benefit learners when delivered via a structured curriculum. In addition, procedural skills training in a simulated environment has been shown to transfer to the real-life clinical setting. In 2005, Issenberg et al published a review of the features and uses of simulation training that lead to effective learning.⁶¹ After reviewing 109 articles that specifically used simulation as an educational intervention and not for assessment alone, Issenberg and colleagues noted that feedback, repetitive practice, and curricular intervention were among the top three features that lead to effective learning. Of note, in this same article, it was noted that simulator validity was at the bottom of the list of features that lead to effective learning. In essence, trainees need protected time to engage in simulation-based learning exercises that have a high-level focus on deliberate and repetitive practice based on personalized feedback. This model is very similar to that used to train professional athletes.⁶²

Transfer of Training

The determination that simulation-based education is effective requires assessment of training effect in either the clinical setting or one with a demonstrated relationship to a clinical setting. The latter might result from comparison to a validated “gold standard” training method. Establishing a relationship between lab-based training and performance in the OR requires validated measures of operative skills such as the widely used Global Assessment of Operative Laparoscopic Skills (GOALS) method described by Vassiliou.⁶³ The majority of studies of laparoscopic simulation training that examine transfer of skills to the clinical OR make comparisons to control groups without highly structured and non-simulation based training. The results of these studies should eliminate any doubts that surgical learners, especially students and residents, can achieve training benefits from both proficiency-based and time- or repetition- or session number-based simulation practice. When the results of proficiency-based training are dissected out from the other models of training, consistently higher levels of clinical or

animal OR performance is observed with such training compared to without.⁶⁴⁻⁶⁷ In one such review of skills transfer studies conducted between 2007 and 2013, Dawe reported results for general surgery and gynecology procedures using different virtual reality and non-VR laparoscopic simulation platforms (Table 53-3).^{48,67-77} For the 12 randomized controlled trials with surgical residents as study subjects, all but one showed significantly better clinical performance for intervention groups compared to non-simulation-trained controls.

The comprehensive reviews of skills transfer data underscore the wide disparities in study design characteristics, metrics, simulator types, and the difficulties in comparing effectiveness of different simulation interventions. The “transfer effectiveness ratio” (TER) has been forwarded as a means of expressing the relative magnitude of the training effect and may provide a basis for comparison of cost or time efficiency of different training methods.⁷⁸ To determine TER for a simulation training effort, one would calculate the difference in clinical effort (time or some other measure such as number of cases) between simulator-trained and alternative-trained groups to achieve a desired level of clinical performance, divided by training time received by the simulator-trained group.

Korndorffer raised concerns with studies of transfer of training when, irrespective of the improved results in lab performance with proficiency-based practice, residents studied by their group did not readily meet performance standards for more advanced skills set by expert surgeons in practice.⁷⁹ Looking for opportunities to maximize the effectiveness of simulation training, Stefanidis proposed training to “automaticity” by adding a secondary visuospatial task to practice with laparoscopic suturing, but only after proficiency levels were achieved with more standard laparoscopic suturing practice.⁸⁰ It was suggested that the added attentional challenge likely prompted the achievement of automaticity, the end result of which was much greater performance than was seen for proficiency-based practice alone. It is not clear, however, that simply adding to task difficulty improves training results if learner capabilities are not taken into account. In a separate study, Stefanidis also reported that increased task difficulty during proficiency-based training causes measurable increases in cognitive workload and that when confronted with these challenges, novice learners did not perform better than those in proficiency-based training at a lower level of difficulty, suggesting a possible mismatch between task challenges and capacity to learn.⁸¹ More work is required to characterize the proper balance of training difficulty and the capacity for learning in specific learners or learner groups.

Virtual Reality

The use of virtual reality (VR) simulation as a way to deliver training experiences in surgery was proposed by Satava in 1993.⁸² Within a few years, practical applications of this technology led to the first commercially available laparoscopic simulators and studies to determine their value. The earliest and most functional VR platform was MIST-VR which permitted manipulation of abstract virtual objects using a realistic physical interface that transduced instrument motion into actions that could be observed in the virtual environment (Fig. 53-4).⁸³ Even without a force feedback apparatus and haptic, or “sense of touch,” cues expected with instrument-instrument or instrument-object interactions, learners could experience the psychomotor challenges of videolaparoscopy and iteratively train until

Table 53-3

Randomized trials studying the effects of virtual reality training on surgical and OB-GYN resident operative performance vs. control trainees without virtual reality training

AUTHOR (YEAR)	PARTICIPANTS (N) AND SIMULATOR	PROCEDURE ASSESSED	CONCLUSION
Ahlberg et al ⁶⁸ (2007)	PGY 1–2 surgery residents IG (7); Lap Sim VR simulator CG (6) no simulation	Laparoscopic cholecystectomy	IG made fewer errors ($P = 0.004$), exposure ($P = 0.040$), clipping and tissue division ($P < 0.008$), and dissection ($P < 0.031$) compared with CG
Banks et al ⁶⁹ (2007)	PGY 1 GYN residents IG (10); Limbs & Things box trainer CG (10) no simulation	Bilateral tubal ligation	IG scored higher than CG with all three evaluation tools: task-specific checklist ($P = 0.002$), OSATS ($P = 0.003$), pass-fail grade ($P = 0.003$)
Cosman et al ⁷⁰ (2007)	Junior surgical trainees IG (5); Lap Sim VR simulator CG (5) no simulation	Laparoscopic cholecystectomy (clip application and cystic artery division)	IG had fewer errors ($P = 0.05$), better bimanual coordination ($P = 0.05$), higher global score ($P = 0.04$) than CG
Gala et al ⁷¹ (2013)	GYN residents IG (48); FLS box trainer CG (54) no simulation	Pomeroy bilateral tubal ligation	IG had higher OSATS progression score than CG ($P = 0.03$)
Hogle et al ⁷² (2009)	PGY 1 surgery residents IG (6); Lap Sim VR simulator CG (6) no simulation	Laparoscopic cholecystectomy	No significant difference between IG and CG in GOALS Domain areas of depth perception, bimanual dexterity, efficiency, tissue handling, autonomy
Larsen et al ⁷³ (2009)	First- and second-year OB-GYN registrars IG (13); Lap Sim VR simulator CG (11) no simulation	Salpingectomy	IG had higher score than CG in OSA-LS scale ($P < 0.001$). IG completed procedure faster than CG ($P < 0.001$)
Sroka et al ⁴⁸ (2010)	PGY 1–3 surgery residents IG (8); FLS box trainer CG (8) no simulation	Laparoscopic cholecystectomy (excision from liver bed)	IG had higher total GOALS score than CG ($P < 0.001$) and better GOALS domain scores for bimanual dexterity ($P = 0.04$), tissue handling ($P = 0.04$)
Van Sickle et al ⁷⁴ (2008)	PGY 3, 5–6 surgery residents IG (11); MIST-VR simulator CG no simulation	Nissen fundoplication (placement of intracorporeal sutures)	IG completed task in less time ($P < 0.003$), committed fewer errors ($P < 0.01$), and had fewer needle manipulations ($P < 0.05$) than CG
Zendejas et al ⁷⁵ (2011)	Surgery residents IG (26); Guildford MATTU TEP hernia task trainer CG (24) no simulation	TEP inguinal hernia repair	IG faster on first procedure ($P < 0.001$) and had higher participation rates ($P < 0.001$). For subsequent repairs IG remained faster than CG. GOALS score higher for IG ($P = 0.001$). Complications and overnight stay less likely for first TEP procedure in IG ($P < 0.05$).
Palter et al ⁷⁶ (2012)	PGY 2–4 surgery residents IG (9); curriculum including simulation training on LapSim VR simulator CG (9) no simulation	Right hemicolectomy	IG had higher OSATS score ($P = 0.030$) than CG. IG able to perform more operative steps than CG ($P = 0.021$)
Palter et al ⁷⁷ (2013)	PGY 1–2 surgery residents IG (9); curriculum including simulation training on LapSim VR simulator and on FLS box trainer CG (9) no simulation	Cholecystectomy	IG had higher OSATS scores for first four procedures ($P = 0.004$, $P = 0.036$, $P = 0.021$, $P = 0.023$)

PGY = postgraduate year; IG = intervention group; CG = control group; VR = virtual reality; OSATS = Objective Structured Assessment of Technical Skills; GOALS = Global Operative Assessment of Laparoscopic Skills; OSA-LS = Objective Structured Assessment of Laparoscopic Salpingectomy; TEP = totally extraperitoneal.

Simulators: LapSim VR simulator (Surgical Science, Gothenburg, Sweden); laparoscopic stimulator and Minimal Access Therapy Unit (MATTU) (Limbs and Things, Bristol, UK); Fundamentals of Laparoscopic Surgery (FLS) Training Box simulator (SAGES, Los Angeles, California, USA); Minimally Invasive Surgical Trainer—Virtual Reality (MIST-VR; Mentice, Gothenburg, Sweden).

Modified with permission from Dawe SR, Pena GN, Windsor JA, et al. Systematic review of skills transfer after surgical simulation-based training. *Br J Surg*. 2014 Aug;101(9):1063-1076.

Figure 53-4. The surgical interface for MIST VR (A), consisting of right- and left-handed laparoscopic instruments on a gimbaled mount that transduces instrument motions into digital spatial data, which determine the location and actions of instruments in the virtual space (shown in B) in the course of manipulating two-handed virtual objects. Although basic renderings of geometric shapes, these virtual objects could be grasped, positioned, and treated with electrocautery instruments, and they were shown to be an effective means to transfer skills to clinical surgery despite a relatively low level of fidelity to human tissues and absence of haptic feedback in the instrument interface.

performance goals for precision, efficiency, and error avoidance were achieved. Performance measurement was automated and included time, instrument motion, and electrocautery use metrics, as well as a tally of the occurrence of predefined errors. All metrics were free of human observer bias. Early studies of

4► VR training using both proficiency-based and non-proficiency-based training methods showed it to be an effective means of improving laparoscopic skill both in the lab and in the operating room compared to non-VR trained controls.^{68,84-87} Since the first studies of this type were performed almost 20 years ago, several comprehensive reviews of the growing body of literature on VR have continued to support the conclusion that skills acquired in VR transfer to the clinical setting (Table 53-3), not only for laparoscopy, but also for flexible endoscopy, sinusoscopic surgery, and endovascular interventions.^{66,67,88-91} Largely due to small study sizes and some

design limitations, the quality of evidence of these studies is consistently described as below level I.

Based on available evidence, expanded use of VR for skills training could be justified, but few comparisons of training effectiveness have been made between physical laparoscopic video trainer (“box” trainer) and laparoscopic VR simulator-based training. Crossover studies designed to determine if training in one environment improves performance in the other have not been especially helpful in defining the value of either. Only a few studies have compared the effects of the two training methods on OR performance (Table 53-4). Although some advantage has been suggested, the prevailing view is that both can be used for highly effective laparoscopic practice. Until better comparisons

5► are made, use of proficiency-based training in the context of a larger curriculum appears to be the best way to achieve good training results irrespective of the training platform used.

