Three-fourths of the patients who come to the hospital with bleeding peptic ulcer will stop bleeding if given acid suppression and nothing by mouth. However, one fourth will continue to bleed or will rebleed after an initial quiescent period, and virtually all the mortalities (and all the operations for bleeding) occur in this group. This group can be fairly well delineated based on clinical factors related to the magnitude of the hemorrhage, comorbidities, age, and endoscopic findings. Shock, hematemesis, transfusion requirement exceeding four units in 24 hours, and certain endoscopic stigmata (active bleeding or visible vessel) define this high-risk group. Risk stratification tools have proven useful in predicting rebleeding and death, and in identifying a low risk cohort. As can be seen in Table 26-9, the maximal Blatchford score is 23, and the maximal Rockall score is 11. The former does not use endoscopic criteria and may be better in identifying the low-risk cohort. Studies have shown that a Blatchford score of 1 or less, or a Rockall score of 2 or less, identifies patients who are very unlikely to be suffering from life-threatening upper GI bleeding. The shorter modified Blatchford score may be just as useful (BUN, Hgb, pulse, BP; maximal score 16).¹¹¹ High-risk patients benefit from endoscopic therapy to stop the bleeding, while low-risk patients with low-risk lesions can be promptly discharged and treated as outpatients. The most common endoscopic hemostatic modalities used are injection with epinephrine and electrocautery. In a case with exposed vessel, mechanical hemostasis using clips is useful to control the bleeding.¹¹² Biopsy should be performed to evaluate for *H pylori* infection. Persistent bleeding or rebleeding after endoscopic therapy is an indication for repeat endoscopic treatment. Surgery should be considered after two endoscopic failures. Elderly patients and patients with multiple comorbidities do not tolerate repeated episodes of hemodynamically significant hemorrhage, and they may benefit from early elective operation after initially successful endoscopic treatment, especially if they have a high-risk ulcer.

Planned surgery under controlled circumstances often yields better outcomes than emergent surgery. Deep bleeding ulcers on the posterior duodenal bulb or lesser gastric curvature are high-risk lesions because they often erode large arteries less amenable to nonoperative treatment, and early operation should be considered.

Perforated peptic ulcer usually presents as an acute abdomen. The patient can often give the exact time of onset of the excruciating abdominal pain. Initially, a chemical peritonitis

develops from the gastric and/or duodenal secretions, but within hours a bacterial peritonitis supervenes. The patient is in obvious distress, and the abdominal examination shows peritoneal signs. Usually, marked involuntary guarding and rebound tenderness is evoked by a gentle examination. Upright chest X-ray shows free air in about 80% of patients (Fig. 26-32). Once the diagnosis has been made, the patient is given analgesia and antibiotics, resuscitated with isotonic fluid, and taken to the operating room. Fluid sequestration into the third space of the inflamed peritoneum can be impressive, so preoperative fluid resuscitation is mandatory. Sometimes, the perforation has sealed spontaneously by the time of presentation, and surgery can be avoided if the patient is doing well. Nonoperative management is appropriate only if there is objective evidence that the leak has sealed (i.e., radiologic contrast study), and in the absence of clinical peritonitis.

Gastric outlet obstruction occurs in no more than 5% of patients with PUD. It is usually due to duodenal or prepyloric ulcer disease, and it may be acute (from inflammatory swelling and peristaltic dysfunction) or chronic (from cicatrix). Patients typically present with nonbilious vomiting and may have profound hypokalemic hypochloremic metabolic alkalosis and dehydration. Pain or discomfort is common. Weight loss may be prominent, depending on the duration of symptoms. A succussion splash may be audible with stethoscope placed in the epigastrium. Initial treatment is nasogastric suction, IV hydration and electrolyte repletion, and acid suppression. The diagnosis is confirmed by endoscopy. Most patients admitted to the hospital nowadays with obstructing ulcer disease require intervention, either balloon dilation or operation. Cancer must be ruled out because most patients who present with the symptoms of gastric outlet obstruction will have a pancreatic, gastric, or duodenal malignancy.

Medical Treatment of Peptic Ulcer Disease

PPIs are the mainstay of medical therapy for PUD, but high-dose H_2 RAs and sucralfate are also quite effective. Patients hospitalized for ulcer complications should receive high-dose intravenous PPI and, when discharged, should be considered for lifelong PPIs unless the definitive cause is eliminated or a definitive operation performed. Peptic ulcer patients should stop smoking and avoid alcohol and NSAIDs (including aspirin). Patients who require NSAIDs or aspirin to treat other medical conditions should always take concomitant PPIs or high dose H_2 receptor blockers. Testing for *H pylori* infection is performed, and if it is found, it should be treated with one of several acceptable regimens (Table 26-10).¹¹³ If initial *H pylori* testing is negative and ulcer symptoms persist, an empirical trial of anti-*H pylori* therapy is reasonable since false-negative *H pylori* tests are not uncommon. Generally, acid suppression can be stopped after 3 months if the ulcerogenic stimulus (e.g., *H pylori*, NSAIDs, or aspirin) has been removed. However, long-term maintenance PPI therapy should be considered in all patients admitted to hospital with ulcer complications, all high-risk patients on NSAIDs or aspirin (the elderly or debilitated), and all patients requiring anticoagulation or antiplatelet agents or those with a history of recurrent ulcer or bleeding. Consideration should also be given to maintenance PPI therapy in refractory smokers with a history of peptic ulcer. Sucralfate acts locally on mucosal defects and is well tolerated, and occasionally it is useful as a supplement to acid suppression.

Table 26-9

Risk-stratification tools for upper gastrointestinal hemorrhage^a

A. BLATCHFORD SCORE	
AT PRESENTATION	POINTS
Systolic blood pressure	
100–109 mmHg	1
90–99 mmHg	2
<90 mmHg	3
Blood urea nitrogen	
6.5–7.9 mmol/L	2
8.0–9.9 mmol/L	3
10.0–24.9 mmol/L	4
≥25 mmol/L	6
Hemoglobin for men	
12.0–12.9 g/dL	1
10.0–11.9 g/dL	3
<10.0 g/dL	6
Hemoglobin for women	
10.0–11.9 g/dL	1
<10.0 g/dL	6
Other variables at presentation	
Pulse ≥100 beats/min	1
Melena	1
Syncope	2
Hepatic disease	2
Cardiac failure	2

B. ROCKALL SCORE	
VARIABLE	POINTS
Age	
<60 y	0
60–79 y	1
≥80 y	2
Shock	
Heart rate >100 beats/min	1
Systolic blood pressure <100 mmHg	2
Coexisting illness	
Ischemic heart disease, congestive heart failure, other major illness	2
Renal failure, hepatic failure, metastatic cancer	3
Endoscopic diagnosis	
No lesions observed, Mallory-Weiss syndrome	0
Peptic ulcer, erosive disease, esophagitis	1
Cancer of the upper GI tract	2
Endoscopic stigmata of recent hemorrhage	
Clean base ulcer, flat pigmented spot	0
Blood in upper GI tract, active bleeding, visible vessel, clot	2

^aPanel A shows the values used in the Blatchford risk-stratification score, which ranges from 0 to 23, with higher scores indicating higher risk. Panel B shows the Rockall score, with point values assigned for each of three clinical variables (age and the presence of shock and coexisting illnesses) and two endoscopic variables (diagnosis and stigmata of recent hemorrhage). The complete Rockall score ranges from 0 to 11, with higher scores indicating higher risk. Patients with a clinical Rockall score (Age + Shock + Coexisting illness) of 0 or a complete Rockall score of 2 or less are considered to be at low risk for rebleeding or death.

Figure 26-32. Pneumoperitoneum on upright chest X-ray in patient with perforated ulcer.

Surgical Treatment of Peptic Ulcer Disease

The indications for surgery in PUD are (in order of decreasing frequency) perforation, obstruction, bleeding, and intractability or nonhealing.^{114,115} Gastric cancer must always be considered in patients with gastric ulcer or gastric outlet obstruction. Today, most patients undergoing emergent operation have simple patch of a perforated ulcer or oversewing of a bleeding ulcer.^[92] Simultaneous performance of vagotomy either truncal or highly selective is increasingly uncommon, probably due to surgeon unfamiliarity with the procedure and reliance on postoperative PPIs to decrease acid secretion. But even in the current era, vagotomy may improve outcomes in emergency

ulcer surgery.¹¹⁶⁻¹¹⁸ Before denying the stable low-risk patient a highly selective vagotomy or truncal vagotomy and drainage as an adjunct to simple patch or oversew, the surgeon should consider that many patients having emergency operation for peptic ulcer will not take long-term PPI, do not have *Helicobacter*, or will continue to smoke or take NSAIDs.

Unfortunately, the data from many excellent randomized clinical trials evaluating elective operation for peptic ulcer over the last several decades may be irrelevant to most patients presenting for ulcer surgery today.¹¹⁴ The large majority of these excellent studies were done in the pre-PPI, pre-*Helicobacter*, pre-NSAID era, and focused on elective operation for intractable disease, an unusual indication for operation nowadays. Thus, today's surgeon should take great care in applying this literature to inform surgical decision making.

Traditionally, the vast majority of peptic ulcers were treated by a variant of one of the three basic operations: parietal cell vagotomy, also called highly selective vagotomy (HSV) or proximal gastric vagotomy, vagotomy and drainage (V+D), and vagotomy and distal gastrectomy. Recurrence rates are lowest but morbidity highest with the latter procedure, while the opposite is true for HSV (Table 26-11).^{114,115}

HSV severs the vagal nerve supply to the proximal two-thirds of the stomach, where essentially all the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus and the remaining abdominal viscera (Fig. 26-33). Thus, the operation decreases total gastric acid secretion by about 75%, and GI side effects are rare. Elective HSV has largely been supplanted by long-term PPI treatment, but the operation, which has a learning curve, may still be useful in the patient (elective or emergent) who is noncompliant with, intolerant of, or cannot afford medical treatment. Historically, HSV has not performed particularly well for type II (gastric and duodenal) and type III (prepyloric) gastric ulcer, perhaps because of hypergastrinemia caused by gastric outlet obstruction and persistent antral stasis.

Table 26-10

Helicobacter pylori therapies (10–14 days)

Clarithromycin triple therapy
standard or double dose PPI twice a day
clarithromycin 500 mg twice a day
amoxicillin 1 g twice a day; or metronidazole 500 mg three times a day
Metronidazole triple therapy
standard or double dose PPI twice a day
metronidazole 500 mg twice a day
amoxicillin 1 g twice a day
Levofloxacin triple therapy
standard dose PPI twice a day
amoxicillin 1 g twice a day
levofloxacin 500 mg daily
Sequential therapy
standard or double dose PPI (10–14 days)
amoxicillin 1 g twice a day (5–7 days); then
clarithromycin 500 mg twice a day and metronidazole 500 mg twice a day (5–7 days)
Bismuth quadruple therapy (commonly used when above regimens fail to eradicate <i>H pylori</i>)
standard dose PPI twice a day
bismuth subsalicylate 300 mg four times a day
tetracycline 500 mg four times a day
metronidazole 250 mg four times a day

PPI = proton pump inhibitor.

Table 26-11

Clinical results of surgery for duodenal ulcer

	PARIETAL CELL VAGOTOMY	TRUNCAL VAGOTOMY AND PYLOROPLASTY	TRUNCAL VAGOTOMY AND ANTRECTOMY
Operative mortality rate (%)	0	<1	1
Ulcer recurrence rate (%)	5–15	5–15	<2
Dumping (%)			
Mild	<5	10	10–15
Severe	0	1	1–2
Diarrhea (%)			
Mild	<5	25	20
Severe	0	2	1–2

The Taylor procedure, a straightforward laparoscopic operation, consists of a posterior truncal vagotomy and anterior seromyotomy (but anterior HSV is probably equivalent), and it is an attractive and simple alternative to HSV with similar results.

Truncal vagotomy and pyloroplasty, and truncal vagotomy and gastrojejunostomy are the paradigmatic *vagotomy and drainage procedures*. HSV may be substituted for truncal vagotomy. The advantage of V + D is that it can be performed safely and quickly by the experienced surgeon. The main disadvantages are the side effect profile (10% of patients have significant dumping and/or diarrhea). During truncal vagotomy

Figure 26-34. Truncal vagotomy. (Reproduced with permission from Zollinger RM Jr, Zollinger RM Sr: *Zollinger's Atlas of Surgical Operations, 8th ed.* New York, NY: McGraw-Hill Education; 2003.)

(Fig. 26-34), care must be taken not to perforate the esophagus, a potentially lethal complication. Intraoperative frozen section confirmation of at least two vagal trunks is prudent; additional vagal trunks are common. Unlike HSV, V + D is widely accepted as a successful definitive operation for complicated PUD. It has been described as a useful part of the operative treatment for bleeding duodenal and gastric ulcer, perforated duodenal and gastric ulcer, and obstructing duodenal and gastric (types II and III) ulcer. When applied to gastric ulcer, the ulcer should be excised or biopsied.

Truncal vagotomy denervates the antropyloric mechanism, and therefore, some sort of procedure is necessary to ablate or bypass the pylorus. Gastrojejunostomy is a good choice in patients with gastric outlet obstruction or a severely diseased proximal duodenum. The anastomosis is done between the proximal jejunum and the most dependent portion of the greater gastric curvature, in either an antecolic or retrocolic fashion (Fig. 26-35). Marginal ulceration is a potential complication.

Figure 26-35. Retrocolic gastrojejunostomy. Note mesocolon sutured to stomach (b, c, d). (Reproduced with permission from Zuidema GD, Yeo CJ: *Shackelford's Surgery of the Alimentary Tract, 5th ed. Vol. II.* Philadelphia, PA: Elsevier/Saunders; 2002.)

Figure 26-36. A through D. Heineke-Mikulicz pyloroplasty. (Reproduced with permission from Zinner MJ: Atlas of Gastric Surgery. New York, NY: Elsevier/Churchill Livingstone; 1992.)

Mechanical complications are also possible such as afferent or efferent loop obstruction, internal hernia, and intussusception. Pyloroplasty is useful in patients who require a pyloroduodenotomy to deal with the ulcer complication (e.g., posterior bleeding duodenal ulcer), in those with limited or focal scarring in the pyloric region, or when gastrojejunostomy is technically difficult. The most commonly performed pyloroplasty is the Heineke-Mikulicz type (Fig. 26-36). Other occasionally useful techniques include the Finney (Fig. 26-37) and the Jaboulay pyloroplasties (Fig. 26-38). These more extensive pyloroplasty techniques may make subsequent distal gastric resection more difficult and/or hazardous.

Although *vagotomy and antrectomy* (V + A) is associated with a very low ulcer recurrence rate and is applicable to many patients with complicated PUD (e.g., bleeding duodenal and

gastric ulcer, obstructing peptic ulcer, nonhealing gastric ulcer, and recurrent ulcer), V + A has a higher operative mortality risk (compared with HSV or V + D), and is irreversible. Following antrectomy, GI continuity may be reestablished with a Billroth I gastroduodenostomy (Fig. 26-39) or a Billroth II loop gastrojejunostomy (Fig. 26-40). Since antrectomy routinely leaves a 60% to 70% gastric remnant, routine reconstruction as a Roux-en-Y gastrojejunostomy should be avoided (Fig. 26-41). Although the Roux-en-Y operation is an excellent procedure for keeping duodenal contents out of the stomach and esophagus, in the presence of a large gastric remnant, this reconstruction will predispose to marginal ulceration and/or gastric stasis.

V + A should be avoided in hemodynamically unstable patients, and in patients with extensive inflammation and/or scarring of the proximal duodenum, because secure

Figure 26-37. A through D. Finney pyloroplasty. ant. = anterior; Duod. = duodenum; Stom. = stomach. (Reproduced with permission from Zuidema GD: Shackelford's Surgery of the Alimentary Tract, 4th ed. Philadelphia, PA: Elsevier/Saunders; 1996.)

anastomosis (Billroth I) or duodenal closure (Billroth II) may be difficult.

Distal gastrectomy without vagotomy (usually about a 50% gastrectomy to include the ulcer) has traditionally been the procedure of choice for type I gastric ulcer. The addition of vagotomy should be considered for type II and III gastric ulcers (because the pathophysiology is more analogous to duodenal ulcer), or if the patient is believed to be at increased risk for recurrent ulcer, or perhaps even if Billroth II reconstruction is contemplated (to decrease the chance of marginal ulcer). Subtotal gastrectomy (75% distal gastrectomy) without vagotomy is rarely used to treat PUD today, although it was the most popular ulcer operation at the middle of the last century.

Pylorus preserving gastrectomy (PPG) was first reported as a surgical option for gastric ulcer that could minimize both

dumping and duodenogastric reflux. Though not widely adopted for this indication, in some centers PPG is considered a good minimally invasive surgical option for early gastric cancer.^{119,120}

Choice of Operation for Peptic Ulcer. The choice of operation for the individual patient with PUD depends on a variety of factors, including the type of ulcer (duodenal, gastric, recurrent, or marginal), the indication for operation, and the condition of the patient. Other important considerations are intra-abdominal factors (duodenal scarring/inflammation, adhesions, or difficult exposure), the ulcer diathesis status of the patient, the surgeon's experience and personal preference, whether *H pylori* infection is present, the need for NSAID therapy, previous treatment, and the likelihood of future compliance with treatment. Table 26-12 shows the surgical options for managing various aspects of PUD.

Figure 26-38. A through D. Jaboulay pyloroplasty. ant. = anterior; Duod. = duodenum; Stom. = stomach. (Reproduced with permission from Zuidema GD: Shackelford's Surgery of the Alimentary Tract, 4th ed. Philadelphia, PA: Elsevier/Saunders; 1996.)

In general, resective procedures have a lower ulcer recurrence rate, but a higher morbidity and mortality rate (see Table 26-11) compared to nonresective ulcer operations. Because ulcer recurrence often is related to *H pylori* and/or NSAIDs, it is usually managed adequately without reoperation. Thus, gastric resection to minimize recurrence in duodenal ulcer disease is usually not justified; resection for gastric ulcer remains the standard because of the risk of cancer. Clearly, the modern trend in peptic ulcer operation could be described as “less is more.”^{121,122}

Bleeding Peptic Ulcer

Bleeding is the most common cause of ulcer-related death, but only rarely do patients with bleeding gastric or duodenal ulcer

require operation today. The success of endoscopic treatment and medical therapy for bleeding PUD has resulted in the selection of a small subgroup of high-risk patients for today's surgeon. It is likely that patients currently coming to operation for bleeding PUD are at higher risk for a poor outcome than ever before. The surgical options for treating bleeding PUD include suture ligation of the bleeder; suture ligation and definitive nonresective ulcer operation (HSV or V + D); and gastric resection (usually, including vagotomy and ulcer excision). Gastric ulcer requires biopsy if not resected.

The management of bleeding peptic ulcer is summarized in the algorithm provided in Fig. 26-42. All patients admitted to the hospital with bleeding peptic ulcer should be adequately

Figure 26-39. A and B. Billroth I gastroduodenostomy. (Reproduced with permission from Zinner MJ: Atlas of Gastric Surgery. New York, NY: Elsevier/Churchill Livingstone; 1992.)

resuscitated and started on IV PPI.¹²⁵ Most patients will stop bleeding with these measures alone, but about 25% will continue to bleed or will rebleed in hospital. It is important to identify this high-risk group early with clinical and endoscopic parameters because, essentially, all the deaths from bleeding ulcer occur in

this group. Surgical consultation is mandatory, and endoscopic hemostatic therapy (cautery, epinephrine injection, clipping) is indicated and usually successful in these high-risk patients.¹²⁶ Indications for operation include massive hemorrhage unresponsive to initial endoscopic control, recurrent hemorrhage

^aUnless the patient is in shock or moribund, a definitive procedure should be considered.

^bOperation of choice in low-risk patient.

GJ = gastrojejunostomy; HSV = highly selective vagotomy; V + A = vagotomy and antrectomy; V + D = vagotomy and drainage.

requiring multiple transfusions after two attempts at endoscopic control, ongoing hemorrhage and transfusion with limited availability of blood for transfusion or lack of availability of a therapeutic endoscopist, early rehospitalization for bleeding ulcer, and concurrent indications for surgery such as perforation or obstruction. Patients with massive bleeding from high-risk lesions (e.g., posterior duodenal ulcer with erosion of gastroduodenal artery, or lesser curvature gastric ulcer with erosion of left gastric artery or branch) should be considered for operation as should those presenting in shock, those requiring more than four units of blood in 24 hours or eight units of blood in 48 hours, and those with ulcers >2 cm in diameter. The mortality rate for surgery for bleeding peptic ulcer is around 20%. Angiography and embolization may be useful in some patients.

Operation for Bleeding Peptic Ulcer (Fig. 26-43)

The two operations most commonly used for bleeding duodenal ulcer are oversewing of the ulcer with or without vagotomy and drainage,¹²¹ or V + A. Oversewing alone results in a higher rebleeding rate but a lower operative mortality rate than definitive operation. When the mortality for reoperation for rebleeding is considered, the overall mortality is probably comparable for the two approaches. Patients who are in shock or medically unstable should not have gastric resection.

An initial pyloromyotomy incision allows access to the bleeding posterior duodenal ulcer, and an expeditious Kocher maneuver allows the surgeon to control the hemorrhage with the left hand if necessary. Heavy suture material on a stout needle is used to place figure-of-eight sutures or a U-stitch to secure the bleeding vessel at the base of the posterior duodenal ulcer. Multiple sutures are usually necessary. Once the surgeon is unequivocally convinced that hemostasis is secure, a pyloroplasty can be performed. If the patient is stable, vagotomy may be considered if the surgeon is experienced and the vagotomy straightforward. If the patient is not a high operative risk and V + A is selected, smaller duodenal ulcers are resected with the specimen; larger bleeding duodenal ulcers must often be left behind in the duodenal stump. In this situation, suture hemostasis must be attained and a secure duodenal closure accomplished. The anterior wall of the open duodenum can be sutured to either the proximal or distal lip of the posterior ulcer once the bleeding vessel has been sutured. The duodenal closure can be buttressed with omentum and the duodenum should be decompressed, either with a lateral duodenostomy or retrograde tube via the proximal jejunum or well secured nasogastric tube secured with tip well into afferent limb. Right upper quadrant closed suction peritoneal drainage is important. Use of a feeding jejunostomy is also considered. A Billroth II anastomosis reestablishes gastrointestinal continuity.

The initial management of bleeding gastric ulcers and the indications for operation are similar to those for bleeding duodenal ulcer. These lesions tend to occur in older and/or medically complicated patients, and this fact may increase the operative risk. However, experience shows that planned surgery in a resuscitated patient results in a better operative survival rate than emergent operation in a patient who has rebled and is in shock. Distal gastric resection to include the bleeding ulcer is the procedure of choice for bleeding gastric ulcer. Second best is V + D with oversewing and biopsy of the ulcer to rule out cancer. Oversewing of the bleeder and biopsy followed by long-term acid suppression is a reasonable alternative in high-risk or unstable patients.