Table 53-4

Studies comparing laparoscopic operative performance after training on virtual reality simulators vs. videoscopic box trainers

AUTHOR (YEAR)	STUDY ARMS (N)	SUBJECTS	PROFICIENCY-BASED TRAINING?	CONCLUSIONS
Hamilton et al ⁹² (2002)	VR (24) Box trainer (25)	First- and second-year surgical residents	No	Improved rater-blinded global assessments of laparoscopic cholecystectomy for VR but not box-trainer trained subjects
Youngblood et al ⁹³ (2005)	VR (16) Box trainer (17) No training (13)	Medical students	No	VR-trained students performed better than box trainer-trained on selected tasks in live porcine model. Both trained groups outperformed nontrained.
Diesen et al ⁹⁴ (2011)	VR (10) Box trainer (8)	Interns Medical students	No	No difference in interval blinded video assessments of animal OR task performance

VR = virtual reality; OR = operating room.

VR simulator systems are significant capital investments for simulation centers that have competing procurement priorities. In a prospective randomized trial, Orzech analyzed the cost impact of each type of training across Canadian residency programs and found that the transfer of training effect was greater for VR as compared to the box trainer group. However, box trainer use was found to be more cost effective except in larger residencies.⁹⁵ Although the reasons for the latter finding require further analysis, the high acquisition costs of VR systems can be offset by an economy of scale benefit not realized with physical models where staffing for purposes of task setup and assessment and consumable items related to many tasks represent additive costs. Flexible endoscopy VR simulator device sharing was shown to work effectively for a skills acquisition program across a network of Texas institutions where procurement of numerous such simulators might not be practical.⁹⁶

The role of haptics has been debated for laparoscopic VR simulators since the inclusion of sophisticated force feedback hardware adds substantially to the cost of surgical VR as well as to system computing demands. In simulated endoscopic and laparoscopic procedures, effective haptic cues are important contributors to the fidelity of the experience. For basic skills acquisition these features have not been shown to offer significant advantages over nonhaptic VR systems, although for more advanced skills haptic cues may permit greater precision of instrument use.^{97,98} However, surgical VR has advanced to the point where inventories of procedure types offered on specific commercially available systems are quite extensive and these will inevitably increase and encompass entire procedures. The realism of the user experience, including the haptic experience, may prove essential to effective learning of advanced surgical skills in a new generation of VR devices. The current generation of laparoscopic simulators are highly capable devices with a high degree of graphical realism, full haptic features, and numerous tasks available for training

basic and procedural skills for general surgical, urologic, and gynecologic procedures (Fig. 53-5).

Despite encouraging progress made in VR simulation, two separate publications in 2007 and 2015 identified ongoing computational challenges in development of very high-fidelity simulations for surgery.^{99,100} These include the unique VR problems of modeling human tissues and the added demands of rendering the appropriate deformations when tissues are manipulated. One of the practical examples of this is that of guidewire behavior during VR as compared to real-life endovascular procedures, where variable elasticity characteristics of blood vessel walls were observed to result in real tissue or wire deformations that the VR software could not depict accurately.¹⁰¹ Also identified were disparities between levels of resourcing for surgical VR versus mainstream computer gaming, raising important questions on how the full power of this technology can be realized to more fully simulate complex operations with a high degree of fidelity and realism.

Virtual Reality for Flexible Endoscopy

The use of virtual reality simulation to train for flexible endoscopy procedures is now well established and supported by consistent evidence of both skills transfer. Sedlack compared colonoscopy skills between small groups of inexperienced VR-trained and nontrained gastroenterology fellows and found that VR training resulted in farther progression into the colon, better inspection skills, and a higher percentage of completed studies (those that reached the cecum).¹⁰² This performance advantage extended out to 30 posttraining procedures. In the years since that report, four randomized controlled trials of VR training with blinding to training status during posttraining clinical colonoscopy have been conducted.¹⁰³⁻¹⁰⁶ Despite methodological issues with each of these trials (no proficiency-based training, unsupervised VR practice on one, vaguely defined training characteristics of control groups), all but one showed training benefits for

Figure 53-5. Three different current generation laparoscopic virtual reality simulators. **A.** LapVR VR Simulator, CAE Healthcare, Sarasota, FL. **B.** Symbionix LAP Mentor VR simulator, Littleton, CO. **C.** LapSim VR simulator, Surgical Science AB, Gothenburg, Sweden.

previously inexperienced VR-trained residents versus controls, especially in the earlier posttraining clinical cases based on either subjective determination of competency or measurement of procedure length. The study that did not show improved clinical performance compared to controls was a noninferiority comparison to control subjects with undefined patient-based training where the two groups performed comparably well. Randomized trials of VR training for upper endoscopy have shown significant performance advantages in both procedure length and subjective assessment of competency compared to both nontrained and patient-based training control groups.¹⁰⁷⁻¹⁰⁹

Based on the highly standardized test environment that can be experienced in VR and concurrent validity to clinical endoscopy, the SAGES FES program utilizes VR flexible endoscopy simulation for certification of skills. Systematic review of published literature on VR flexible endoscopy skills cite the need for better quality evidence in support of best training practices and improved patient outcomes.¹¹⁰ Further study is required, especially in the area of proficiency-based VR flexible endoscopy training, which has been generally underutilized.

Virtual Reality for Endovascular Interventions

Virtual reality simulation has been shown to be an effective alternative to training with animal or cadaver models for catheter-based vascular interventions. Current simulations allow development of basic guidewire and catheter handling skills, as well as practice in use of fluoroscopy, angioplasty, and stenting techniques. Procedural training for coronary, carotid, renal, neuro, peripheral vascular, and other interventions are feasible with measurement of learner performance in numerous areas such as procedure and fluoroscopy time, contrast use, and intervention effectiveness. Simulators display fluoroscopy images and allow for the selection and insertion of

virtual catheter, balloon, and stent types, which are pertinent to the procedure being performed (Fig. 53-6). In small randomized trials, VR training has been shown to increase residents' peripheral angioplasty skills with transfer of lab-acquired skills to the clinical OR.^{111,112} After having previously shown that VR simulator assessment can effectively discriminate the level of clinical experience with carotid artery stenting among experienced interventionalists, Van Herzele demonstrated that experienced interventionalists could also significantly increase carotid artery stenting skills following a 2-day intensive course of didactic and VR training for this procedure.^{113,114} Following training, decreased procedure and fluoroscopy time and decreased time for placement and retrieval of the embolic protection device were observed. Although differing clinical outcomes were not seen in this small study, it was noted that internal carotid artery spasm frequency decreased after training.

The incorporation of actual patient vascular anatomic information taken from computerized tomography data into a vascular interventional simulation as an aid to procedural planning or technical procedure performance has been referred to as "mission rehearsal" or more commonly now, procedure specific rehearsal or procedure specific simulation. It has been described most extensively for carotid artery stenting procedures and highlights how VR simulation can be directed toward the immediate problems of clinical practice. Cates' brief report of a single procedure was followed by small studies further demonstrating the feasibility and general impressions of the value of this method.¹¹⁵⁻¹¹⁷ In a randomized comparison of trainees who performed either part-task rehearsal or rehearsal of the entire procedure, Willaert reported that a similar performance benefit could be achieved, suggesting a potentially more time-efficient way to train, although the embolic protection device was in place slightly longer in the part-task-trained group.¹¹⁸

Figure 53-6. Representation of patient-specific aortic vascular anatomy during simulation of endovascular aortic replacement (EVAR) for abdominal aortic aneurysm, with distal graft limbs in the ballerina (A. crossed) and standard (B. uncrossed) configurations. This example of patient-specific rehearsal requires preparation the virtual aorta from a DICOM (Digital Imaging and Communications in Medicine) format file of patient computed tomography (CT) or CT angiogram imaging data. Image is rendered on ANGIO Mentor VR simulator (3D Systems, Littleton, CO). (Reproduced with permission from Pakeliani D, Van Herzele I, Lachat ML, et al: EVAR 2020: Training Future Aortic Specialists. *Emerging needs and the role of simulation.* Endovascular Today 2017 March;16(3):95-100.)

In a recent multinational European study, Desender and colleagues randomized a series of 100 patients scheduled to undergo elective endovascular aneurysm repair (EVAR) for infrarenal aortic aneurysm to either have their procedure rehearsed with VR simulation preoperatively or to have the procedure performed without rehearsal.¹¹⁹ There were 26% fewer minor errors, 76% fewer major errors, and a 27% fewer errors causing procedural delay in the VR rehearsal group. In addition, this group had significantly fewer angiograms performed to visualize proximal and distal graft landing zones. In a follow-up of this study, Desender reported that patient-specific rehearsal before EVAR resulted in alteration of the operative plan for proximal landing zone (54%), distal landing zone (76%), stent graft main body size (16%), contralateral limb size (34%) or orientation (16%), and iliac extension size (28%). Ninety-two percent of these changes were implemented during the actual EVAR case.¹¹⁹

Patient-Specific VR Surgery Simulation

In addition to patient specific rehearsal for endovascular interventions, VR simulations for OR surgical procedures have begun to use patient imaging data to rehearse procedures preoperatively. While many surgeons consciously and subconsciously mentally rehearse procedures before entering the operating room, this process does not allow for fully explicit information sharing between team members. Moreover, even when the surgeon verbalizes a plan for other members of the OR team after the mental rehearsal, it is not uncommon to unintentionally exclude important details that team members may value. The use of anatomically accurate VR simulations, based on patient-specific anatomy, may allow for team-based rehearsals and reduce the risk of human error. In addition, VR-based rehearsals may also facilitate doctor-patient communication.¹²⁰

Patient-specific VR simulations have recently emerged for a variety of complex operations including pancreatectomies, hepatectomies, renal surgery, and hand surgery.¹²⁰⁻¹²³ For one of the renal surgery simulations, patient-specific computed tomography (CT) data was captured and used to create 3D imaging for incorporation into the simulation.¹²² The anatomical accuracy of various structures such as arteries, veins, ureters, and even tumors was reported to be high. Another group compared the appearance of individual vascular structures while performing several patient-specific virtual hepatectomies simultaneously with real-life hepatectomies and also noted a high degree of accuracy. In addition, similar to the way CT angiograms are used in the OR for surgical planning, this group was able to increase and decrease the transparency level of the patient specific VR simulation and use it both as a real-time operative guide (minimal transparency mode) as well as an operative planning guide (high transparency—vessel only view). This enabled one system to be used seamlessly throughout the actual operation.¹²³

According to reports, the time needed to create patient-specific VR simulations is relatively short. On average, it took approximate 2.5 hours each for both the hepatectomy and pancreatectomy simulations.¹²⁰ In addition, compared to the use of 3D printed simulations, patient-specific VR simulations are readily reusable and do not consume as many resources. While these recent advances are quite promising, patient-specific VR simulators are a new technology, and thus additional studies are required to more fully understand the pros and cons of introducing this technology into the patient care arena. As there continues to be major improvements in patient-specific 3D rendering,

including organ and tissue deformation in reaction to surgical manipulation, this increases the possibility of even more sophisticated and accurate VR simulations that can be used for preoperative planning and rehearsing for complicated procedures.