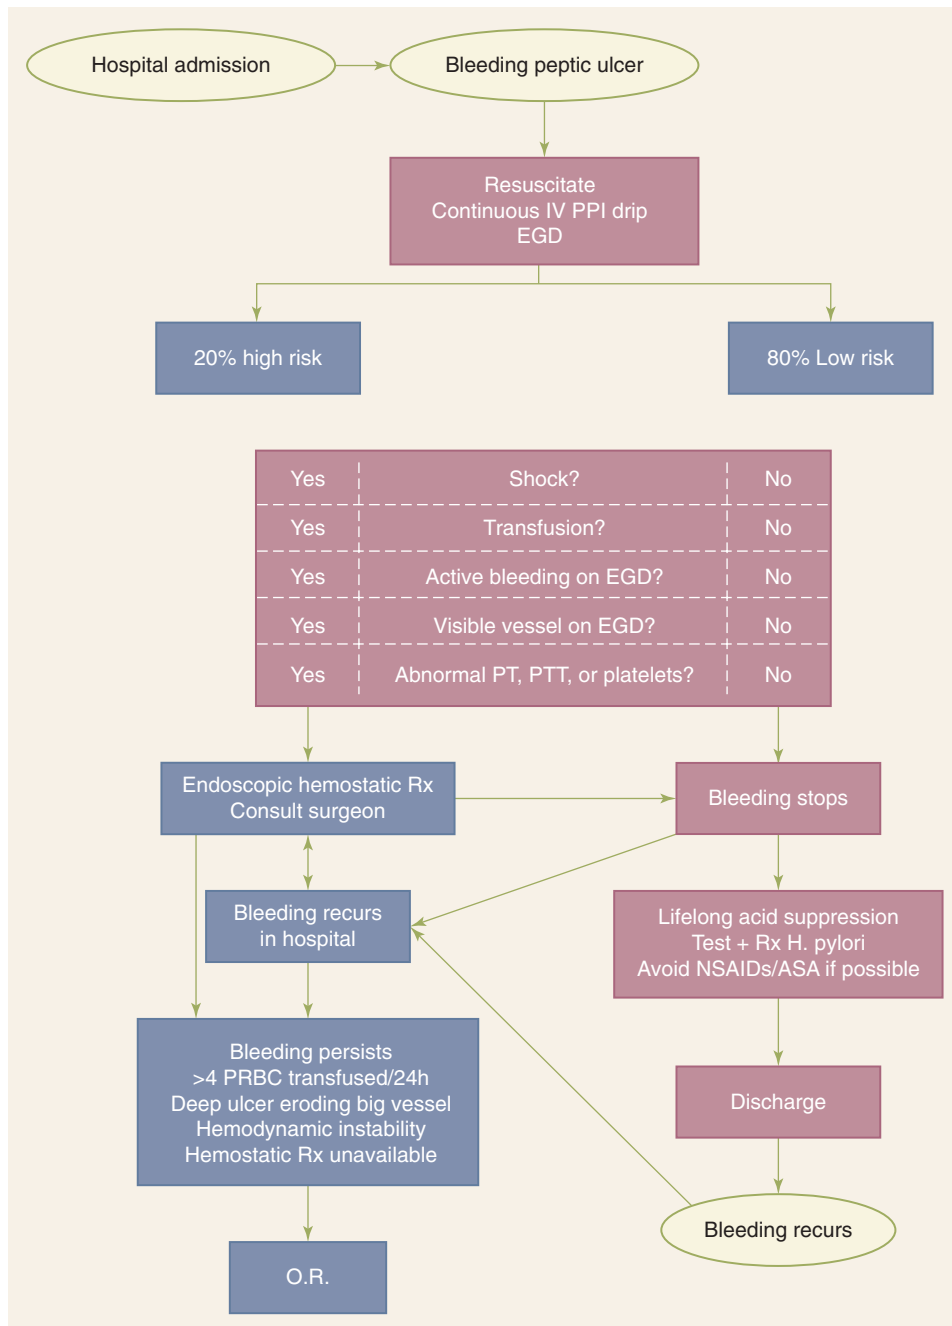

Figure 26-42. Algorithm for the treatment of bleeding peptic ulcer. ASA = acetylsalicylic acid; EGD = esophagogastroduodenoscopy; O.R. = operating room; PPI = proton pump inhibitor; PRBC = unit of packed red blood cells; PT = prothrombin time; PTT = partial thromboplastin time; Rx = treatment.

Perforated Peptic Ulcer (Fig. 26-44)

Perforation is the second most common complication of peptic ulcer, but nowadays it is a much more common indication for operation than bleeding. As with bleeding ulcer, NSAID and/or aspirin use have been inextricably linked with perforated PUD, especially in the elderly population.⁶¹ Surgery is almost always indicated for ulcer perforation, although occasionally nonsurgical treatment can be used in the stable patient without peritonitis in whom radiologic studies document a sealed perforation. Patients with acute perforation and GI blood loss (either chronic or acute) should be suspected of having a second ulcer or a GI cancer.

The options for surgical treatment of perforated duodenal ulcer are simple patch closure, patch closure and HSV, or patch closure and V + D. Simple patch closure, currently the most commonly performed operation for perforated peptic ulcer, is the procedure of choice in patients with hemodynamic instability and/or exudative peritonitis signifying a perforation >24 hours old. In stable patients without longstanding perforation, particularly those with chronic symptoms or failure of medical treatment, the addition of HSV should be considered. Vagotomy and drainage is also an acceptable definitive operation for perforated duodenal ulcer, but occasionally side effects are disabling, and if gastrojejunostomy has been performed,

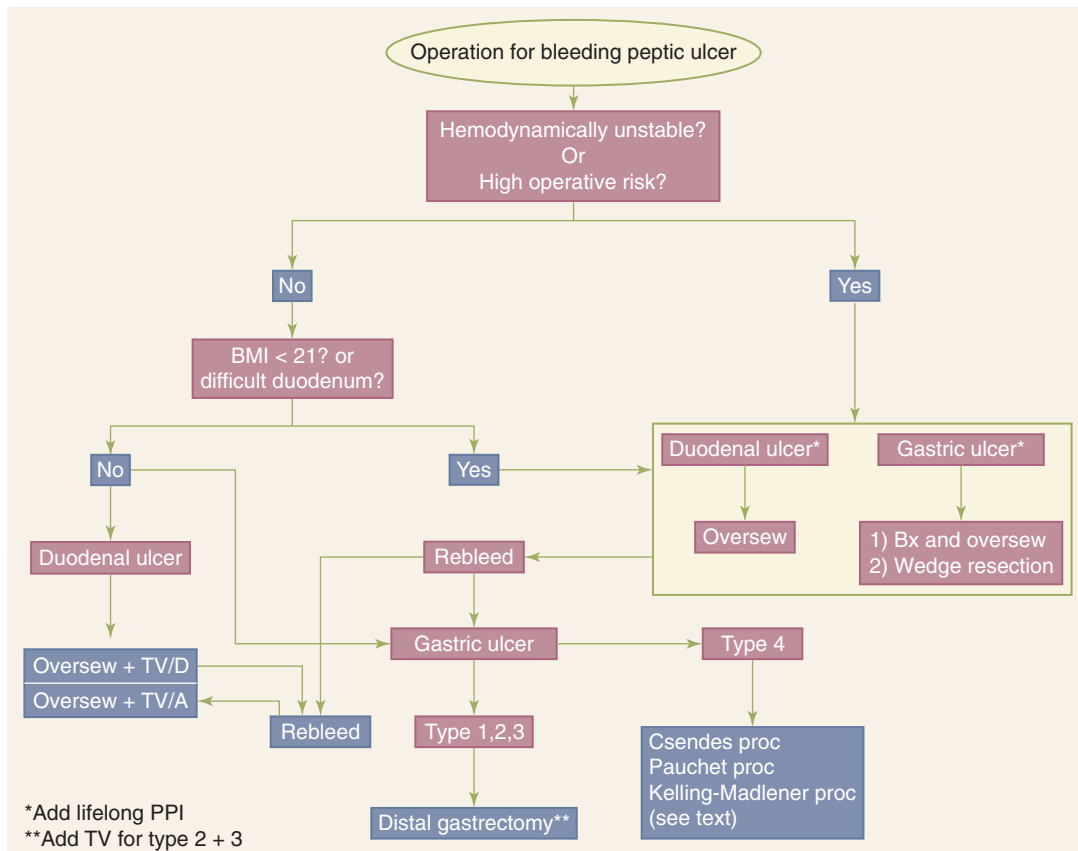

Figure 26-43. Algorithm for operation for bleeding peptic ulcer. BMI = body mass index; Bx = biopsy; PPI = proton pump inhibitor; proc = procedure; TV = truncal vagotomy; TV/A = truncal vagotomy and antrectomy; TV/D = truncal vagotomy and drainage.

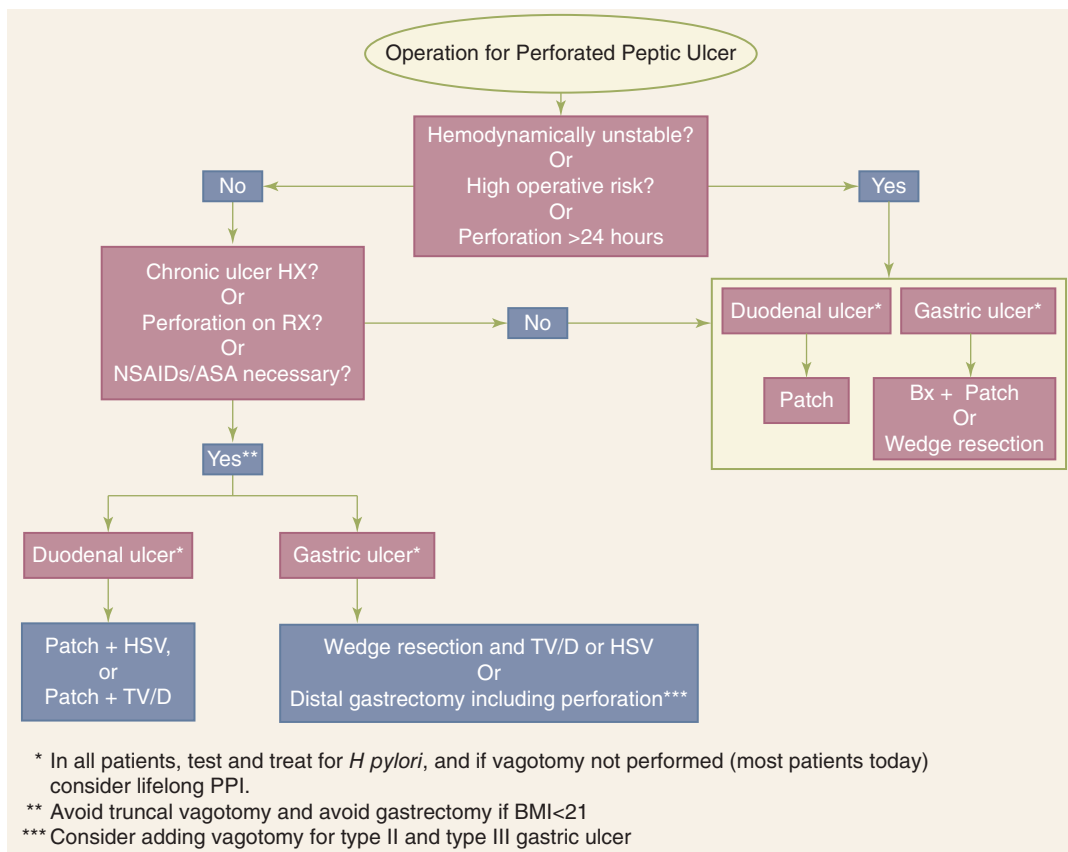

Figure 26-44. Algorithm for operation for perforated peptic ulcer. ASA = acetylsalicylic acid; BMI = body mass index; Bx = biopsy; HSV = highly selective vagotomy; Hx = history; PPI = proton pump inhibitor; Rx = treatment; TV/D = truncal vagotomy and drainage.

marginal ulcer can be life-threatening. In the United States and Western Europe, there is clearly a trend away from definitive operation for perforated duodenal ulcer.^{92,121}

In the stable patient without multiple operative risk factors, perforated gastric ulcers are best treated by distal gastric resection. Vagotomy is usually added for type II and III gastric ulcers. Patch closure with biopsy; or local excision and closure; or biopsy, closure, truncal vagotomy, and drainage are alternative operations in the unstable or high-risk patient, or in the patient with a perforation in an inopportune location. All perforated gastric ulcers, even those in the prepyloric position, should be biopsied if they are not removed at surgery.

Obstructing Peptic Ulcer

Acute ulcers associated with obstruction due to edema and/or motor dysfunction may respond to intensive antisecretory therapy and nasogastric suction. But most patients with significant obstruction from chronic ulceration will require some sort of more substantial intervention. Endoscopic balloon dilation can often transiently improve obstructive symptoms, but many of these patients ultimately fail and come to operation.¹²³

The standard operation for obstructing PUD is vagotomy and antrectomy. Alternatively, vagotomy and gastrojejunostomy should be considered if a difficult duodenal stump is anticipated with resection. HSV and gastrojejunostomy may be comparable to V + A for obstructing ulcer disease,¹²⁴ and this procedure is appealing because it can be done laparoscopically and does not complicate future resection, if needed. However, potentially curable gastric or duodenal cancers can be missed with this approach.