Robotic Surgery Simulators

After the da Vinci surgical system was first introduced in the United States in 1999, a number of simulation systems for teaching robotic surgery emerged. While there have been several versions of the da Vinci system deployed worldwide, the basic system components usually include dual hand controls, foot pedals, and a controllable 3D camera.¹²⁴ Consistency in these system components allow for similar consistency in simulation design and delivery. Currently, there are four different simulators geared towards imparting some level of competency in using the da Vinci System: the SEP-Robot (SurgicalSim Educational Platform Robot; SimSurgery, Oslo, Norway); RoSS (Robotic Surgery Simulator-Simulated Surgical Systems, San Jose, CA); dV-Trainer (Mimic Simulation, Seattle, WA), and the da Vinci Skills Simulator (Intuitive Surgical, Santa Clara, CA).^{124,125} The SEP-Robot is a desktop-like system for training robotic skills in a VR graphical interface. The da Vinci Skills Simulator, also called the “backpack,” is a hardware system that loads VR simulations into the actual da Vinci console.¹²⁶ The RoSS and dV-Trainer systems are stand-alone devices with surgical controls resembling those of the da Vinci system.¹²⁴ These simulators largely focus on hand-eye coordination, tissue manipulation, suturing and knot tying.¹²⁷ The major benefit of VR simulators for training da Vinci robotic skills is that they produce performance metrics including time, error measures, and motion analysis.¹²⁴ These simulators are increasingly being used for training novice surgeons in robotic skills for a variety of surgical specialties.

When assessing simulator validity, researchers have noted **6▶** that the use of robotic surgery simulators does translate to the clinical environment and the learning curve for initial console training for surgeons is significantly decreased.^{124,126} Unfortunately, the available robotic surgery simulators still come with a high sticker price and varying agreement on the level of fidelity that is currently present in these technologies.¹²⁴ These deficiencies are likely due to the early stage of the robotic surgery approach, and it is likely that cheaper and more sophisticated systems will be available in the near future.¹²⁸

Fundamentals of Robotic Surgery

The Fundamentals of Robotic Surgery (FRS) is a robotic surgical skills training and assessment program designed to provide a proficiency-based curriculum of basic technical skills to prepare surgeons for performing robotic surgery procedures across a wide range of specialties. The FRS program was developed over a 2-year period by subject matter experts from multiple surgical societies, surgical educational societies, surgical boards, and other governing organizations through a series of four consensus conferences, which included over 80 international robotic surgery experts, behavioral psychologists, medical educators, statisticians, and psychometricians.¹²⁹ The multidisciplinary team of experts agreed upon the critical skills and tasks to be included in a comprehensive basic curriculum, and a task deconstruction was performed to identify the tasks, subtasks, and errors that needed to be measured. A modified Delphi methodology was then used to create a matrix of specific robotic surgery tasks, common errors, desired outcomes, and quantitative metrics to

Table 53-5

The four online modules for the fundamentals of robotic surgery curriculum

Module 1	Introduction to Surgical Robotic Systems, includes an overview of minimally invasive surgery, advantages of robotic assisted surgery, components of robotic systems, and system functionality
Module 2	Didactic Instructions for Robotic Surgery Systems, provides an overview of robotic surgery systems, as well as detailed information regarding the pre-, intra-, and postoperative phases
Module 3	Psychomotor Skills Curriculum, consists of background and general principles of the psychomotor tasks, an introduction to the physical model on which the tasks are performed, and general scoring guidelines for all the tasks, followed by detailed descriptions of each task, including the targeted primary and secondary skills and metrics
Module 4	Team Training and Communication Skills, includes background on the degradation of situation awareness and the TeamSTEPPS process followed by detailed content covering communication, situational awareness, mutual support, leadership, the preoperative phase, robotic docking, intraoperative phase, postoperative phase, and a review of five scenarios

support those outcomes. Finally, a second round classic Delphi anonymous rating was used to ensure concurrence, prioritize the task rankings, and eliminate low-scoring tasks.

All trainees must first complete an online curriculum consisting of four modules. Each of the four online modules is followed by a short quiz, requiring a minimum of 70% correct to proceed in the training (Table 53-5). The curriculum also includes a cumulative, cognitive test following completion of all modules.

Following online course completion, trainees must complete seven psychomotor exercises using a surgical robot, a simulated abdomen, and an 18-cm, removable dome model (Fig. 53-7).

The psychomotor exercises consist of the following tasks: docking/instrument insertion, ring tower transfer, knot tying, railroad track, 3rd arm cutting, puzzle piece dissection, and vessel energy dissection (Table 53-6).

NONTECHNICAL SKILLS

For surgeons, the term “nontechnical skills” refers to the cognitive knowledge and teamwork-related abilities that must be integrated with psychomotor skills and abilities. There are no sharp demarcations between these areas of skill, but different simulation methods are suitable for training each, and all should be addressed.

High-Fidelity Patient Simulation and Team Skills

Recognition of the role of human factors in the occurrence of preventable errors has spawned various efforts to train behaviors conducive to high-performing teams. Crew resource management (CRM) training utilizing simulation has been credited with increased safety in aviation.^{130,131} Lessons learned from CRM have been adapted to medical training with simulators focusing on medical team performance in complex clinical situations. This development came about in the 1990s driven primarily by anesthesiologists responsible for establishing the first high-fidelity simulation environments.^{132,133} These were developed for simulation of crisis-level events where management could be practiced under realistic but safe conditions.¹³⁴⁻¹³⁶ Such training could be scaled to involve a single learner to focus on clinical management up to an entire care team able to practice team processes. Development of a program for such training requires an understanding of the principles underlying team effectiveness and the specific characteristics of an expert team. In a 2012 discussion paper on team-based health care emerging from the Best Practices Innovation Collaborative of the Institute of Medicine (IOM) Roundtable on Value & Science-Driven Health Care, such principles were clearly laid out following a careful analysis of effective medical teams across the country (Table 53-7).¹³⁷ This document provides an excellent review of characteristics and values that surgical teams can aspire to. The necessity to train these skills has been widely accepted as

Figure 53-7. A. The simulated abdominal cavity for training in the Fundamentals of Robotic Surgery. B. The 18-cm removable dome model featuring well-defined areas for executing each of the seven psychomotor exercises outlined in Table 53-6. (Used with permission from the Institute for Surgical Excellence.)

Table 53-6

The seven psychomotor dome tasks for the fundamentals of robotic surgery curriculum

Task 1: Docking/ Instrument Insertion	The first psychomotor exercise provides training and assessment of proper docking and instrument insertion using the simulated abdomen.
Task 2: Ring Tower Transfer	The trainee removes a ring from the right middle tower and places it on the lower left tower. Primary skills assessed include hand, eye, and instrument coordination, camera navigation, and use of the camera pedal.
Task 3: Knot Tying	The trainee ties a surgeon's knot to approximate two eyelets such that they touch each other. Primary skills assessed include appropriate handling of suture material and tying secure knots.
Task 4: Railroad Track	The trainee must perform horizontal mattress suturing through a series of target points to approximate the tissue. Primary skills assessed include holding and manipulation of the needle, following the curve of the needle, utilizing the full range of motion of the endowrist, and using graspers.
Task 5: 3rd Arm Cutting	The trainee must switch control between different instruments to use the monopolar scissors to cut a simulated vein. Primary skills assessed include switching between and controlling multiple robot arms and cutting.
Task 6: Puzzle Piece Dissection	In this task, the trainee must cut and remove a puzzle shape without incising the underlying tissue or cutting outside of the lines. Primary skills assessed include dissection, cutting, atraumatic tissue handling, sharp dissection, and blunt dissection.
Task 7: Vessel Energy Dissection	The trainee must dissect through a fat layer to expose a vessel then coagulate the vessel at two points and finally cut the vessel between the two coagulated points. Primary skills assessed include accurate activation and use of energy sources, dissection of vessels and tissues, cutting and coagulation of vessels, and multiple arm control.

a means of increasing the safety of healthcare. There are methods to accomplish medical team training that do not involve simulation, but high-fidelity patient simulation has proven to be highly effective in increasing health care team competency, and systematic reviews have given evidence based endorsement of this approach.¹³⁸

7► Simulation training for communication and other teamwork-pertinent nontechnical skills requires learners to be embedded in realistic scenarios pertinent to a healthcare team's

Table 53-7

Principles of team-based health care

- **Shared goals:** The team—including the patient and, where appropriate, family members or other support persons—works to establish shared goals that reflect patient and family priorities, and can be clearly articulated, understood, and supported by all team members.
- **Clear roles:** There are clear expectations for each team member's functions, responsibilities, and accountabilities, which optimize the team's efficiency and often make it possible for the team to take advantage of division of labor, thereby accomplishing more than the sum of its parts.
- **Mutual trust:** Team members earn each other's trust, creating strong norms of reciprocity and greater opportunities for shared achievement.
- **Effective communication:** The team prioritizes and continuously refines its communication skills. It has consistent channels for candid and complete communication, which are accessed and used by all team members across all settings.
- **Measurable processes and outcomes:** The team agrees on and implements reliable and timely feedback on successes and failures in both the functioning of the team and achievement of the team's goals. These are used to track and improve performance immediately and over time.

actual clinical responsibilities where activities and interactions prompted by the simulated clinical circumstances can be practiced and observed. The computer-driven high-fidelity manikin simulator serving as the "patient" at the center of these activities can be monitored and controlled to demonstrate realistic physiology consistent with the clinical condition needed for the scenario.¹³⁹ Software-driven, physiologic changes from the baseline state can occur in response to either manual commands or programmed adjustments to accurately depict, for example, new, ongoing and unexpected clinical developments with blood loss, sepsis, or myocardial ischemia. Basic interventions such as airway management, drug administration and wound care for mouldaged body parts can also be performed. Hybrid simulations using both manikin and open abdominal or laparoscopic surgical simulators have also been used to extend scenarios to an operating room setting, with all members of the surgical team engaged in their role-specific tasks.^{136,140,141} These events can be conducted in a dedicated simulation suite or in an actual clinical area where it would be termed *in situ simulation*.

The postsimulation debriefing is an essential component of simulation-based team training. This is where learning points are reinforced and progress towards desired knowledge, attitudes, and behavior can be developed.^{142,143} Participants are prompted to reflect on the events of the simulation and to openly discuss positive and negative aspects of the experience. The debriefing environment and discussion ought to be open, nonjudgmental, and directed at improvement in individual and overall team performance. A facilitator with strong content knowledge should ensure that the discussion includes identification of gaps between the observed and desired performance. An

effective facilitator is cognizant of the need to keep the debriefing learner-centric and to keep discussion focused on opportunities for improvement. Although debriefing is uniformly viewed as essential to health care team simulation effectiveness and structured debriefing models are frequently cited as highly effective, there is no consensus on which specific methods, including video review debriefings, represent best practices.¹⁴⁴ Quality of implementation is consistently cited as the most important contributing factor to effectiveness of debriefing.

The complexity of team-managed clinical events makes measurement of team performance challenging, but several assessment tools have been developed and used successfully in simulation settings. NOTECHS (Non-Technical Skills) and the NOTSS (Non-Technical Skills for Surgeons) instruments have been used to study nontechnical abilities of individuals in surgical teams.^{141,145-147} The principal focus of these rating scales is on the quality and effectiveness of situational awareness and communication. Instruments such as the Mayo High Performance Teamwork scale or the surgery-specific OTAS (Observational Team Assessment Scale) place focus on the team dynamics that extend beyond the single team member.^{148,149} These have been used to detect changes in team performance with training. Rosen suggested a framework for a best practices approach to team performance assessment in simulation that details specific applications of measurement techniques in the simulation training environment.¹⁵⁰

Simulation training directed at nontechnical skills has been shown to improve clinical performance and improve knowledge and attitudes about team functioning as measured in simulated surgical settings such as the trauma bay and the OR for interdisciplinary surgical teams and for surgical trainees.^{136,151-154} Two

systematic reviews of simulation training to increase team skills in the operating room consistently bear out this result, but both also cited the small number of studies where simulation training effects were investigated in the clinical OR setting and lack of evidence of improved clinical outcomes with such training.^{155,156}

ERROR PREVENTION

Error avoidance and prevention are the overarching goals of surgical care and the time-honored focus of surgical training.¹⁵⁷ Faculty who are responsible for training the next generation of highly qualified surgeons must facilitate the delicate balance between resident autonomy and patient safety. From a training perspective, gradual increases in patient responsibility, autonomous decision-making, and operative action provide a critical opportunity for independent hands-on performance, critical thinking, and action-based skill assessment. However, resident autonomy must be balanced with the goal of delivering high-quality, error-free patient care. A key component to achieving residency training goals includes exposure to techniques and strategies for avoiding errors. The relationship between errors and patient safety is well established in the literature and is also the cornerstone of the case review process for surgical morbidity and mortality conferences.¹⁵⁸ Simulation technology allows trainees the opportunity to execute a variety of tasks and procedures while also experiencing the cognitive demands of surgery, including error correction and surgical planning decisions. Fig. 53-8 presents a framework for categorizing surgical errors that may take place on the cognitive-motor continuum.¹⁵⁹

Simulation-based curricular approaches to exposing and training surgical errors include (a) the use of error-enabled

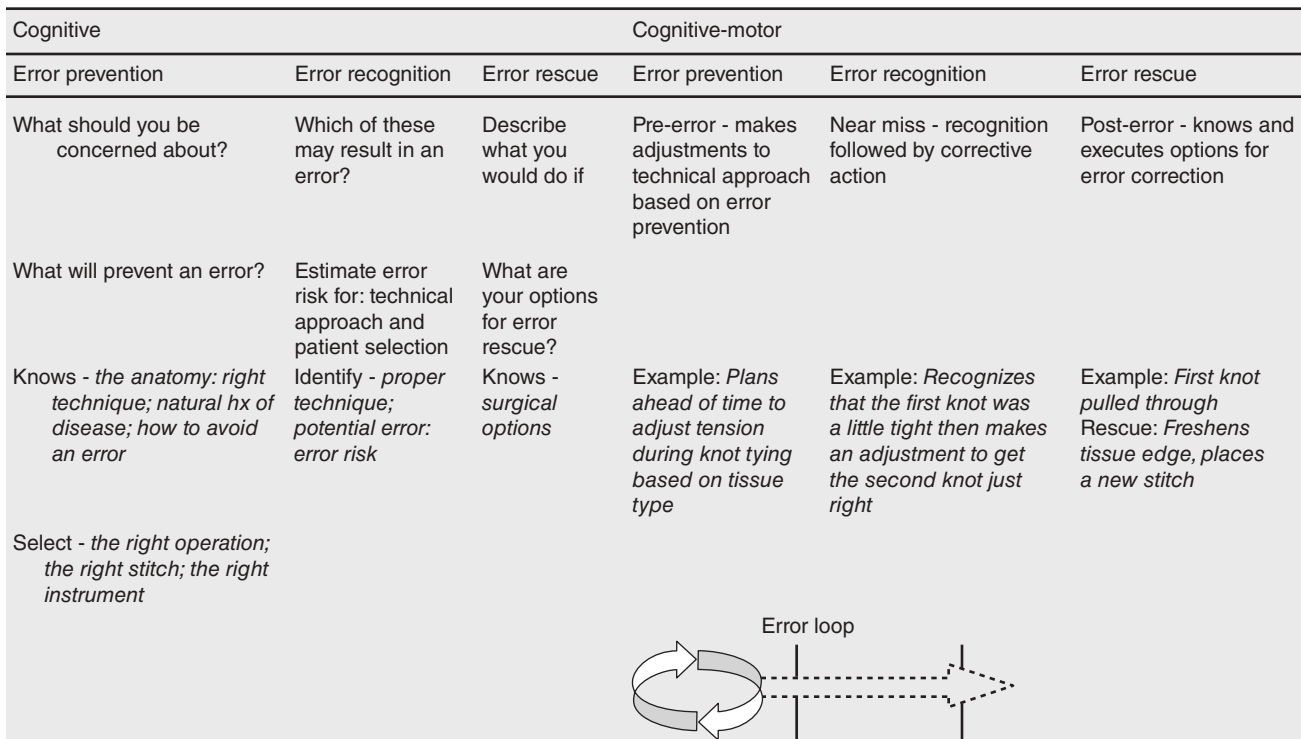

Figure 53-8. A framework for understanding error prevention, error recognition, and error rescue/correction during both the cognitive phase as well as the cognitive-motor phase where there is fluid integration and updating of motor and cognitive decisions. This fluid integration allows for an error loop, as each decision is based on the results of each motor action in a dynamic fashion where an error can take place with each decision or action. (Reproduced with permission from Pugh CM, Santacaterina S, DaRosa DA, et al: Intra-operative decision making: more than meets the eye, J Biomed Inform. 2011 Jun;44(3):486-496.)

simulations, where the learner can make any of a variety of errors during the course of the task; and (b) the use of forced-error simulations, where the learner experiences a specific, usually unexpected error and demonstrates error management as well as options for correction. Error management is a human factors process that includes making, detecting, and correcting errors.^{160,161} Several studies show that there is wide variation in the timing and type of operative decisions that residents make when interacting with an error-enabled simulation.^{112,162-164} Specific error training simulations have been developed using a cognitive task analysis approach to guide the design of error scenarios. Cognitive task analysis involves the use of structured interviews to explore how experts approach the error management process, including intraoperative decision-making and technical approaches.^{165,166} The error-enabled approach allows for a broad assessment of learning needs. The forced-error approach allows instructors to engage in specific error management skills and metrics. Error-enabled and forced-error surgical simulation trainers have been used in a variety of research and training modules to allow observation and assessment of surgical residents as they independently perform operative procedures and practice the error management process.^{112,166,167}

Another approach to error training and assessment is the use of assessments that focus on errors. Current assessment tools for surgical skills include task-specific and global rating scales, final product analysis, and documentation of critical failures.^{160,168} These existing tools for assessing surgical residents largely focus on manual techniques and procedure time and do not capture the cause of resident performance failures.¹⁶⁹ Use of error-related theories in human factors allows for the development of error-centric skills assessments.^{161,170,171} One study used previously developed human error classifications, including omission versus commission and cognitive versus technical as a means of assessing surgical residents.¹⁶² Omission errors were defined as failure to perform a step entirely. Commission errors represented failure to perform a step correctly. For example, failure to measure the hernia defect was categorized as an omission error, whereas measuring the hernia defect with an inaccurate method was categorized as a commission error. Errors in information, diagnosis, and strategy were categorized as cognitive, and errors in action, procedure, or mechanics were classified as technical. Use of assessment surveys with this type of differentiation allows for development of error metrics in surgery and focused error training and feedback.¹⁷²

SIMULATION AND PATIENT OUTCOMES

Surgical simulation training is intended to make patient care safe and free of avoidable errors and to maximize opportunities for good clinical outcomes. The Kirkpatrick four-level scale (Table 53-8) characterizes educational intervention effects, including those that might improve surgeon performance in clinical settings (Kirkpatrick level 3) or those that might actually improve patient outcomes (Kirkpatrick level 4).¹⁷³ Despite the expanding use of simulation in proficiency-based practice models over at least 15 years, there are surprisingly few studies of simulation-based surgical training that can be described as Kirkpatrick level 4. On the other hand, there are numerous studies showing that clinician performance during the course of clinical care is improved after simulation training (Kirkpatrick level 3). As detection of changes in clinical

Table 53-8

Kirkpatrick level scale of educational outcomes

KIRKPATRICK LEVEL	LEVEL DESCRIPTION	DESCRIPTION FOR SIMULATION
Level 1	Reaction	Did the learner perceive value in using a simulator or participating in simulation training?
Level 2	Learning	Did the learner's knowledge, skill, or attitude improve as a result of the simulation training?
Level 3	Behavioral change	Did the knowledge, skills, and attitudes acquired during simulation transfer to the clinical environment?
Level 4	Institutional impact	Did the simulation training program lead to improved patient outcomes?

Data from Cox T, Seymour N, Stefanidis D: Moving the Needle: Simulation's Impact on Patient Outcomes, *Surg Clin North Am*. 2015 Aug;95(4):827-838.

outcomes can be quite challenging, it may be difficult to isolate simulation training effects from numerous other factors that can also affect patient outcomes. When looking specifically at a low-frequency complication event such as bile duct injury with laparoscopic cholecystectomy, the detection of a small, positive training effect is statistically improbable. However, the use of available Kirkpatrick level 3 data to support assumptions about training benefits is fully supportable given the preponderance of literature showing such benefit.

The best current evidence for improved patient outcomes with simulation is that of technical and cognitive training for central venous catheter (CVC) insertion. In 2009, Barsuk et al monitored catheter-related bloodstream infection incidence in an ICU setting over a 32-month period before and after institution of proficiency-based simulation training. After simulation-trained medical residents began performing CVC insertion, an 85% reduction in these infections was observed (3.2 per 1000 catheter-days reduced to 0.50 infections per 1000 catheter-days).¹⁷⁴ Subsequently, the same group reported that the financial savings realized with these improved outcomes amounted to a 7:1 return of the investment for the training.¹⁷⁵ In a similar single unit observational study, Burden et al reported a reduction in catheter-related bloodstream infection incidence from 6.47 per 1000 catheter days to 2.44 per 1000 catheter days after training intervention and comparable financial savings with shorter ICU and hospital stays.¹⁷⁶ Single cohort studies have inherent weaknesses, but a somewhat smaller randomized trial of simulation training versus traditional apprenticeship model-trained controls also showed this reduced infection incidence (1.0 vs. 3.4 infections per 1000 catheter-days, respectively).¹⁷⁷

Riley and colleagues conducted a study in three small community hospitals, administering TeamSTEPPS (Team Strategies and Tools to Enhance Performance and Patient Safety) didactic team training to perinatal care teams at one hospital, TeamSTEPPS with an accompanying program of in situ simulations at a second, and no intervention at the third hospital, which

served as the study control.^{178,179} The simulation interventions were designed to involve triage, labor and delivery, and OR components of care. Perinatal outcomes were assessed using the Weighted Adverse Outcomes Score (WAOS). Simulation training resulted in improved clinical results with a 37.4% decrease in WAOS observed in the simulation intervention group, while similar benefit was not observed in either the didactic-trained or control groups.

TeamSTEPS with supplemental simulation training was also studied by Capella and colleagues for team performance and patient outcomes in trauma care.¹⁸⁰ Trauma resuscitations for successive 2-month periods separated by didactic and scenario-based simulation training to subjectively-defined proficiency levels (33 before training, 40 after training) were assessed in multiple teamwork domains including overall performance using the TPOT (Trauma Team Performance Observation Tool). Significant improvements were observed post training in leadership, situational monitoring, mutual support, communication, and overall scoring. In addition, time to OR was also observed to decrease. Steinemann and colleagues reported on a larger number of trauma resuscitations, 141 before and 103 after in situ trauma bay patient simulation training with accompanying didactic instruction.¹⁸¹ Although significant improvements in patient outcomes were not observed in this study, resuscitation time did decrease following training.