Intractable or Nonhealing Peptic Ulcer

Intractability should be an unusual indication for peptic ulcer operation nowadays. The patient referred for surgical evaluation because of intractable PUD should raise red flags for the surgeon: Maybe the patient has a missed cancer; maybe the patient is noncompliant (not taking prescribed PPI, still taking NSAIDs, still smoking); maybe the patient has *Helicobacter* despite the presence of a negative test or previous treatment. Because acid secretion can be totally blocked and *H pylori* eradicated with modern medication, the question remains: "Why does the patient have a persistent ulcer diathesis?" The surgeon should review the differential diagnosis of nonhealing ulcer before any consideration of operative treatment (Table 26-13).

Table 26-13

Differential diagnosis of intractability or nonhealing peptic ulcer disease

Cancer
Gastric
Pancreatic
Duodenal
Persistent <i>Helicobacter pylori</i> infection
Tests may be false-negative
Consider empiric treatment
Noncompliant patient
Failure to take prescribed medication
Surreptitious use of NSAIDs
Motility disorder
Zollinger-Ellison syndrome

Surgical treatment should be considered in patients with nonhealing or intractable PUD who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation, or hemorrhage), or suspected malignancy. Definitive operation, particularly gastric resection, should be considered most cautiously in the thin or marginally nourished individual.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients, based on the unproven theory that if all other methods have failed to heal the ulcer, a large operation is required. Although there are good data in the surgical literature suggesting that the majority of patients do well after the larger elective ulcer operations, most of these data are several decades old and may not be particularly relevant to the modern patient.¹¹⁴ Candidates for ulcer operation today are different than those of 30 to 50 years ago. One might argue that current medical care has healed the typical peptic ulcers, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation.

If surgery is necessary, a lesser operation may be preferable. It is prudent to avoid truncal vagotomy and/or distal gastrectomy as the initial elective operation for intractable peptic ulcer in the thin or asthenic patient. Alternatives for intractable duodenal ulcer include HSV with or without gastrojejunostomy (reversible drainage operation). In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise, distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy in patients with type I or type IV (juxta-esophageal) gastric ulcers because they are usually associated with acid hyposecretion. Type IV gastric ulcers may be difficult to resect as part of a distal gastrectomy, and a variety of surgical techniques have been described to treat these more proximal lesions (Fig. 26-45).

Zollinger-Ellison Syndrome¹²⁷⁻¹²⁹

ZES is caused by the hypersecretion of gastrin, typically by a duodenal or pancreatic neuroendocrine tumor (i.e., gastrinoma). Most cases (80%) are sporadic, but 20% are inherited. The inherited or familial form of gastrinoma is associated with multiple endocrine neoplasia type I (MEN I), which is characterized by parathyroid, pituitary, and pancreatic (or duodenal) tumors. Gastrinoma is the most common islet cell tumor in patients with MEN I. Patients with MEN I usually have multiple gastrinomas, and surgical cure is usually not achievable; sporadic gastrinomas are more often solitary and are more often amenable to surgical cure. About 50% to 60% of gastrinomas are malignant, with lymph node, liver, or other distant metastases at operation. Five-year survival in patients presenting with metastatic disease is approximately 40%. More than 90% of patients with sporadic, completely resected gastrinoma will be cured.

The most common symptoms of ZES are epigastric pain, GERD, and diarrhea. More than 90% of patients with gastrinoma have peptic ulcers. Most ulcers are in a typical location (proximal duodenum), but atypical ulcer location (distal duodenum, jejunum, or multiple ulcers) should prompt an evaluation for gastrinoma. Gastrinoma also should be considered in the differential diagnosis of recurrent or refractory peptic ulcer, secretory diarrhea, gastric rugal hypertrophy, esophagitis with stricture, bleeding or perforated ulcer, familial ulcer, peptic ulcer with hypercalcemia, and gastric neuroendocrine tumor (carcinoid). The majority of patients with ZES have been symptomatic for several years before definitive diagnosis and,

Figure 26-45. Operations for gastric ulcer. (Reproduced with permission from Feldman M, Sharschmidt BF, Sleisenger MH: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management 6th ed.* Philadelphia, PA: Elsevier/Saunders; 1998.)

in general, patients with ZES and MEN1 are diagnosed in their 20s and 30s, while those with sporadic ZES more typically are diagnosed in their 40s and 50s.

ZES is an important element in the differential diagnosis of hypergastrinemia (Fig. 26-46). All patients with gastrinoma have an elevated gastrin level, and hypergastrinemia in the presence of elevated BAO strongly suggests gastrinoma. Patients with gastrinoma usually have a BAO >15 mEq/h or >5 mEq/h if they have had a previous procedure for peptic ulcer. Acid secretory medications should be held for several days before gastrin measurement, because acid suppression may falsely elevate gastrin levels. Causes of hypergastrinemia can be divided into those associated with hyperacidity and those associated with hypoacidity (see Fig. 26-46). The diagnosis of ZES is confirmed by the secretin stimulation test. An IV bolus of secretin (2 U/kg) is given, and gastrin levels are checked before and after injection. An increase in serum gastrin of 200 pg/mL or greater suggests the presence of gastrinoma. Patients with gastrinoma should have serum calcium and parathyroid hormone levels determined to rule out MEN1 and, if present, parathyroidectomy should be considered before resection of gastrinoma.

About 80% of primary tumors are found in the gastrinoma triangle (Fig. 26-47), and many tumors are small (<1 cm), making preoperative localization difficult. Transabdominal ultrasound is quite specific, but not very sensitive. CT will detect most lesions >2 cm in size, and MRI is comparable. EUS is more sensitive than noninvasive imaging tests, but it still misses many smaller lesions or lesions in inaccessible locations (e.g., the pancreatic tail). Somatostatin receptor scintigraphy (the octreotide scan) or Gallium-68 dotatate PET/CT are sensitive and specific when the pretest probability of gastrinoma is high and may identify sites of regional or distant metastatic disease (Fig. 26-48). Angiographic localization studies are infrequently performed for gastrinoma. Both diagnostic angiography and transhepatic selective venous sampling of the portal system have been supplanted by selective arterial secretin infusion, which helps to

localize the tumor as inside or outside the gastrinoma triangle. This study too, is rarely performed given increasing availability of endoscopic ultrasonography and accurate nuclear medicine imaging.

All patients with sporadic (nonfamilial) gastrinoma should be considered for surgical exploration. The lesions can be located in over 90% of patients, and a majority are cured by extirpation of the gastrinoma.^{130,131} A thorough intraoperative exploration of the gastrinoma triangle and pancreas is essential, but other sites (i.e., liver, stomach, small bowel, mesentery, and pelvis) should be evaluated as part of a thorough intra-abdominal evaluation to find the primary tumor, which is most often solitary and often in the duodenal wall. The duodenum and pancreatic head should be extensively mobilized and intraoperative ultrasound should be utilized. Intraoperative EGD with transillumination may be considered. If the tumor cannot be located, longitudinal duodenotomy with inspection and palpation of the duodenal wall is performed. Lymph nodes from the portal, peripancreatic, and celiac drainage basins should be removed. Ablation or resection of hepatic metastases when identified should be considered.

The management of gastrinoma in patients with MEN I is controversial because patients are infrequently cured by operation. Acid hypersecretion in patients with gastrinoma can always be managed with high-dose PPIs. Highly selective vagotomy may make management easier in some patients and should be considered in those with surgically untreatable or unresectable gastrinoma. Gastrectomy for ZES is not indicated.

STRESS GASTRITIS AND STRESS ULCER

Stress gastritis is a peculiar entity that has all but disappeared from the clinical (if not endoscopic) lexicon, largely due to better critical care and acid suppression or cytoprotective agents (e.g., sucralfate) in the intensive care unit (ICU). Stress gastritis and stress ulcer are probably due to inadequate gastric mucosal

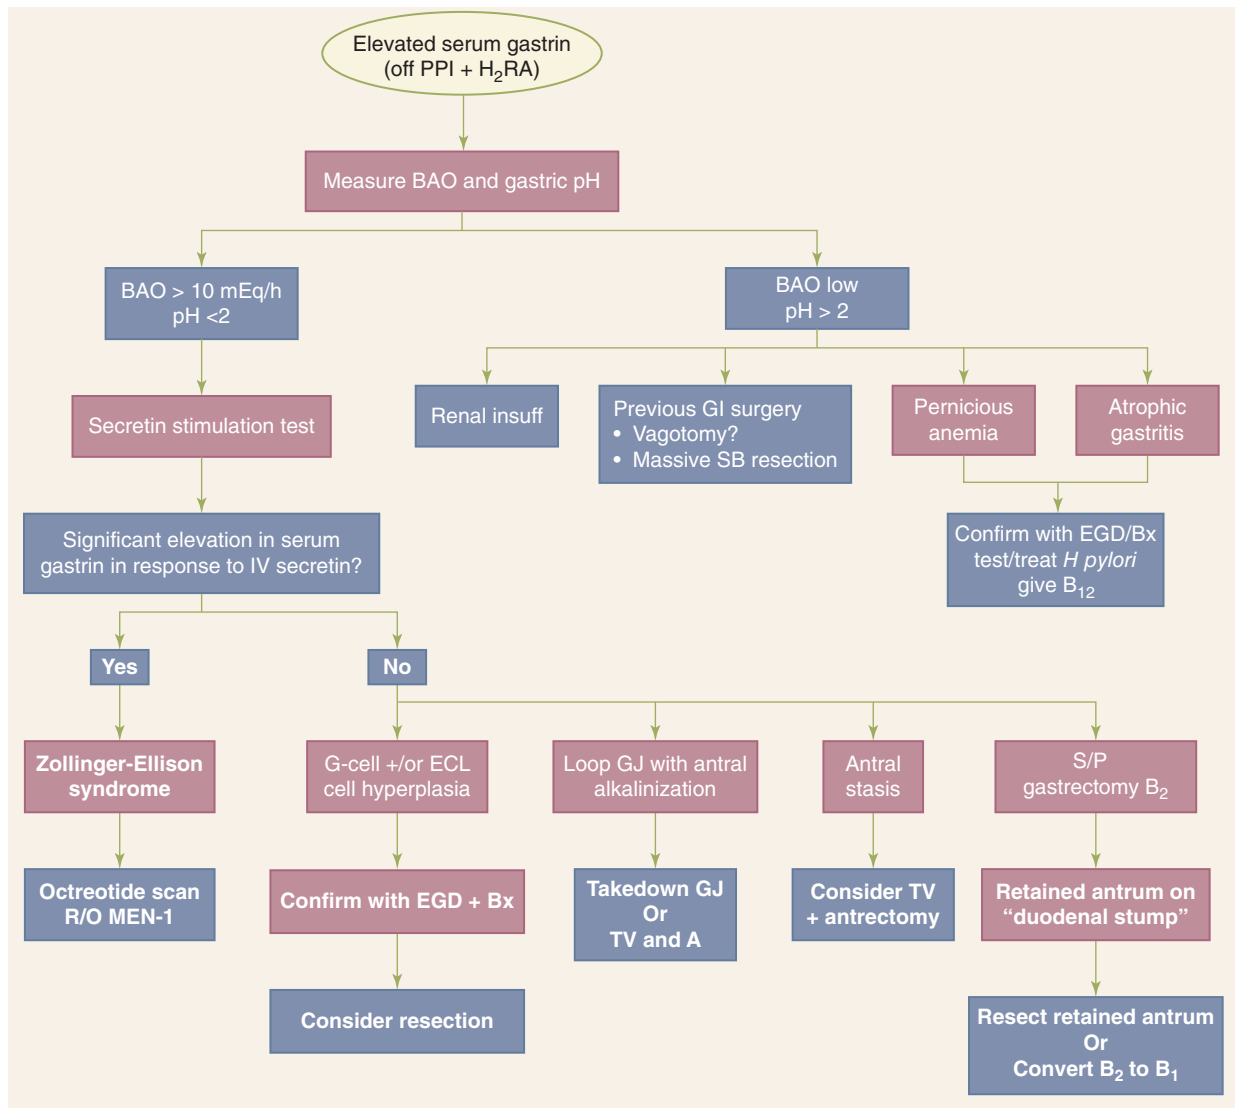

Figure 26-46. Algorithm for diagnosis and management of hypergastrinemia. BAO = basal acid output; B₁ = Billroth 1; B₂ = Billroth 2; Bx = biopsy; ECL = enterochromaffin-like; EGD = esophagogastroduodenoscopy; GJ = gastrojejunostomy; H₂RA = histamine 2 receptor antagonist; insuff = insufficiency; MEN1 = multiple endocrine neoplasia type I; PPI = proton pump inhibitor; R/O = rule out; SB = small bowel; S/P = status post; TV = truncal vagotomy; TV and A = truncal vagotomy and antrectomy.

blood flow during periods of intense physiologic stress. Adequate mucosal blood flow is important to maintain the mucosal barrier and to buffer any back-diffused hydrogen ions. When blood flow is inadequate, these processes fail and mucosal breakdown occurs. Modern intensive care, with emphasis on adequate tissue perfusion and oxygenation, has undoubtedly decreased the severity of gastric mucosal injury seen in the ICU today. Although it is still common to see small mucosal erosions when performing upper endoscopy in the ICU, it is rare for these lesions to coalesce into the larger bleeding erosions that plagued the ICU patient 30 to 50 years ago. The rationale for routine acid suppression in the ICU, supported by excellent data from clinical trials and the laboratory, is that less mucosal injury will be caused in the potentially weakened gastric mucosa if there is less luminal acid.¹³² There are some studies suggesting that routine acid suppression leads to overgrowth of gastric bacteria, which increases the incidence and/or severity of aspiration pneumonia in the ICU.^{133,134} Nevertheless, acid suppression, particularly in the severely ill patient, remains an important part of clinical pathways in most ICUs.¹³⁵ In the extraordinarily rare

patient requiring operation today for hemorrhagic stress gastritis, the surgical options include V + D with oversewing of the major bleeding lesions, or near total gastrectomy. Angiographic embolization and endoscopic hemostatic treatment should be considered as well.