In a comprehensive review of literature examining simulation impact on patient outcomes, Zendejas identified 50 studies purporting to show patient outcomes.¹⁸² For the majority of these, the quality of clinical outcomes evidence was considered low, and appropriate validity data were reported for results in only a small number of published reports. In a subsequent review of 1328 articles resulting from an exhaustive literature search, Cox identified 12 individual articles that reported sufficient patient outcomes data to be considered Kirkpatrick level 4.¹⁸³ Concerns regarding the relatively few studies of this nature are primarily methodological and relate to the preponderance of use of the observational pre- and posttraining study model with its inherent bias risk, rather than randomized controlled trials. These studies have also tended to be quite limited in size. In surgery, the general areas of surgeon performance that have lent themselves to study of educational outcomes in the clinical setting after simulation training include technical abilities and observable behaviors during team-based activities. The use of decreased operative time or technical errors as clinical outcomes after simulation training might suggest, but do not clearly establish, a patient safety or other efficacy benefit. However, these metrics have frequently been used to make the case for the potential for such benefits in skills transfer studies for procedures such as laparoscopic cholecystectomy and laparoscopic hernia repair.^{56,63} There is a clear need to obtain high quality evidence of how proficiency-based simulation training impacts surgical patient outcomes.

In a recent study examining intern response to pediatric codes, simulation training was shown to significantly reduce the time to request help, to initiate bag-mask ventilation, and to initiate chest compressions.¹⁸⁴ Citing the rarity of pediatric codes, investigators measured this effect in in mock code situations using patient simulators. This use of a high-fidelity simulation environment as a surrogate for clinical events, that might otherwise be difficult to observe, may be the only practical model available for the study of provider performance outcomes with educational interventions.

SIMULATION TRAINING FOR THE PRACTICING SURGEON AND MAINTENANCE OF SKILL

Given the current requirement for FLS and FES certification in residency, some authors have posed the important question of whether such certification should be applied more broadly to surgeons in practice.¹⁸⁵ In a 2012 press release, both the ACS and SAGES made the recommendation that all surgeons performing laparoscopy obtain FLS certification. The potential to lower malpractice litigation risk under a self-insurance model was used as justification to certify 37 surgeons in FLS in the Harvard system in 2009.¹⁸⁶ In a recent report, surgical oncologists new to minimally invasive inguinal lymph node dissection (MILND) were FLS tested prior to performance of their first clinical procedures, which were video-assessed using the GOALS scoring method.¹⁸⁷ The FLS score was shown to correlate with both GOALS results and operative time but not lymph node yield. However, evidence that a lab-based technical and cognitive skills test predicts observed operative technical skill in practicing surgeons is promising and warrants investigative follow-up.

At the present time, the American Board of Surgery's requirements for Maintenance of Certification (MOC) do not specifically include any certification of technical skills that might use surgical simulation.¹⁸⁸ Nonetheless, simulation training and testing can be made available to surgeons in practice to provide an avenue for specific training. Although most investigations of VR use for laparoscopy have examined basic skills acquisition in the lab setting far in advance of any measured impact in the clinical OR, a recent innovative study of the use of a VR simulator for "warm-up" practice immediately before a procedure showed that this improved OR performance.¹⁸⁹ As new surgical procedures and technologies are introduced to clinical practice, simulation training solutions could serve just as important a purpose to prepare for these as simulation training methods currently serve for laparoscopic surgery. In a recent publication relating to practicing surgeons, Sullivan et al. provide a framework for development of simulation-based certification models for both trainees and faculty surgeons.¹⁹⁰

FUTURE CONSIDERATIONS

Simulation-based training and assessment is firmly established in surgical education, especially in graduate medical education where learners have been more extensively studied than any other simulation user group. The immediate future of simulation

9► in surgery will likely see expanded use of proficiency-based training given the consistent demonstrations of effectiveness in improving surgeon skills and improved educational outcomes as measured in clinical settings.

The question of what types of simulation-based assessments and training activities might be possible raises questions of where technological advances might open new opportunities.¹⁹¹ The advancement of virtual reality is inevitable, and much richer virtual experiences entering the mainstream in surgical education seems likely in the near future. Three-dimensional printing technology has been growing in its use and applications and has greatly facilitated the development of anatomically accurate bench top simulations for complex surgical procedures. Some of the materials allow for elegant instrument-based dissections, including the use of electrosurgery.¹⁹²⁻¹⁹⁴

10▶ Advances in wearables, motion tracking, and sensor technologies allow for a wide variety of hybrid and augmented experiences in simulation as well as extensive opportunities for the development of new performance metrics. One study using sensor technology for evaluating clinical breast examination skills noted key performance differences in experienced physicians. Both the sensor data and sensor-guided video analysis allowed for skill quantifications that were previously unknown but critical to performance excellence.¹⁹⁵⁻¹⁹⁶

Opportunities for remote collaboration are now greatly improved with higher internet speeds, improvements in augmented reality technology, and ever-increasing camera resolution. VIPAR (Virtual Interactive Presence and Augmented Reality) allows for the visual field of a surgeon to be converted to a simulation and projected in a remote location.¹⁹⁷⁻¹⁹⁸ As such, the system allows for intraoperative collaboration and telementoring.¹⁹⁹

Irrespective of what new simulation and engineering technologies emerge, these technologies are here not just to stay but to grow as assessment and educational tools. This presents abundant opportunities for simulation leaders in surgery to improve the delivery of care by defining best practice in simulation applications and keeping step with current and future changes in surgical practice.

INTRODUCTION

Surgical education has changed significantly over the past two decades. Disruptive forces such as work hour restrictions and the advent of laparoscopy have forced educators to rethink how and where to teach residents. Technologies, including the internet and web-based applications, have further enabled educators to redesign surgical education (Fig. 54-1). The internet has become an integral tool not just in surgical education but also in Americans' lives by changing the way that people communicate with each other, access information, and conduct their daily lives. Today, almost 9 in 10 American adults use the internet.

- 1▶ Furthermore, the internet has revolutionized education by allowing for expanded reach, asynchronous learning whereby students and instructors do not have to be on the same time schedule, and multimedia materials.
- 2▶

Like internet usage, social media has seen a rise in adoption over the past decade. Social media is a term that encompasses multiple computer-mediated platforms that are used for creating and sharing information, ideas, and other content. Social media facilitates communication and interactions across virtual networks. Commonly used platforms include Facebook, Twitter, Snapchat, and Instagram. Social media can be used for multiple purposes including social and professional networking; however, this chapter will focus on its uses in surgical education.

WEB-BASED EDUCATION

Web-based educational resources include lectures and webinars, simulators, assessment tools, and interactive mentoring and coaching. Furthermore, entire web-based curricula have been developed that can link to online resources such as journal articles, interactive anatomy modules, and videos of operations. There are multiple advantages to web-based education. For surgical trainees, web-based educational materials allow access regardless of time of day or night, provide interactive tools for learning (i.e., anatomy), and videos for viewing operations and procedures. Furthermore, for practicing surgeons, web-based educational resources include forums for sharing challenging cases and procuring advice, activities for obtaining continuing

education, and rapid access to information about new technologies and research. However, there may also be disadvantages in terms of costs and technical problems.

Multiple studies have evaluated learning outcomes after implementation of web-based educational interventions. In surgical education, these interventions may be used to teach patient care and decision-making via online case studies, convey knowledge using online didactic materials, or introduce surgical skills. However, studies evaluating these interventions tend to be nonrandomized, small, and single center. A 2008 systematic review and meta-analysis by Cook et al evaluated the effect of internet-based learning across healthcare in general. The review suggested that internet-based learning is better than no intervention but has similar effectiveness as traditional educational methods. A more recent 2015 systematic review by Jayakumar et al focused on web-based education in surgery. They reported a positive effect, but the majority of studies included in the review lacked a control. Based on the current literature, the internet should be considered one tool among many that can facilitate learning. However, further studies are necessary to identify the key elements that improve effectiveness. Web-based educational materials should be developed keeping adult learning theories and principles in mind.

3▶ Web-based surgical curricula have been developed both at an institutional and at a national level. A widely-used curriculum is the Surgical Council on Resident Education (SCORE) curriculum, which is available via an online portal. Developed in 2006, SCORE is based on the six core competencies required of a graduating resident: patient care, medical knowledge, professionalism, communication, practice-based learning, and systems-based practice. SCORE is the result of an ongoing collaborative effort of the American Board of Surgery, American College of Surgeons, American Surgical Association, Association of Program Directors in Surgery, Association for Surgical Education, Residency Review Committee for Surgery of the Accreditation Council of Graduate Medical Education, and Society of American Gastrointestinal and Endoscopic Surgeons. The SCORE curriculum provides content for topics to be covered during a 5-year general surgery residency and is adding fellowship-level content as well. The SCORE Portal modules for each topic include learning objectives, discussion

Key Points

- 1▶ The internet has become an integral tool not just in surgical education but also in Americans' lives by changing the way that people communicate with each other, access information, and conduct their daily lives.
- 2▶ The internet has revolutionized surgical education by allowing for expanded reach— asynchronous learning whereby students and instructors do not have to be on the same time schedule—and multimedia materials such as interactive lessons and videos.
- 3▶ Despite the appeal of web-based education, systematic reviews and meta-analyses have failed to identify high-quality studies demonstrating that it is superior to standard educational methods in improving learning outcomes.
- 4▶ Web-based and virtual reality simulators can be used both to teach technical skills and to assess performance. Virtual reality simulators have been effective in training surgeons on technical skills that translate to operating room performance.
- 5▶ Online and social media–based journal clubs can overcome barriers associated with traditional journal clubs such as lack of a convenient time and no local clinical or methodological experts. However, they may require more time and commitment from the leaders, and they may not be as effective as traditional, in-person, faculty-moderated journal clubs.
- 6▶ Social media rapidly and exponentially increases the spread of information.
- 7▶ Multiple pitfalls exist with regards to web and social media–based education, including but not limited to: (a) need for more widespread adoption and use, (b) lack of accuracy and regulatory oversight over educational content, (c) issues regarding patient confidentiality and privacy, (d) nondisclosure of conflicts of interest, and (e) paucity of evidence for effectiveness of these materials for improving knowledge, attitudes, skills, and outcomes.
- 8▶ Social media has become a necessary component of surgical practice.

questions, text resources and videos, and self-assessment quizzes. Although improvements in quality examination performance among residencies that subscribe to SCORE are promising, no studies have definitely demonstrated that SCORE use improves resident knowledge, skills, or clinical performance.

Web-based education can also be used for assessing and teaching surgical skills. In 2013, Birkmeyer et al performed a study that correlated surgical skills in bariatric surgery, based on blinded reviews of videotaped operations, to clinical outcomes. The ability to discriminate surgeons with good and poor technical skills using video-based assessments has significant implications for training surgeons and for evaluating their performance. With regards to training, multiple web-based and virtual reality simulators have been developed that allow residents to practice tasks and skills repetitively at their own pace and on their own time. These simulators can quantify efficiency of motion and time to complete a task as well as provide

real-time feedback. These metrics have been demonstrated to have construct validity (in that they measure what they are supposed to be measuring) and criterion validity (in that they correlate with operative performance). For example, randomized trials have demonstrated that surgical simulation training correlates with decreased operative time and improves subjectively rated performance on technical skills in the live setting. Web-based assessments have also been used in combination with physical simulators to provide similar metrics.

With regards to surgeons in practice, there has been increased enthusiasm for the use of video-based coaching to complement intraoperative teaching. In particular, postoperative review of videotaped procedures allows surgeons to receive individualized feedback about opportunities for improvement without the time constraints or pressures of the operating room. Randomized trials of surgical coaching in simulated settings suggests benefits over traditional simulator training, and larger trials in a live setting are ongoing. Although most coaching occurs face-to-face, there are opportunities to use web-based coaching. As an example, telementoring has been used to proctor surgeons in the operating room, even across the globe.

Barriers to web-based education include the up-front costs for development and the need for technical expertise. As already noted, web-based education for teaching knowledge may not be more effective than traditional methods. On the other hand, simulation and video-based coaching hold significant promise in improving training in and assessment of surgical skills. However, widespread implementation of video-based coaching will require a culture shift for surgeons to accept assistance and resources such as time, availability of coaches, and finances. Ongoing studies will provide data regarding the effectiveness of these educational strategies.

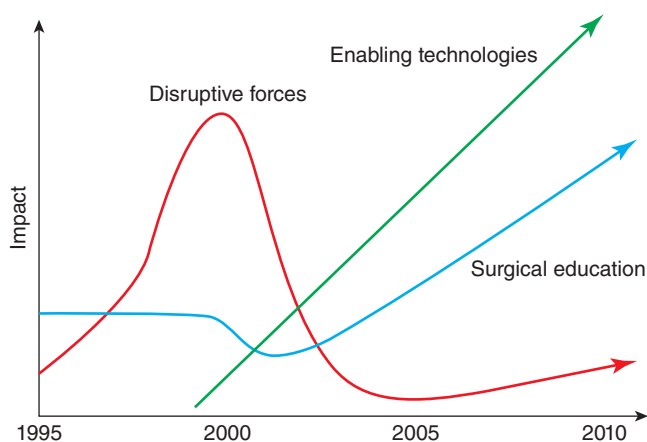

Figure 54-1. The relationship between disruptive forces, enabling technologies, and surgical education. (Reproduced with permission from Pugh CM, Watson A, Bell RH, Jr, et al. *Surgical education in the internet era.* *J Surg Res.* 2009 Oct;156(2):177-182.)

SOCIAL MEDIA–BASED EDUCATION

What is Social Media?

Social media is a term describing websites and web-based applications that enable users to share ideas, information, and

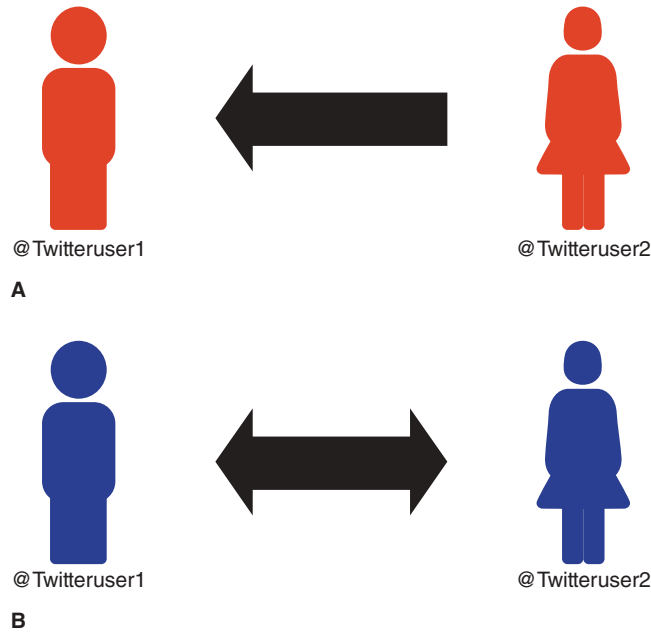

Figure 54-2. Social media usage can be (a) unidirectional or (b) bidirectional. User names on Twitter are denoted by “@”. **A.** @Twitteruser2 is following @Twitteruser1. She is receiving all of his messages in her Twitter feed. However, @Twitteruser1 does not follow her back and therefore does not receive her messages in return. **B.** @Twitteruser1 and @Twitteruser2 follow each other. Therefore, they each receive each other’s messages in their Twitter feeds.

content through virtual networking. Although social media is often used to interact with friends and family, social media can also be used for educational and professional purposes. Examples include Twitter-based journal clubs, Facebook-based discussion forums, and professional networking sites such as LinkedIn or ResearchGate. Social media platforms can serve different purposes including social networking, microblogging, blogging, photo sharing, video sharing, and crowdsourcing.

Commonly used social media platforms in surgery include Facebook, Twitter, and YouTube. Facebook is the most popular social networking site; it can be accessed via desktops, laptops, and mobile phones. It allows users to exchange information, photos, and videos with specified contacts or “friends” with whom there is a two-way relationship. Twitter is another popular social media platform. It is a microblogging site that, like Facebook, allows exchange of messages and photos but limits messages or tweets to 140 characters or less. Twitter users may have one or two-way relationships with other users. Followers of a user receive all of that person’s tweets in their Twitter feed. YouTube is a social media platform that allows users to share videos.

Social media usage in surgery may be unidirectional or bidirectional (Fig. 54-2). For example, journals such as the *New England Journal of Medicine* may have a large number of followers but may be following very few users back. Given that the number of journal articles published daily has risen exponentially, particularly with the advent of open access journals, keeping up with the surgical literature can be overwhelming. Following journals on social media is one strategy for staying updated. Although conventional media outlets such as newspapers and news channels may draw attention to practice-changing studies, social media is another platform by which such information can be promoted and disseminated by journals. Many surgical journals have an online and social media presence, and

many have social media editors who curate the posted materials. Popular social media platforms for journals include Facebook and Twitter. Both platforms allow journals to post text, figures, and links to abstracts or journal articles. Both platforms allow others to share information or comment on articles. However, Twitter restricts text to 140 characters. A recent innovation that may counteract the limited number of allowed characters is the visual abstract, which is a concise pictorial representation of an article’s key points (Fig. 54-3). Recently, a prospective, case-control crossover study was performed whereby tweets about articles from *Annals of Surgery* were either accompanied by a visual abstract or tweeted with text alone. Accompaniment of a tweet with a visual abstract resulted in a threefold increase in article visits. Thus, the majority of journal followers may merely receive the information about new publications (unidirectional flow of information). However, users may also choose to respond to posts with comments (bidirectional flow of information).

Figure 54-3. A visual abstract is a graphical summary of the main results of a journal article.

Journals may promote bidirectional flow of information by hosting social media–based journal clubs. From an educational standpoint, journal clubs have traditionally served not only as an adjunct to lectures but also as a forum to teach about critical appraisal of the literature. Furthermore, when facilitated by faculty with clinical expertise on the subject being discussed, surgical trainees can better evaluate how to incorporate the evidence into practice. However, barriers to traditional journal clubs may include poor participation, lack of a convenient time, or absence of local expertise in either the clinical topic or research methodology. Social media–based journal clubs can help to overcome these barriers by allowing for asynchronous discussion and expert moderators. Online journal clubs can be carried out in real time, but they also

5a ▶ allow respondents to comment hours or even days later to a conversation. Multiple specialties, including surgery, have developed social media–based journal clubs. Tips for successfully launching an online journal club can be garnered from the expanding experience with them (Table 54-1).

Social media–based journal clubs in surgery have been conducted via Facebook, Twitter, or a combination of the two platforms. They have also taken the form of a blog. Although commonly associated with personal journals or diaries, blogs can also be found on professional websites that are updated frequently by a person or group (i.e., by a journal or surgical society). Conversations from journal club discussions can also be compiled and summarized into a transcript either manually or using web-based applications such as Storify. These transcripts can be posted on the journal website or shared. Furthermore,

summaries from either in-person or online journal clubs can be added to the PubMed citation via PubMed Commons.

Preliminary data suggests that online journal clubs increase discussion about articles, views of the abstract, and downloads (Fig. 54-4). For example, the International General Surgery Journal Club held four moderated discussions of journal articles on Twitter between March and June 2014. The reviewed articles covered topics relating to bariatric surgery (March), venous thromboembolism in trauma (April), diverticulitis (May), and contralateral prophylactic mastectomy for breast cancer (June). Although the authors and invited experts only moderated discussions for 3 days, Twitter activity increased in the days preceding and following these discussions. Furthermore, daily views of the article and downloads increased correspondingly. Thus, online journal clubs are a potential strategy for increasing surgeon education about seminal articles.

While social media–based journal clubs hold much appeal, there is a paucity of data regarding their effectiveness in teaching participants about critical appraisal skills. A multicenter

5b ▶ randomized trial compared journal clubs moderated by a faculty member to online discussions. Surgical residents in both arms utilized modules developed by the Evidence Based Reviews in Surgery Steering Committee; these modules include the relevant guide to critical appraisal and a methodological and clinical review. Residents randomized to the moderated group scored higher on a validated test evaluating critical appraisal skills. Further study is required to assess the effectiveness of social media–based journal clubs in disseminating new knowledge as well as in teaching critical appraisal.

Table 54-1**Ten tips for setting up an online journal club**

	TIP
1	Create an online home page that serves as a launching pad for your journal club discussions
2	Develop and register a hashtag on Twitter
3	Incorporate not only Twitter but other collaborative platforms as part of your online journal club
4	Ensure that the time of the journal club is convenient for your target audience
5	Help prepare participants by aggregating other online resources relevant to the article
6	Consider inviting the authors of the featured article or other experts in the field
7	Suggest journal club participants consider using specific Twitter management applications during the Tweet chat
8	Engage the participants to cultivate and incentivize more discussion
9	Connect to the online community by following and engaging with other relevant social media accounts
10	Link back to the original paper by inserting a comment on PubMed Commons

Data from Chan TM, Thoma B, Radecki R, et al. Ten steps for setting up an online journal club, *J Contin Educ Health Prof.* 2015 Spring;35(2):148-154.

Live-Tweeting Conferences

Traditionally, surgeons have attended regional and national conferences to network, learn new information relevant to their practice, and exchange ideas. However, with the advent of social media, surgeons no longer have to physically attend a conference to perform all those activities. Live-tweeting is a term used to describe the posting of comments on Twitter about an event while it is ongoing. Multiple surgical and nonsurgical societies have adopted Twitter to expand the reach of their conferences. By denoting tweets as emanating from a specific conference with a unique hashtag, the reach and number of impressions can actually be measured (Fig. 54-5). The reach refers to the number of unique recipients of messages from a specific group of Twitterers (or people posting on Twitter). Impressions refers to each time a message was delivered to a recipient; a recipient may receive the same message more than once. Neither reach nor impressions measure whether the recipient read the tweet. As an example of how reach and impressions can be used to provide metrics for social media, the Healthcare Hashtag Project allows registered conference hashtags to track the latest tweets, the most prolific Twitterers of conference-related tweets, the most commonly mentioned Twitterers, and the number of impressions (Fig. 54-6) (<https://www.symplur.com/healthcare-hashtags/>). As noted in the figure, social media rapidly and exponentially increases the spread of information. Transcripts of conference-related tweets

6 ▶ can also be assembled to allow a conversation thread to be organized into a cohesive discussion.