ATROPHIC GASTRITIS

Atrophic gastritis is characterized by atrophy or disappearance of gastric glands and loss of parietal and chief cells. The most common cause is chronic *H pylori* infection, particularly in the corporal distribution (as opposed to the antral distribution which is more typically associated with peptic ulcer disease). Auto-immune destruction of cells (pernicious anemia) and chemical irritation (e.g., bile reflux) can also result in atrophic gastritis. Some patients with atrophic gastritis develop intestinal metaplasia in the gastric mucosa that may progress to dysplasia and then to gastric cancer. Numerous cofactors have been implicated, including diet, altered gastric microbiome, genetics, and hypergastrinemia. Patients with atrophic gastritis are at risk for

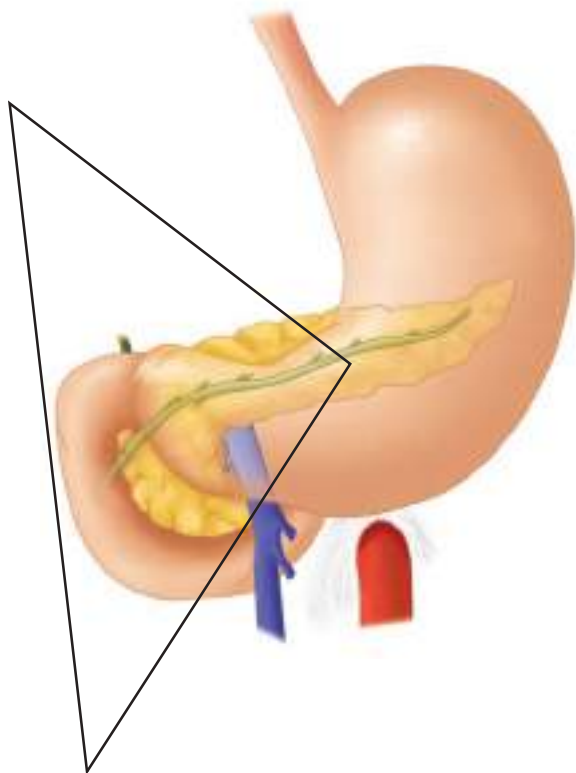

Figure 26-47. Gastrinoma triangle. (Reproduced with permission from Ritchie WP, Steele G, Dean RH: General Surgery. Philadelphia, PA: Lippincott Williams & Wilkins; 1995.)

gastric cancer and should undergo periodic endoscopic surveillance. Metaplastic atrophic gastritis and dysplastic atrophic gastritis in particular, are markers of increased risk for gastric cancer. Patients with high grade dysplasia may benefit from gastrectomy. Cancer risk is related to the extent of the atrophic gastritis and intestinal metaplasia, and grading systems have been developed to stratify cancer risk based on endoscopic findings. Two such systems are the operative link on gastritis assessment (OLGA) and the operative link on gastric intestinal metaplasia (OLGIM) assessment.^{136,137} These systems define the severity (“stage”) of atrophic gastritis based on the histologic grading of at least five gastric biopsies (lesser and greater curve antrum;

Figure 26-48. Positive gallium-68 dotatate scan in patient with gastrinoma.

lesser and greater curve corpus; angularis incisura). Since pathologists are more likely to agree on the histological diagnosis of intestinal metaplasia than they are on atrophic gastritis, the latter tool (OLGIM) may be more useful in stratifying gastric cancer risk. Patients stratified as stage 3 or 4 gastritis and those with pernicious anemia may benefit from surveillance endoscopy every 3 years. Serum markers are also useful in helping to identify patients with atrophic gastritis who usually have increased serum gastrin and iron deficiency due to parietal cell loss and hypochlorhydria or achlorhydria; decreased pepsinogen I levels due to chief cell loss; and B₁₂ deficiency due to parietal cell loss and concomitant loss of intrinsic factor.

MALIGNANT NEOPLASMS OF THE STOMACH

The most common primary malignant gastric neoplasm is adenocarcinoma (95%); lymphoma and GIST account for most of the remaining cases (Table 26-14). Other rare primary malignancies include neuroendocrine tumor, angiosarcoma, carcinosarcoma, and squamous cell carcinoma. Occasionally the stomach is a site of hematogenous metastasis from other sites (e.g., melanoma or breast cancer). Malignant tumors from adjacent organs may also invade the stomach by direct extension (e.g., colon or pancreas) or by peritoneal dissemination (e.g., ovary or appendiceal).

Adenocarcinoma

Epidemiology. Gastric cancer is the fourth most common cancer type and the second leading cause of cancer death worldwide. Over the past century, there has been a dramatic decrease in the incidence of gastric cancer in most Western industrialized countries (Fig. 26-49). This decrease has been largely in the so-called intestinal form rather than in the diffuse form of gastric cancer. In Asia and Eastern Europe, gastric cancer remains a leading cause of cancer death. In 2017 in the United States, approximately 28,000 new cases of stomach cancer were diagnosed (17,750 in men and 10,250 in women), and 10,960 deaths will be attributed to this disease (6720 in men and 4240 in women).¹³⁸ The estimated 5-year survival rate is 27%, up from about 15% in 1975.

In general, gastric cancer is a disease of the elderly, and it is twice as common in blacks as in whites. In younger patients, tumors are more often of the diffuse variety and tend to be large, aggressive, and poorly differentiated, sometimes involving the entire stomach (linitis plastica). Gastric cancer has a higher incidence in groups of lower socioeconomic status.

Figure 26-49. Gastric cancer incidence and death rates per 100,000 population in men and women, in different regions and countries. (Reproduced with permission from *The Global Cancer Observatory - All Rights Reserved, September, 2018.*)

Etiology. Gastric cancer is more common in patients with pernicious anemia, blood group A, or a family history of gastric cancer. When patients migrate from a high-incidence region to a low-incidence region, the risk of gastric cancer decreases in the subsequent generations born in the new region. This strongly suggests an environmental influence on the development of gastric cancer. Environmental factors appear to be more important in the pathogenesis of the intestinal form of gastric cancer compared to the diffuse form. The commonly accepted risk factors for gastric cancer are listed in Table 26-15.

Diet and Drugs A diet high in pickled, salted, or smoked food is found in many regions of high gastric cancer risk. Dietary nitrates have been implicated as a possible cause of gastric cancer. Gastric bacteria (more abundant in the achlorhydric stomach of patients with atrophic gastritis, a risk factor for gastric cancer) convert nitrate into nitrite, a known carcinogen. A diet high in fresh fruits and vegetables and rich in vitamin C and E has been shown to decrease the risk of gastric cancer. The reduced consumption of nitrate-rich preserved foods seen with the widespread availability of refrigeration has been suggested as a cause of the dramatic decrease in gastric cancer seen in North America and Western Europe over the last century.

Table 26-15

Factors increasing or decreasing the risk of gastric cancer

Increase risk

- Family history
- Diet (high in nitrates, salt, fat)
- Familial polyposis
- Gastric adenomas
- Hereditary nonpolyposis colorectal cancer
- Helicobacter pylori* infection
 - Atrophic gastritis, intestinal metaplasia, dysplasia
- Previous gastrectomy or gastrojejunostomy (>10 y ago)
- Tobacco use
- Ménétrier's disease

Decrease risk

- Aspirin
- Diet (high fresh fruit and vegetable intake)
- Vitamin C

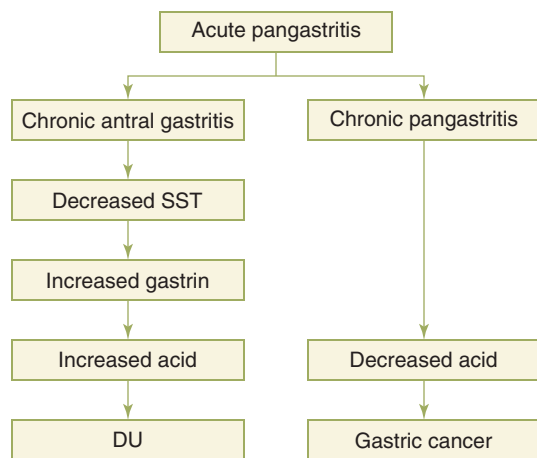

Figure 26-50. *Helicobacter*, gastritis, and the pathogenesis of duodenal ulcer (DU) or gastric cancer.

Tobacco use probably increases the risk of stomach cancer, and alcohol use probably has no effect. Regular aspirin use may be protective.

Helicobacter pylori^{80,139} The risk of gastric cancer in patients with chronic *H pylori* infection is increased about threefold. Compared to uninfected patients, patients with a history of gastric ulcers are more likely to develop gastric cancer (incidence ratio 1.8, 95% confidence interval 1.6–2.0), and patients with a history of duodenal ulcers are at decreased risk for gastric cancer (incidence ratio 0.6, 95% confidence interval 0.4–0.7). This may be due to the fact that some patients develop antral-predominant disease (predisposing to duodenal ulcer and somehow protecting against gastric cancer), while other patients develop corpus-predominant gastritis, resulting in hypochlorhydria and somehow predisposing to gastric ulcer and gastric cancer (Fig. 26-50).¹⁰ The theoretical sequence for development of gastric adenocarcinoma is diagrammed in Fig. 26-51.^{10,80} Recently, it has been demonstrated that bone marrow-derived stem cells play a key role in the pathogenesis of gastric adenocarcinoma in

patients with chronic *H pylori* infection.⁸⁰ However, it must be recognized that gastric adenocarcinoma is a multifactorial disease. Not all patients with gastric cancer have *H pylori*, and there are some geographic areas with a high prevalence of chronic *H pylori* infection and a low prevalence of gastric cancer (the “African enigma”). Finally, *H pylori*-infected patients seem to be at decreased risk for the development of adenocarcinoma of the distal esophagus and cardia region.¹⁴⁰ Perhaps corporeal gastritis decreases acid secretion, creating a less damaging refluxate and thus reducing the risk for Barrett’s esophagus, the precursor lesion for these tumors.