Interactive Forums and Communities

Interactive forums and communities are another method by which both the internet and social media can be used for

Figure 54-4. Impact of a social media-based journal club on Twitter activity, hypertext markup language (HTML) views, and portable document format (PDF) downloads. **A.** Activity during a Twitter-based journal club such as the International General Surgery Journal Club (IGSJC) can be tracked by denoting the journal club related tweets with a hashtag (#IGSJC). Twitter activity increased during each of four journal clubs. **B.** Daily HTML views and PDF downloads of featured articles also increased around the time period of the four Twitter journal clubs. (Unpublished data from Sarah Bryczowski and Michael E. Zenilman.)

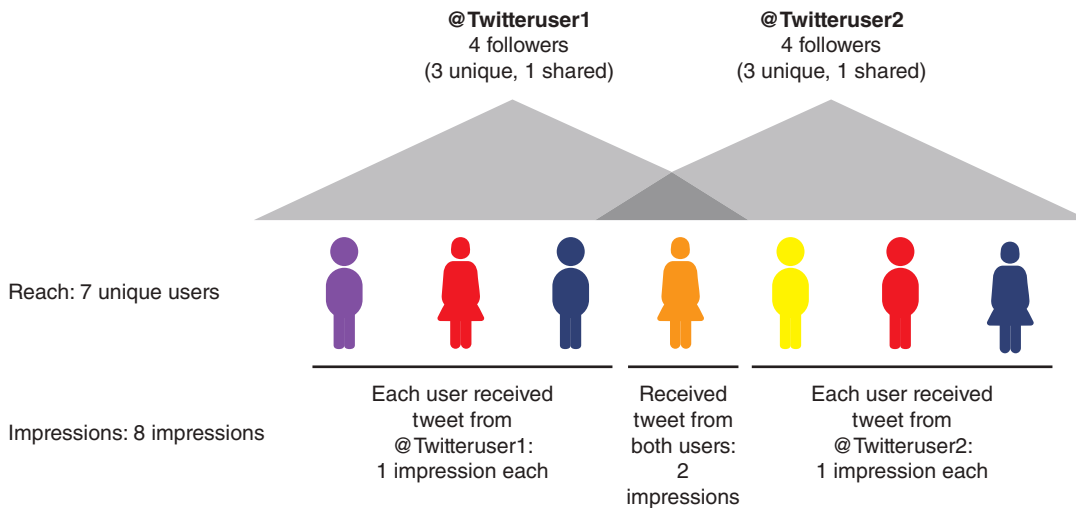

Figure 54-5. Difference between reach and impressions in Twitter. If there are two Twitter users and each has three unique followers and one shared follower, then there are seven unique recipients of their combined tweets. Their total **reach** is seven unique users. If both users tweet the same message, then one user will have received the message twice. However, each time the message was delivered counts as an **impression**; thus, the followers will have a total of eight impressions.

72 Participants

2 Avg Tweets/Hour

4 Avg Tweets/Participant

Figure 54-6. Example of conference analytics from Healthcare Hashtags (<https://www.symplur.com/healthcare-hashtags/>). Surgery conferences can tag tweets by using a prespecified hashtag (i.e., #SurgeryConference) to denote conference-related messages. These can then be tracked. A mention occurs when a user includes another user's name in the tweet. Note in the example that even if there are only a few users tweeting about a conference, the number of impressions can be large if several of those users have a large number of followers. For example, @User13 only tweeted 13 times but had 103,937 impressions.

educational purposes. They are examples of crowdsourcing whereby information is gathered by enlisting the assistance of a large number of participants. Crowdsourcing often involves the general public or a loosely defined group of individuals as opposed to outsourcing, which tasks a project to a specific company or group. For example, Wikipedia is an example of crowdsourcing. In surgery, an example of crowdsourcing are the web-based communities formed by the American College of Surgeons. Members can belong to one or more communities which are based on specialty (i.e., general surgery or endocrine surgery), geography (i.e., Florida Chapter), level of education (i.e., medical students or senior surgeons), special interest (i.e., surgeon writers), or issue (i.e., quality improvement and advocacy). Members can post and respond to discussion threads that cover a wide range of topics including advice for challenging cases, surgical history, and political issues.

An example of a social media-based interactive forum is the International Hernia Collaboration (IHC) which is housed on Facebook. Participants include not only surgeons but also healthcare providers and industry representatives interested in improving outcomes after hernia surgery. Membership in the IHC is limited to those who have been vetted and approved. The forum allows members to ask for advice on difficult cases, debate controversial topics, post step-by-step instructions on procedures or management strategies, and disseminate information rapidly to a wide audience. Collaborative forums such as the IHC allow for real-time, interactive, case-based, continuing education.

Public Education

The educational opportunities provided by the internet and social media are not limited to healthcare providers. The internet and social media are also being increasingly used to educate patients and their families. There are multiple media through which health education is spread, including, but not limited to, online or social media discussion forums run by patients, patient support groups, healthcare providers, or healthcare organizations; blogs or newsrooms; or electronic and mobile health patient portals. Social media allows patients rapid access to information regardless of time or location. However, as noted in the following section, the accuracy of social media-based educational materials cannot be guaranteed, and patients should utilize caution in relying on the information to make important healthcare decisions.

PITFALLS IN WEB AND SOCIAL MEDIA-BASED EDUCATION

Despite the many advantages of web and social media-based education, significant potential pitfalls still remain. First, widespread adoption and utilization is a challenge. Although internet and mobile phone usage is prevalent, effectiveness of web-based educational materials is dependent upon trainees' and surgeons' uptake of the technology and available resources. Despite increasing availability of the internet and mobile technology, not all surgeons use it for educational purposes. For example, a systematic review and meta-analysis by Guraya et al found that three out of four medical students use social networking sites, but only one out of five uses them for educational purposes. Furthermore, lack of utilization can impact educational effectiveness. In the previously mentioned multicenter trial comparing a moderated journal club to an online version, low participation in the Internet journal club was postulated to be a significant factor in the poorer performance on a critical appraisal test. More attention to instructional design may improve uptake and effectiveness. A systematic review and meta-analysis by Cook et al determined that features such as interactivity, practice exercises, repetition, and feedback are associated with improved learning outcomes. The authors also noted that the evidence base upon which to design internet-based learning programs is limited by poor study methodology, failure to use conceptual frameworks, and lack of adherence to reporting standards. Thus, while the aforementioned features should be considered in designing future web and social media-based educational programs, further evidence-based guidance is needed.

Second, the quality of information available online and via social media may not be accurate or reliable. Multiple reports have been published regarding the inaccuracies of web-based educational materials. Surgeons and surgical trainees should carefully evaluate the source of educational material, search for conflicts of interest that may result in biased information, assess how recently the information was updated, and cross-check references. The lay public may have more difficulty in identifying trustworthy surgical educational materials on the internet. Healthcare providers should guide patients to reputable websites and to encourage discussion regarding the accuracy of the content.

Third, useful dialog and advice about difficult cases must be balanced with ethical considerations surrounding patient confidentiality and privacy. Appropriate safeguards must be taken

to ensure that patients cannot be identified based on provided information, that patients have consented to have their information posted anonymously, and that all case-related comments are appropriate and professional. While common sense should be utilized in posting about patient cases, only a few organizations have published guidelines for how to safeguard against potential pitfalls. In 2013, the American College of Physicians Ethics, Professionalism, and Human Rights Committee; the American College of Physicians Council of Associates; and the Federation of State Medical Boards Special Committee on Ethics and Professionalism published a position statement about online medical education (Table 54-2). The paper stated that “Maintaining trust in the profession and in patient–physician relationships requires that physicians consistently apply ethical principles for preserving the relationship, confidentiality, privacy, and respect for persons to online settings and communications.”

Fourth, conflicts of interest must be clearly stated. Journals require authors to declare relevant conflicts of interest, but

Table 54-2

The American College of Physicians Ethics, Professionalism and Human Rights Committee; the American College of Physicians Council of Associates; and the Federation of State Medical Boards Special Committee on Ethics and Professionalism published a position paper on online medical professionalism

Position 1	Use of online media can bring significant educational benefits to patients and physicians, but it may also pose ethical challenges. Maintaining trust in the profession and in patient–physician relationships requires that physicians consistently apply ethical principles for preserving the relationship, confidentiality, privacy, and respect for persons to online settings and communications.
Position 2	The boundaries between professional and social spheres can blur online. Physicians should keep the two spheres separate and comport themselves professionally in both.
Position 3	Email or other electronic communications should only be used by physicians in an established patient–physician relationship and with patient consent. Documentation about patient care communications should be included in the patient’s medical record.
Position 4	Physicians should consider periodically “self-auditing” to assess the accuracy of information available about them on physician-ranking websites and other sources online.
Position 5	The reach of the internet and online communications is far and often permanent. Physicians, trainees, and medical students should be aware that online postings may have future implications for their professional lives.

Data from Farnan JM1, Snyder Sulmasy L, Worster BK, et al: Online medical professionalism: patient and public relationships: policy statement from the American College of Physicians and the Federation of State Medical Boards, *Ann Intern Med.* 2013 Apr 16;158(8):620-627.

multiple studies suggest that these often go unreported. Similarly, conflicts of interest should be disclosed on social media. However, such disclosures may be more difficult on social media due to the limited number of allowable characters (i.e., 140 characters for Twitter) or to the way information is propagated. For example, a surgeon may disclose an industry relationship on an original tweet, but the disclosure may not appear in subsequent comments of a discussion thread. Surgeons posting on social media must make it their ethical and professional obligation to disclose their conflicts of interest. Furthermore, users of social media content must be aware of the potential for bias introduced by undisclosed conflicts of interest and perform due diligence in assessing the reliability of the source. Lastly, regulatory bodies and professional organizations should publish standardized guidelines for disclosing on social media or develop mechanisms by which disclosure can be publicly accessed (such as the Open Payments database).

Fifth, professionalism must always be maintained. Surgeons posting content on the web or on social media must be aware that information will be widely disseminated and available for posterity; messages posted on social media cannot be fully retracted. As already mentioned, surgeons must strive to maintain patient privacy, ensure accuracy of information, and disclose conflicts of interest. Furthermore, surgeons must be aware of unintentional interpretations of messages (i.e., as discriminatory or unprofessional). Multiple studies of health-care providers’ social media sites have identified potentially and clearly unprofessional content; these studies have included medical students, residents, and practicing surgeons. Despite the prevalence of unprofessional content, few surgical residency programs have formal institutional social media policies. Furthermore, the American College of Physicians and Federation of State Medical Boards position statement only addresses a few of the issues surrounding web-based activities including for patient and physician education (Table 54-3).

Table 54-3

Online medical professionalism and education

POSITIONS ON PROFESSIONALISM IN ONLINE PATIENT AND PHYSICIAN EDUCATION

- The Internet can be a powerful tool for education.
- Physicians should guide patients to high quality online resources that are accurate and objective. These sites should have peer-reviewed content or have verifiable mechanisms for quality control of information.
- Online resources for learning can be used by patients and physicians.
- The internet and social networking can be used to improve public health. Physicians engaged in online communities should ensure the security of the networks and restriction of participation to verified users. Clinical scenarios should not contain any personal identifying information, and patient consent should be obtained before sharing the vignette.
- Discussion of frustrations online undermines trust and professionalism and should be avoided.

Data from Farnan JM1, Snyder Sulmasy L, Worster BK, et al: Online medical professionalism: patient and public relationships: policy statement from the American College of Physicians and the Federation of State Medical Boards, *Ann Intern Med.* 2013 Apr 16;158(8):620-627.

Lastly, studies evaluating the effectiveness of web-based education have had varied results. A recent systematic review by Taveira-Gomes et al assessed 251 articles using computer-based learning methodologies in medical education; the number of articles on this topic has increased over time. The most commonly used metrics for evaluating the effectiveness of these methodologies were assessments of knowledge, attitudes, and skills. The majority of studies reported positive effects on these outcomes, although the more rigorous studies (i.e., randomized trials) were less likely to find a positive effect. Online activity (i.e., number of posts or views) was tracked in a few studies, but results were conflicting regarding whether increased engagement correlated with improved performance. This review suggests that high-quality studies are needed of web-based educational interventions and that these studies need to include measures of clinical performance and outcomes.

IMPLICATIONS AND FUTURE DIRECTIONS

The Society of University Surgeons' Social and Legislative Committee issued a position statement entitled: "Social media is a necessary component of surgery practice." Given the rapid **8▶** pace with which technology is advancing and the familiarity of the current generation (Generation Z) with the internet, surgeons have no choice but to harness the power of the internet and social media or risk being left behind. Many journals are phasing out print versions, and several journals are already online only. Furthermore, textbooks may also become a relic from the past as publishers move towards developing digital versions that include interactive graphics, audio, and video.

As surgical education continues to evolve, future directions may include broader indications for utilization of web- and social media-based resources. For example, video-based coaching with face-to-face discussions have been used postoperatively to supplement intraoperative teaching. However, preoperative crowd-sourcing in planning a challenging case or intraoperative video telementoring are other applications of video-based coaching.

Future research efforts should focus on identifying the most effective formats and components of web and social media-based educational interventions, using rigorous methods to compare educational methods, and measuring clinical outcomes. Moreover, standardized guidelines should be instituted in order to safeguard against ethical and professional misconduct.

Furthermore, none of these studies evaluated whether use of social media improved academic performance.*
- Ibrahim AM, Lillemoe KD, Klingensmith ME, Dimick JE. Visual abstracts to disseminate research on social media: a prospective, case-control crossover study. *Ann Surg.* 2017;266(6):e46-e48. *This prospective, case-control crossover study compared the impact of tweets alone versus tweets accompanied by a visual abstract on article visits; there was a threefold increase when visual abstracts accompanied the tweets.*
- Jayakumar N, Brunckhorts O, Dasgupta P, Khan MS, Ahmed K. e-Learning in surgical education: a systematic review. *J Surg Educ.* 2015;72(6):1145-1157. *This systematic review of 38 studies suggested that while the majority of studies evaluating electronic learning in surgical education demonstrate a positive effect, most lack a proper control.*
- McLeod RS, MacRae HM, McKenzie ME, Victor JC, Brasel KJ; Evidence Based Reviews in Surgery Steering Committee. A moderated journal club is more effective than an Internet journal club in teaching critical appraisal skills: results of a multicenter randomized controlled trial. *J Am Coll Surg.*

2010;211(6):769-776. *This multicenter randomized trial reported that surgical residents who participated in a journal club moderated by a faculty member scored higher on a validated test of critical appraisal than those who participated in an online journal club.*

Pugh CM, Watson A, Bell RH Jr, et al. Surgical education in the internet era. *J Surg Res.* 2009;156(2):177-182. *This article describes the factors that led to a change in surgical education over the last two decades.*

Taveira-Gomes T, Ferreira P, Taveira-Gomes I, Severo M, Ferreira MA. What are we looking for in computer-based learning interventions in medical education? A systematic review. *J Med Internet Res.* 2016;18(8):e204. *This systematic review assessed recent studies on computer-based learning (CBL) for types of software platforms and interventions and adherence to current recommendations for CBL research.*

 violence and injury prevention program, 2089–2091
 World Health Organization and, 2088–2089, 2091
 worldwide distribution of, 2078*f*
 Glomerular filtration rate
 age-related changes in, 2052
 in children, 1707
 Glossectomy, 636, 639–640
 Glossoptosis, 1993
 Glottis
 anatomy of, 631, 640
 tumors of, 641–642
 laryngeal preservation techniques in
 treatment of, 642
 laryngectomy in, 641*f*
 Glucagon, 1436–1437
 deficiency in chronic pancreatitis, 1462
 functions of, 1437*t*
 secretion of, 1438–1439
 serum levels of, in glucagonoma, 1483
 Glucagon-like peptide 2 (GLP-2), 1128, 1227*t*
 Glucagonoma, 1482–1483
 Glucocorticoid receptor, 36–37
 Glucocorticoid response elements, 36
 Glucocorticoids, 1683–1684, 1685*t*
 functions of, 1684, 1685*t*
 synthesis of, 36*f*
 Gluconeogenesis
 in injury, 62*f*
 in starvation, 61*f*, 61–62
 Glucose, 1223, 1224*f*
 administration of
 excessive, 65
 in hyperkalemia, 95, 95*t*
 in parenteral nutrition, 74
 blood levels of
 in hyperglycemia. *See* Hyperglycemia
 in hyponatremia, 86
 in injury, 65
 liver functions affecting, 1351
 in pancreas transplantation, 374
 in parenteral nutrition, 73
 postoperative, 427
 in septic shock, 147
 intolerance to, in parenteral nutrition, 74
 metabolism of
 in fasting, 60
 in injury, 65–66, 66*f*
 osmolality of body fluids and, 84
 tolerance tests, 1438
 transport and signaling of, 66, 1223, 1224*f*
 urine levels of, in parenteral nutrition, 73
 Glucose transporters (GLUTs), 1223, 1224*f*
 Glucose-dependent insulinotropic polypeptide, 1438

- Glucose-6-phosphate, 65, 66f
 Glucose-6-phosphate dehydrogenase deficiency, splenectomy in, 1522t, 1524
 Glucuronyl transferase, 1737
 Glutamic-oxaloacetic transaminase, 1353
 Glutamic-pyruvic transaminase, 1353
 Glutamine, 69–70, 1224
 Glycerol as fuel, 64
 Glycogen
 in liver, 60, 61f, 61t
 in muscle, 60, 66
 Glycogenolysis, 61
 Glycopeptides, 166t
 Glycosaminoglycans, 274–275
 Goal directed therapy, 2118
 Goblet cell(s)
 in small intestine, 1220–1221
 in tracheobronchial tree, 669
 Goblet cell carcinomas, 1339
 Goiter
 historical aspects of, 1625
 intrathoracic, sternotomy in, 1661, 1661f
 mediastinal, 1661
 nontoxic, 1641, 1641t, 1642f
 toxic
 diffuse, 1634–1637
 multinodular, 1637–1638
 Goldenhar's complex, 1711
 Goleman, Daniel, 12
 Gonadal dysgenesis, mixed, 1746–1747

postoperative disorders of, 422
pseudocysts of
 in chronic pancreatitis, 1465–1467
 description of, 230, 1432, 1500
pseudopapillary tumor of, 1504
regions of, 1429–1432
secretions of
 composition of, 87*t*, 1437*f*
 description of, 1435–1437, 1437*t*
somatostatinoma of, 1483
transplantation of, 374–378
 back table preparation, 375
 complications in, 363–364, 377
 contraindications to, 374–375
 donor in, 374–375
 historical aspects of, 357, 374
 immunosuppression in, 374, 379
 indications for, 374–375
 islet cell, 378–379
 in chronic pancreatitis, 1480–1481
 immunosuppression for, 379
 after kidney transplantation, 374, 378
 living donor in, 366, 377–378
 operative techniques in, 375*f*–378*f*, 375–376
 bladder drainage procedure, 375–376, 376*f*–377*f*, 378
 enteric drainage procedure, 375–376, 376*f*–377*f*, 378
 organ preservation methods and time in, 365
 procurement and preservation, 374–375

- rejection in, 377
- results of, 378
- simultaneous with kidney transplantation, 374, 378
- survival rates in, 378
- Y-graft reconstruction with, 375, 376*f*
- trauma of, 1429
 - complications in, 230
 - with duodenal injuries, pyloric exclusion procedure in, 230, 231*f*
 - emergent abdominal exploration in, 212
 - identification of, 229
 - Roux-en-Y pancreaticojejunostomy in, 229–230, 230*f*
 - vasoactive intestinal peptide-secreting tumors of, 1482
- Pancreas surgery, traditional Chinese medicine in, 2128
- Pancreastatin, 1437*t*, 1438
- Pancreatectomy
 - in chronic pancreatitis, 1472, 1474–1481
 - in pancreatic cancer, 1493
 - for pancreatic trauma, 229–230
 - in pseudocyst of pancreas, 1467
 - total, with islet cell auto-transplantation, 1480*f*, 1480–1481
- Pancreatic arteries, 1433, 1435
- Pancreatic duct
 - anatomy of, 1432
 - calculi in, extracorporeal shock wave lithotripsy for, 1471, 1471*f*
 - distortion, 1457
 - obstruction of, 1457
 - sphincteroplasty of, 1472–1473, 1473*f*
 - stent placement in, 1471
- Pancreatic intraepithelial neoplasia (PanIN), 1485, 1486*f*
- Pancreatic polypeptide
 - in chronic pancreatitis, 1462, 1463*f*
 - description of, 1436, 1439
 - functions of, 1437*t*, 1439
- Pancreatic secretory trypsin inhibitor (PTSI), 1436
- Pancreatic stone protein (PSP), 1457
- Pancreatic thread protein, 1457
- Pancreaticoduodenal artery, 1433
- Pancreaticoduodenal vein, 1433
- Pancreaticoduodenectomy
 - in duodenal neoplasms, 1244
 - in pancreatic cancer, 1491–1493, 1492*f*–1493*f*
 - anastomosis techniques in, 1493, 1495–1497
 - complications of, 1497–1498
 - outcome and value of, 1498
 - recurrence, 1499
 - in pancreatic injuries, 229
 - traditional Chinese medicine after, 2128
- Pancreaticojejunostomy
 - in chronic pancreatitis, 1473, 1473*f*
 - in pancreatic ascites, 1468, 1468*f*
 - in pancreatic cancer, 1494*f*–1496*f*
 - in pancreatic trauma, 229–230, 230*f*
- Pancreatitis, 172–173, 1439–1481
 - acute, 1439–1449
 - in alcohol use and alcoholism, 1440
 - algorithm for, 1449*t*
 - APACHE-II score in, 1445
 - assessment of severity, 1444–1445
 - cholecystectomy for, 1449
 - colocalization theory of, 1442*f*
 - complications of, 1445*t*, 1447–1448, 1450*t*
 - computed tomography in, 1443*f*, 1443–1444, 1446, 1447*f*
 - definition of, 1439
 - diabetes mellitus after, 1449
 - diagnosis of, 1444
 - drug-induced, 1441
 - etiologies of, 1440, 1440*t*
 - factors affecting severity of, 1444–1446
 - fluid therapy in, 1446