Epstein-Barr Virus About 10% of gastric adenocarcinomas carry the EBV virus. Recently it has been suggested that EBV infection is a late step in gastric carcinogenesis, since EBV transcripts are present in cancer cells but not in the metaplastic cells of precursor epithelium.¹⁴¹

Genetic Factors A variety of genetic abnormalities have been described in gastric cancer (Table 26-16). Most gastric cancers are aneuploid. The most common genetic abnormalities in sporadic gastric cancer affect the *p53* and *COX-2* genes. Over two-thirds of gastric cancers have deletion or suppression of the important tumor-suppressor gene *p53*. Additionally, approximately the same proportion have overexpression of *COX-2*. In the colon, tumors with upregulation of this gene have suppressed apoptosis, more angiogenesis, and higher metastatic potential. Gastric tumors that overexpress *COX-2* are more aggressive. Recently, a germline mutation in the *CDH1* gene encoding E-cadherin was shown to be associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered in patients with these mutations.¹⁴²

Premalignant Conditions of the Stomach Figure 26-52 shows the prevalence of some premalignant conditions associated with the development of early gastric cancer in a series of 1900 cases from Tokyo. By far the most common precancerous lesion is atrophic gastritis. There is a growing appreciation of the important influence of the chronic inflammatory milieu on the genome of mucosal cells. Chronic inflammation leads to both genetic

and epigenetic changes in mucosal cells, which in the stomach leads to the development of gastritis-associated cancer.^{143,144}

Polyps Benign gastric polyps are classified as neoplastic (adenoma and fundic gland polyps) or nonneoplastic (hyperplastic polyp, inflammatory polyp, hamartomatous polyp).¹⁴⁵ In general, inflammatory and hamartomatous polyps have little or no malignant potential. Fundic gland polyps, commonly seen in patients on long-term PPI therapy, are not premalignant, but in patients with familial adenomatous polyposis (FAP), dysplasia in these lesions is not uncommon, and there are numerous reports of gastric cancer arising in a background of fundic gland polyposis in this setting. Hyperplastic polyps usually occur in the setting of chronic inflammation. Large hyperplastic polyps (>2 cm) may harbor dysplasia or carcinoma in situ, and gastric cancer may develop remote from the hyperplastic polyp in an area of associated chronic inflammation. Gastric adenomas are premalignant. Patients with familial adenomatous polyposis (FAP) have a high prevalence of gastric adenomatous polyps (about 50%), and are 10 times more likely to develop adenocarcinoma of the stomach than the general population.¹⁴⁶ Screening EGD is indicated in these families. Patients with hereditary nonpolyposis colorectal cancer may also be at risk for gastric cancer.¹⁴⁷

Atrophic Gastritis Chronic atrophic gastritis (Fig. 26-53) is by far the most common precursor for gastric cancer, particularly the intestinal subtype (see Fig. 26-52). The prevalence of atrophic gastritis is higher in older age groups, but it is also common in younger people in areas with a high incidence of gastric cancer. In many patients, *H pylori* is critical in the pathogenesis of atrophic gastritis. Correa described three distinct patterns of chronic atrophic gastritis: autoimmune (involves the acid-secreting proximal stomach), hypersecretory (involving the distal stomach), and environmental (involving multiple random areas at the junction of the oxyntic and antral mucosa).¹³⁹

Intestinal Metaplasia Gastric carcinoma often occurs in an area of intestinal metaplasia, and the risk of gastric cancer is proportional to the extent of intestinal metaplasia of the gastric mucosa. These observations suggest that intestinal metaplasia is a precursor lesion to gastric cancer. There are different pathologic subtypes of intestinal metaplasia in the stomach, based upon the histologic and biochemical characteristics of the changed mucosal glands. In the complete type of intestinal metaplasia, the glands are lined with goblet cells and intestinal absorptive cells

Figure 26-53. Chronic atrophic gastritis. (Used with permission from Kristen Stashek, MD.)

Figure 26-54. Complete intestinal metaplasia of the stomach. Note intestinal type crypts lined with goblet cells and intestinal absorptive cells. (Used with permission from Kristen Stashek, MD.)

(Fig. 26-54). These cells are indistinguishable histologically and biochemically from their small bowel counterparts. There is evidence that eradication of *H pylori* infection leads to significant regression of intestinal metaplasia and improvement in atrophic gastritis. Treatment of *H pylori* is mandatory for patients with these pathologic findings and *H pylori* infection.

Benign Gastric Ulcer Although once considered a premalignant condition, it is likely that the older literature addressing gastric ulcers was confounded by the inclusion of inadequately biopsied ulcers as “benign,” when, in fact, they were malignant. Regardless, all gastric ulcers should be viewed as malignant until proven otherwise with adequate biopsy and follow-up.

Gastric Remnant Cancer It has long been recognized that stomach cancer can develop in the gastric remnant following subtotal gastrectomy. The extent of risk is controversial, but the phenomenon is real. Most tumors develop >10 years following the initial operation, and they usually arise in an area of chronic gastritis, metaplasia, and dysplasia. This is often near the anastomosis, but many of these tumors are quite large at presentation. Bile or alkali reflux gastritis has been implicated as a precursor, and the greatest number of cases have been reported following Billroth II gastroenterostomy where some transit of pancreatic and biliary secretions through the stomach is obligate. Although Roux-en-Y anastomosis has been suggested to be protective, this hypothesis remains unproven. Stage for stage, the prognosis for gastric stump cancer is similar to that of other proximal gastric cancers.¹⁴⁸

Other Premalignant States Mutations in the E-cadherin gene (*CDH1*) are associated with hereditary diffuse gastric cancer (HDGC). HDGC is an autosomal dominant trait with a high degree of penetrance. Indeed, the lifetime risk of gastric cancer in individuals with pathogenic germline mutations is 70% (in men) and 56% (in women).¹⁴⁹ *CDH1* is a tumor-suppressor gene and a second somatic hit is required for tumorigenesis. The median age at diagnosis of gastric cancer is 38 years. Presentation with clinically significant gastric cancer in this setting is associated with a grave prognosis. Increasing recognition of HDGC has afforded the opportunity for early recognition of pathogenic mutations in relatives of individuals with index cases and utilization of *prophylactic* or early total gastrectomy.¹⁴² Multifocal intramucosal carcinoma is a frequent finding on putative *prophylactic* gastrectomy

specimens, even in patients without a preoperative diagnosis of carcinoma, affirming the role of early intervention. Surgery should be conducted with the aim of complete extirpation of the stomach to squamous lined esophagus proximally and normal duodenal mucosa distally. Mutation-carrying females are also at increased risk of breast cancer, most often lobular carcinomas, and should be carefully monitored.

Up to 10% of gastric cancer cases appear to be familial without a clear-cut genetic diagnosis. First-degree relatives of patients with gastric cancer have a two- to threefold increased risk of developing the disease. Patients with hereditary nonpolyposis colorectal cancer have a 10% risk of developing gastric cancer, predominantly the intestinal subtype. The mucous cell hyperplasia of Ménétrier’s disease is generally considered to carry a 5% to 10% risk of adenocarcinoma. Periodic surveillance EGD is prudent in all the aforementioned conditions. The glandular hyperplasia associated with gastrinoma is not premalignant, but ECL hyperplasia and/or carcinoid tumors can occur.

Pathology

Dysplasia It is generally accepted that gastric dysplasia is the universal precursor to gastric adenocarcinoma. Patients with severe dysplasia should be considered for gastric resection if the abnormality is widespread or multifocal, or EMR if the severe dysplasia is localized. Patients with mild dysplasia should be followed with endoscopic biopsy surveillance, and *Helicobacter* eradication.

Early Gastric Cancer Early gastric cancer is defined as adenocarcinoma limited to the mucosa (T1a) and submucosa (T1b) of the stomach. The entity is common in Asia, where the higher frequency of gastric cancer justified adoption of aggressive surveillance programs. Approximately 10% of patients clinically staged with early gastric cancer will have lymph node metastases. There are several subtypes of early gastric cancer (Table 26-17 and Fig. 26-55). Approximately 70% of early gastric cancers are well differentiated, and 30% are poorly differentiated. The overall cure rate with adequate gastric resection and lymphadenectomy is 95%. In some Japanese centers, 50% of the gastric cancers treated are early stage (compared to less than 20% of resected gastric adenocarcinomas in the United States). Selected patients with early gastric cancer can be treated with endoscopic resection.¹⁵⁰

Table 26-17

Macroscopic types of superficial gastric cancer

Type 0-I (protruding) ^a	Polypoid tumors
Type 0-II (superficial)	Tumors with or without minimal elevation or depression relative to the surrounding mucosa
Type 0-IIa	Slightly elevated tumors (superficial elevated)
Type 0-IIb	Tumors without elevation or depression (superficial flat)
Type 0-IIc	Slightly depressed tumors (superficial depressed)
Type 0-III (excavated)	Tumors with deep depression

^aTumors with less than 3-mm elevation are usually classified as IIa, with more elevated tumors being classified as 0-I.

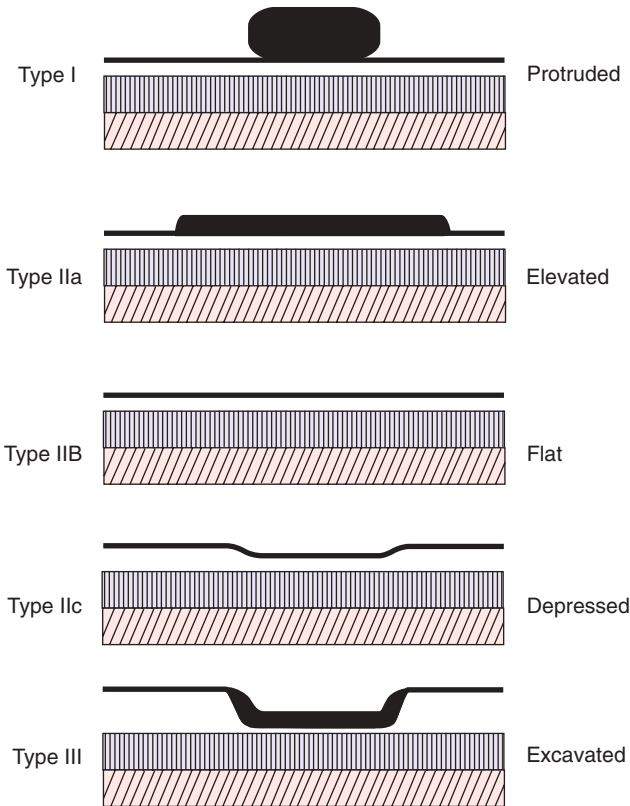

Figure 26-55. Pathologic types of early gastric cancer. (Reproduced with permission from Fenoglio-Preiser CM, Noffsinger AE, Belli J, et al: *Pathologic and phenotypic features of gastric cancer*, *Semin Oncol.* 1996 Jun;23(3):292-306.)

Gross Morphology and Histologic Subtypes Gastric cancer has been subdivided into four morphologic subtypes: polypoid, fungating, ulcerative, and scirrhous. The first two are characterized by a largely intraluminal mass. Polypoid tumors are not ulcerated; fungating tumors are predominantly intraluminal with ulceration. In the latter two gross subtypes, the bulk of the tumor mass is confined to the wall of the stomach. Ulcerative tumors are self-descriptive. Scirrhous tumors infiltrate the entire thickness of the stomach and cover a very large surface area, commonly involve the entire stomach and have a particularly poor prognosis. Although these latter lesions may be technically resectable with total gastrectomy, it is common for both the esophageal and duodenal margins of resection to show microscopic evidence of tumor infiltration; distant metastasis, overt or occult, is frequent and death from recurrent disease within 6 months is common. Palliative chemotherapy may prolong median survival.¹⁵¹

The location of the primary tumor in the stomach is essential in planning an operation. Several decades ago, the large majority of gastric cancers were in the distal stomach. Recently, there has been a proximal migration of tumors, so currently, the distribution is closer to 40% distal, 30% middle, and 30% proximal.

Histology The most important prognostic indicators in gastric cancer are both histologic: lymph node involvement and depth of tumor invasion. Tumor grade (degree of differentiation: well, moderately, or poorly) is also important prognostically.

There are several histologic classifications of gastric cancer. The World Health Organization recognizes several

Table 26-18

histologic types (Table 26-18). The Japanese classification is similar but more detailed. The commonly used Lauren classification separates gastric cancers into intestinal type (53%), diffuse type (33%), and unclassified (14%). The intestinal type is associated with chronic atrophic gastritis, severe intestinal metaplasia, and dysplasia, and tends to be less aggressive than the diffuse type. The diffuse type of gastric cancer is more likely to be poorly differentiated and is associated with younger patients and proximal tumors. The Ming classification also is useful and easy to remember, with only two types—expanding (67%) and infiltrative (33%).

Recently, the significance of human epidermal growth factor receptor-2 (HER2) was reported in patients with gastric cancer. In breast cancer, overexpression of HER2 has been reported in 15% to 25% of cases, and it is well recognized as an unfavorable prognostic factor. The development of molecular targeted agents such as trastuzumab has improved the survival of HER2-positive patients. Likewise, in gastric cancer, HER2 overexpression has been reported in 13% to 30% of patients. HER2 targeting with trastuzumab resulted in improved survival in patients with stage IV gastric cancer, and immunohistochemistry (IHC) staining for HER2 should be performed in recurrent or metastatic cases.¹⁵² Expression of other growth receptors in gastric cancer have been characterized as well, including HER1 (epidermal growth factor receptor) and HER3. The latter is associated with poor prognosis, but efforts to target these receptors for therapeutic benefit are still exploratory.¹⁵³

Pathologic Staging Ultimately, prognosis is related to pathologic stage. The most widespread system for staging of gastric cancer is the tumor-node-metastasis (TNM) staging system based on depth of tumor invasion, extent of lymph node metastases, and presence of distant metastases. This system was developed by the American Joint Committee on Cancer and the International Union Against Cancer, and it has undergone several modifications since it was originally conceived (Table 26-19).

Clinical Manifestations. Most patients who are diagnosed with gastric cancer in the United States have advanced stage III or IV disease at the time of diagnosis. The most common symptoms are weight loss and decreased food intake due to anorexia and early satiety. Abdominal pain (usually not severe and often ignored) is also common. Other symptoms include nausea, vomiting, and bloating. Acute GI bleeding is somewhat unusual (5%), but chronic occult blood loss is common and manifests as iron

deficiency anemia and heme-positive stool. Dysphagia is common if the tumor involves the cardia of the stomach. Paraneoplastic syndromes such as Trousseau's syndrome (thrombophlebitis), acanthosis nigricans (hyperpigmentation of the axilla and groin), or peripheral neuropathy are rarely present.

Physical examination typically is normal. Other than signs of weight loss, specific positive physical findings usually indicate incurability. A focused examination in a patient in whom gastric cancer is a likely part of the differential diagnosis should

include an examination of the neck, chest, abdomen, and rectum. Cervical, supraclavicular (on the left referred to as Virchow's node), and axillary lymph nodes may be enlarged, and can be sampled with fine-needle aspiration cytology. Malignant pleural effusions or ascites, or aspiration pneumonitis may be present. An abdominal mass may indicate a large (usually T4) primary tumor, liver metastases, or carcinomatosis (including Krukenberg's tumor of the ovary). A palpable umbilical nodule (Sister Joseph's nodule) is pathognomonic of advanced disease. Rectal exam may reveal heme-positive stool and hard nodularity extraluminally and anteriorly, indicating so-called drop metastases, or rectal shelf of Blumer in the pouch of Douglas.

Diagnostic Evaluation. Distinguishing between peptic ulcer and gastric cancer on clinical grounds alone can be difficult. Patients over the age of 55 years who have new-onset dyspepsia as well as all patients with dyspepsia and alarm symptoms (weight loss, recurrent vomiting, dysphagia, evidence of GI bleeding, or anemia) or with a family history of gastric cancer should undergo prompt upper endoscopy and biopsy if a mucosal lesion is noted. Essentially, all patients in whom gastric cancer is part of the differential diagnosis should have endoscopy and biopsy. If suspicion for cancer is high and the biopsy is negative, the patient should be reendoscoped and more aggressively biopsied. In some patients with gastric tumors, upper GI series can be helpful in planning treatment. Although a good double-contrast barium upper GI examination is sensitive for gastric tumors (up to 75% sensitive), in most centers, endoscopy has become the gold standard for the diagnosis of gastric malignancy. In addition, recent advances in endoscopy have contributed to the earlier diagnosis of gastric cancer. Magnifying endoscopy with narrow-band imaging (NBI) has undergone technological improvements and can observe the microvascular architecture of the mucosa and microsurface pattern of the lesion. Magnifying endoscopy with NBI has been reported to be accurate and reliable in the diagnosis of early gastric cancer.¹⁵⁴

Preoperative staging of gastric cancer is best accomplished with abdominal/pelvic CT scanning with IV and oral contrast. MRI is probably comparable. The best way to stage the tumor locally is via EUS, which gives fairly accurate (80%) information about the depth of tumor penetration into the gastric wall, and can usually show enlarged (>5 mm) perigastric and celiac lymph nodes. However, there are limitations to tumor staging with EUS. It is highly operator dependent and may underestimate lymph node involvement because normal-sized nodes (<5 mm) can harbor metastases. EUS is most accurate in distinguishing early gastric cancer (T1) from more advanced tumors.

Positron Emission Tomography Scanning Whole-body PET scanning derives its power from the preferential accumulation of positron-emitting 18F-fluorodeoxy glucose in tumor compared to nontumor cells. It is most useful in the evaluation of distant metastasis in gastric cancer, but it can also be useful in locoregional staging. PET scan is accurate when combined with spiral CT (PET-CT)¹⁵⁵ and should be considered before major surgery in patients with particularly high-risk or locally advanced tumors.

Staging Laparoscopy and Peritoneal Cytology Laparoscopy has emerged as a valuable adjunct to gastric cancer staging, particularly in patients with more substantial tumors. This modality allows for rapid identification of macroscopic peritoneal metastases. Peritoneal lavage identifies an additional subset of patients with microscopic dissemination. The prognostic

significance of the latter has been established by several investigators.^{156,157} Gastrectomy should be deferred in patients with positive peritoneal cytology without obvious peritoneal metastases. Patients with gastric cancer who undergo R0 resection (i.e., no gross residual disease) and are found to have positive peritoneal cytology (no gross carcinomatosis) have a much poorer prognosis than those with negative cytology (median survival 14.8 months vs. 98.5 months).¹⁵⁶ Stand-alone laparoscopy may influence management in up to 36% of cases and is increasingly advocated to allow appropriate initial treatment selection. The yield is likely highest in patients with T3 or T4 tumors, proximal tumors, or evidence of regional nodal involvement¹⁵⁸; such patients may benefit from neoadjuvant therapy, and laparoscopy should be offered prior to initiation of treatment. Systemic therapy is the cornerstone of therapy for patients with Stage IV disease and surgery is generally reserved for palliation of symptoms (e.g., an obstructing distal tumor) in patients with metastases identified during laparoscopy.

Treatment. Surgical resection is the only potentially curative treatment for gastric cancer,¹⁵⁹ and most patients with clinically resectable locoregional disease should undergo gastrectomy. The goals of curative surgical treatment are resection of all tumor (i.e., R0 resection and adequate lymphadenectomy to afford accurate staging and provide locoregional control. Generally, the surgeon strives for a grossly negative margin of at least 5 cm, although an evidence base for this is lacking and recent retrospective analyses have suggested that more conservative resections may be adequate.¹⁶⁰ Conversely, complete resection of diffuse tumors sometimes proves challenging, and wider gross margins guided by frozen section are sometimes appropriate. Prior to extending the resection on the basis of a positive frozen section margin, the surgeon should determine whether the microscopic tumor cells are within the wall or on the serosal. The latter may indicate incurable disseminated disease, rendering additional resection proximally or distally moot, particularly when it makes the anastomosis or stump closure more difficult or hazardous.

More than 15 resected lymph nodes are required for adequate staging, a relevant marker of quality of care.^{161,162} Therapeutic nihilism should be avoided, and in the low-risk patient, an aggressive attempt to resect all tumor should be made. The primary tumor may be resected en bloc with adjacent involved organs (e.g., distal pancreas, transverse colon, or spleen) during the course of curative gastrectomy. Palliative gastrectomy may be indicated in the rare patient with incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.¹⁶³

Extent of Gastrectomy The standard operation for gastric cancer is radical subtotal gastrectomy. Unless required for R0 resection, total gastrectomy confers no additional survival benefit and may have adverse nutritional or quality-of-life consequences and higher perioperative morbidity and mortality.¹⁶⁴ Subtotal gastric resection typically entails ligation of the left and right gastric and gastroepiploic arteries at their origins, as well as the en bloc removal of the distal 2/3 of the stomach, including the pylorus and 2 cm of duodenum, the greater and lesser omentum, and all associated lymphatic tissue (Fig. 26-56). In the absence of involvement by direct extension, the spleen and pancreatic tail are not removed.

Reconstruction is usually by Billroth II gastrojejunostomy or Roux-en-Y gastrojejunostomy. The former is associated with

Figure 26-56. A and B. Radical subtotal gastrectomy. vs. = vessels. (Reproduced with permission from Daly JM, Cady B, Low DW: Atlas of Surgical Oncology. St. Louis, MO: Elsevier/Mosby-Year Book; 1993.)

shorter operative time and precludes roux limb stasis. The latter mitigates bile reflux and, therefore, may be associated with better quality of life long term. In East Asia, especially Japan, Billroth-I gastroduodenostomy is frequently performed after distal gastrectomy. Billroth-I gastroduodenostomy consists of one anastomosis (which is usually straightforward and keeps the duodenum in the food stream). In the United States, traditional surgical teaching eschews gastroduodenostomy following gastric cancer resection because of the possibility of anastomotic recurrence and obstruction. A risk of remnant carcinoma attributed to bile reflux has been invoked in support of Roux-en-Y reconstruction over Billroth II or I. Strong evidence linking reconstruction approach to long-term oncologic outcome is lacking.

Total gastrectomy with Roux-en-Y esophagojejunostomy may be required for R0 resection (Fig. 26-57) and is frequently the optimal operation for patients with proximal gastric adenocarcinoma. The construction of a jejunal pouch is associated with superior nutritional recovery in some but not all reports, and is a consideration.¹⁰² Proximal subtotal gastric resection,

Figure 26-57. Reconstruction after total gastrectomy. Jejunal pouch (not shown here) should be considered. (Reproduced with permission from Zinner MJ: *Atlas of Gastric Surgery*. New York, NY: Elsevier/Churchill Livingstone; 1992.)

a technically feasible alternative to total gastrectomy for some proximal gastric tumors, requires esophagogastrectomy to a denervated distal gastric remnant, and functional outcomes are generally poor.¹⁶⁵ Pyloroplasty in this setting virtually guarantees bile esophagitis, and if the pylorus is left intact, gastric emptying may be problematic. An isoperistaltic jejunal interposition (Henley loop) between the esophagus and antrum may mitigate some of the adverse symptoms associated with this operation but adds additional complexity.

Extent of Lymphadenectomy The 3rd edition of Japanese classification of gastric carcinoma defines lymph node stations on the basis of anatomic landmarks. Lymph node stations 1 to 12 and 14V are classified as regional and metastasis to any other lymph nodal stations constitute distant disease (M1) (see Fig. 26-4). So-called D1 lymphadenectomy in distal gastrectomy requires the dissection of stations 1, 3, 4sb, 4d, 5, 6, and 7. Additional resection of stations 8a, 9, 11p, and 12a constitute D2 lymphadenectomy. D1 lymphadenectomy in total gastrectomy requires dissection of stations 1 through 7; D2 lymphadenectomy includes stations 8a to 12a as well. The operation most commonly performed in the United States for gastric cancer is a D1 resection and involves removal of the primary tumor with perigastric nodes. The standard operation for gastric cancer in Asia and specialized U.S. centers is D2 gastrectomy, which involves a more extensive lymphadenectomy (removal of the D1 and D2 nodes). In addition to the tissue removed in a D1 resection, D2 gastrectomy includes the superior peritoneum overlying the mesocolon and, selectively, the pancreas, as well

Table 26-20

Gastric cancer 5-year survival and operative mortality in the United States and Japan

	MARUYAMA (JAPAN), 1971–1985	AMERICAN COLLEGE OF SURGEONS, 1982–1987	MEMORIAL SLOAN KETTERING, 1985–1994
No. patients	3176	18,365	675
Stage I	91%	50%	84%
Stage II	72%	29%	61%
Stage III	44%	13%	29%
Stage IV	9%	3%	25%
Operative mortality	1%	7%	3%

as nodes along the common hepatic and splenic arteries, and the celiac axis. Splenectomy and distal pancreatectomy are not routinely performed because this has been shown to increase the morbidity and mortality of the operation.^{166,167}

The purported survival advantage of D2 gastrectomy in gastric cancer is illustrated in Table 26-20, which shows the 5-year survival rates for gastric cancer stratified by pathologic stage for the United States and Japan. Randomized prospective trials have not confirmed this survival advantage. Two studies showed increased operative mortality with D2 gastrectomy, but the most recent study did not (Table 26-21).^{166,168,169} With extended lymphadenectomy, much of the morbidity and mortality is attributable to performance of splenectomy and distal pancreatectomy, which are no longer routinely included as part of the D2 gastrectomy. Because D2 lymphadenectomy in total gastrectomy requires the dissection of station 10 (i.e., splenic hilar lymph nodes) splenectomy is still selectively performed, particularly for locally advanced fundic tumors.

Longer-term follow-up from the Dutch lymphdenectomy trial demonstrating a disease-specific survival advantage with D2 dissection¹⁷⁰ as well as recognition that pancreas and spleen preserving dissection can be performed with low morbidity¹⁶⁹ have provided momentum for increased utilization of D2 gastrectomy at high-volume centers in the United States and Europe. Some experts have argued that the D2 operation affords better staging and informs more rational decision-making regarding multimodality therapy. Without question, D2 provides a better yield of evaluable nodes. Given the frequent inadequacy of lymph node evaluation with gastrectomy in the United States and the association with poorer outcomes, greater attention to the conduct of the operation and pathologic specimen evaluation is clearly desirable. Whether better outcomes after more extensive dissection are an epiphenomenon of improved pathologic staging, or a function of therapeutic benefit, remains unclear.

Chemotherapy and Radiation for Gastric Cancer The actuarial 5-year survival rates for resected gastric adenocarcinoma stages I, II, and III in the United States are approximately 75%, 50%, and 25%, respectively. Because most surgical patients have stage II disease or greater, adjuvant therapy is indicated in the majority of patients who undergo initial resection. Adjuvant chemotherapy alone has not proven effective, at least in studies from Europe and the United States.¹⁷¹ Several studies from

Japan and Korea have indicated a survival advantage with adjuvant chemotherapy after D2 gastrectomy.¹⁷²⁻¹⁷⁴ The discordance between outcomes in Asia and those from the United States and Europe have been attributed to differences in disease biology or treatment approaches. Proponents of the latter suggest that D2 lymphadenectomy provides sufficient locoregional control and that chemotherapy alone has efficacy after optimal surgery. A

6▶ preferred adjuvant approach in the United States incorporates chemotherapy and radiation based on the results of the Intergroup trial. This prospective randomized study of adjuvant treatment with chemotherapy (5-fluorouracil and leucovorin) and radiation (4500 cGy) demonstrated a survival benefit in resected patients with stage II and III adenocarcinoma of the stomach.¹⁷⁵ Only 10% of patients entered in the study actually had D2 gastrectomy, and most (54%) had less than an adequate D1 gastrectomy. Because adequacy of lymphadenectomy has been correlated with survival, particularly in patients with stage III gastric cancer, it has been suggested that the benefits of adjuvant chemoradiation shown in this study would be vitiated by a more extensive operation.

Neoadjuvant chemotherapy has emerged as a viable alternative to adjuvant chemoradiotherapy in Europe and the United States. Theoretical advantages of this approach include more consistent completion of multimodality therapy, downstaging, earlier treatment of micrometastatic disease, and the ability to gauge response at the in situ tumor. The MAGIC trial, a randomized controlled trial comparing perioperative epirubicin, cisplatin, and 5-fluorouracil to surgery alone demonstrated a survival advantage and supported this approach in patients with at least stage II disease.¹⁷⁶ A subset of patients with very symptomatic tumors may not be eligible for this approach, and the perception that systemic therapy is an ineffective detour for patients who require locoregional control with surgery is sometimes hard to overcome. Regardless, neoadjuvant approaches are increasingly utilized, and even more rigorous regimens incorporating radiotherapy or targeted agents have been explored, sometimes with promising outcomes.¹⁷⁷

Recent clinical trials from Asia suggest the potential benefit of adjuvant chemotherapy after D2 lymphadenectomy in patients with advanced gastric cancer. These trials compared surgery alone and surgery plus adjuvant chemotherapy including oral fluoropyrimidines in resected advanced gastric cancer.^{172,173}

A study from the Japan Clinical Oncology Group showed a 69% overall 5-year survival rate in patients with clinically curable T2b, T3, and T4 gastric cancer, treated with D2 gastrectomy alone.¹⁷⁸ A subsequent trial from Korea demonstrated a survival advantage with adjuvant capecitabine and oxaliplatin after D2 gastrectomy compared to D2 gastrectomy alone.¹⁷³ It is uncertain whether this approach can be translated to patients in the United States.

Although the prognosis of metastatic or recurrent gastric cancer is poor, systemic chemotherapy provides a significant survival benefit over the best supportive care.^{179,180} Agents that have shown activity against gastric cancer include 5-fluorouracil (5-FU), cisplatin, doxorubicin, methotrexate, taxanes, and camptothecin. Until recently, 5-FU-based chemotherapy, especially in combination with platinum, played a key role in the treatment for the unresectable gastric cancer as well as several types of cancer, such as colon and lung. In the 1990s, the introduction of novel anticancer agents such as camptothecin, taxanes, third-generation platinum, and new oral fluoropyrimidines, improved the prognosis of unresectable gastric cancer.^{179,180}

It is likely that targeted molecular agents will have an increasing role in treating gastric cancer. Recently, Trastuzumab, a humanized molecular antibody reactive against the extracellular domain of HER2, increased the effectiveness of cytotoxic chemotherapy in patients with HER2 over-expressing advanced gastric cancer.¹⁵² Other large trials are ongoing. Determination of HER2 gene amplification status may have prognostic significance.¹⁸¹

Endoscopic Resection¹⁸² The short- and long-term morbidity associated with gastrectomy and the relatively infrequent dissemination of superficial (i.e., T1) tumors to regional nodes have compelled exploration of endoscopic resection for selected lesions. Numerous East Asian centers have demonstrated that some patients with early gastric cancer are adequately treated with endoscopic mucosal resection (EMR). EMR is most appropriate for patients in whom the probability of lymph node metastasis is low. According to the Japanese treatment guidelines for gastric cancer, EMR is a standard treatment for well differentiated gastric cancer confined to the mucosa (T1a), measuring less than 2 cm and without signs of ulceration. Such lesions are associated with a negligible risk of lymph node metastasis.

En bloc resection is required to evaluate margins for confirmation of complete resection. The development of endoscopic submucosal dissection (ESD) allows en bloc resection of larger tumors. This has increased the feasibility of endoscopic resection of larger lesions (<3 cm) at experienced centers. If pathologic evaluation of the resected specimen does not demonstrate ulceration, penetration of the muscularis mucosae, or lymphatic invasion, the risk of lymph node metastases is less than 1%. Even the occasional patient with higher risk stigmata may be managed endoscopically, particularly in the presence of comorbidities that preclude safe operation.

Screening for Gastric Cancer. In Japan, it clearly has been shown that patients participating in gastric cancer screening programs have a significantly decreased risk of dying from gastric cancer. Thus, screening is effective in a high-risk population. Screening the general population in the United States (a low-risk country) is probably not justified, but patients clearly at risk for gastric cancer probably should have periodic endoscopy and biopsy. This includes patients with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, gastric adenomas, Ménétrier's disease, intestinal metaplasia or dysplasia, and remote gastrectomy or gastrojejunostomy.

Gastric Lymphoma

Gastric lymphomas generally account for about 4% of gastric malignancies. Over half of patients with non-Hodgkin's lymphoma have involvement of the GI tract. The stomach is the most common site of primary GI lymphoma, and over 95% are non-Hodgkin's type. Most are B-cell type, thought to arise in mucosa associated lymphoid tissue (MALT), although most high-grade gastric lymphomas are without any characteristics of the low-grade MALT neoplasm.¹⁸³ About half of gastric lymphomas are histologically low grade, and about half are high grade. Interestingly, the normal stomach is relatively devoid of lymphoid tissue. However, in the setting of chronic gastritis, the stomach acquires MALT, which can undergo malignant degeneration. Again, *H pylori* is thought to be the culprit. In populations with a high incidence of gastric lymphoma, there is a high incidence of *H pylori* infection; patients with gastric lymphoma also usually have *H pylori* infection.¹⁸⁴

Low-grade MALT lymphoma, essentially a monoclonal proliferation of B cells, presumably arises from a background of chronic gastritis associated with *H pylori*. These relatively innocuous tumors then undergo degeneration to high-grade lymphoma, which is the usual variety seen by the surgeon. Remarkably, when the *H pylori* is eradicated and the gastritis improves, the low-grade MALT lymphoma often disappears. Thus, low-grade MALT lymphoma is not a surgical lesion. Careful follow-up is necessary particularly in those lesions with a t(11:18) translocation, thought to be a risk factor for a more aggressive MALT lesion. If low-grade lymphoma persists after *H pylori* eradication, radiation should be considered for disease clinically confined to the stomach (stage I), while chemotherapy with or without radiation is used for more advanced lesions (Fig. 26-58).

Patients with high-grade gastric lymphoma require aggressive oncologic treatment for cure and present with many of the same symptoms as gastric cancer patients. However, systemic symptoms such as fever, weight loss, and night sweats occur in about 50% of patients with gastric lymphoma. The tumors may bleed and/or obstruct. Lymphadenopathy and/or organomegaly suggest systemic disease. Diagnosis is by endoscopy and biopsy.

Much of the tumor may be submucosal, and an assiduous attempt at biopsy is necessary. Primary lymphoma is usually nodular with enlarged gastric folds. A diffusely infiltrative process akin to linitis plastica is more suggestive of secondary gastric involvement by lymphoma. A diligent search for extragastric disease is necessary before the diagnosis of localized primary gastric lymphoma is made. This includes EUS; CT scanning of the chest, abdomen, and pelvis; and bone marrow biopsy. Most

▶ patients with high-grade gastric lymphoma are currently treated with chemotherapy and radiation, without surgical resection. Treatment-related perforation or bleeding is an unusual but recognized complication. For disease limited to the stomach and regional nodes, radical subtotal D2 gastrectomy may be performed, especially for bulky tumors with bleeding and/or obstruction. Palliative gastrectomy for tumor complications also has a role. Certainly, a multidisciplinary team should be involved in managing patients with primary gastric lymphoma.

Gastrointestinal Stromal Tumor

GISTs arise from interstitial cells of Cajal (ICC) and are distinct from leiomyoma and leiomyosarcoma, which arise from smooth muscle.^{185,186} Prognosis in patients with GIST tumors depends on tumor size, location, and mitotic count. Metastasis, when it occurs, is typically by the hematogenous route. Virtually all GISTs should be resected along with a margin of normal tissue. Most GISTs (and almost no smooth muscle tumors) express c-KIT (CD117) or the related PDGF receptor A, as well as CD34; almost all smooth muscle tumors (and almost no GISTs) express actin and desmin. These markers can often be detected on specimens obtained by fine-needle aspiration¹⁸⁷ and are useful in differentiating between GIST and smooth muscle tumor histopathologically. Lesions that are definitively leiomyoma by histopathologic criteria can be observed if small and asymptomatic. Larger or symptomatic gastric leiomyomas are adequately treated by enucleation or wedge resection. Lesions that are definitively GIST or leiomyosarcoma are best treated by resection with negative margins. Most equivocal lesions should be resected provided that the patient has a reasonable operative risk.

Two-thirds of all GISTs occur in the stomach and have a more favorable prognosis than do GISTs occurring in other locations. Epithelial cell stromal GIST is the most common cell type arising in the stomach, and cellular spindle type is the next most common. The glomus tumor type is seen only in the stomach. Smaller lesions are usually found incidentally, although they occasionally may ulcerate and cause bleeding. Larger lesions may produce symptoms of weight loss, abdominal pain, fullness, early satiety, and bleeding. An abdominal mass may be palpable. Metastasis is by the hematogenous route, most often to liver.

Diagnosis is by endoscopy and biopsy, although the interpretation of the latter may be problematic. When performed, a transluminal (i.e., endoscopic) approach to biopsy is preferred to a percutaneous one, to avoid the potential for fragmentation and peritoneal seeding. A nondiagnostic biopsy does not preclude resection of a suspicious appearing lesion. Metastatic workup entails CT of the abdomen, and pelvis (chest X-ray suffices in lieu of CT of the chest for most patients). Most GISTs are solitary. Local resection with clear margins is adequate surgical treatment but is sometimes impractical for larger prepyloric or pyloric channel tumors, or those near the GE junction.

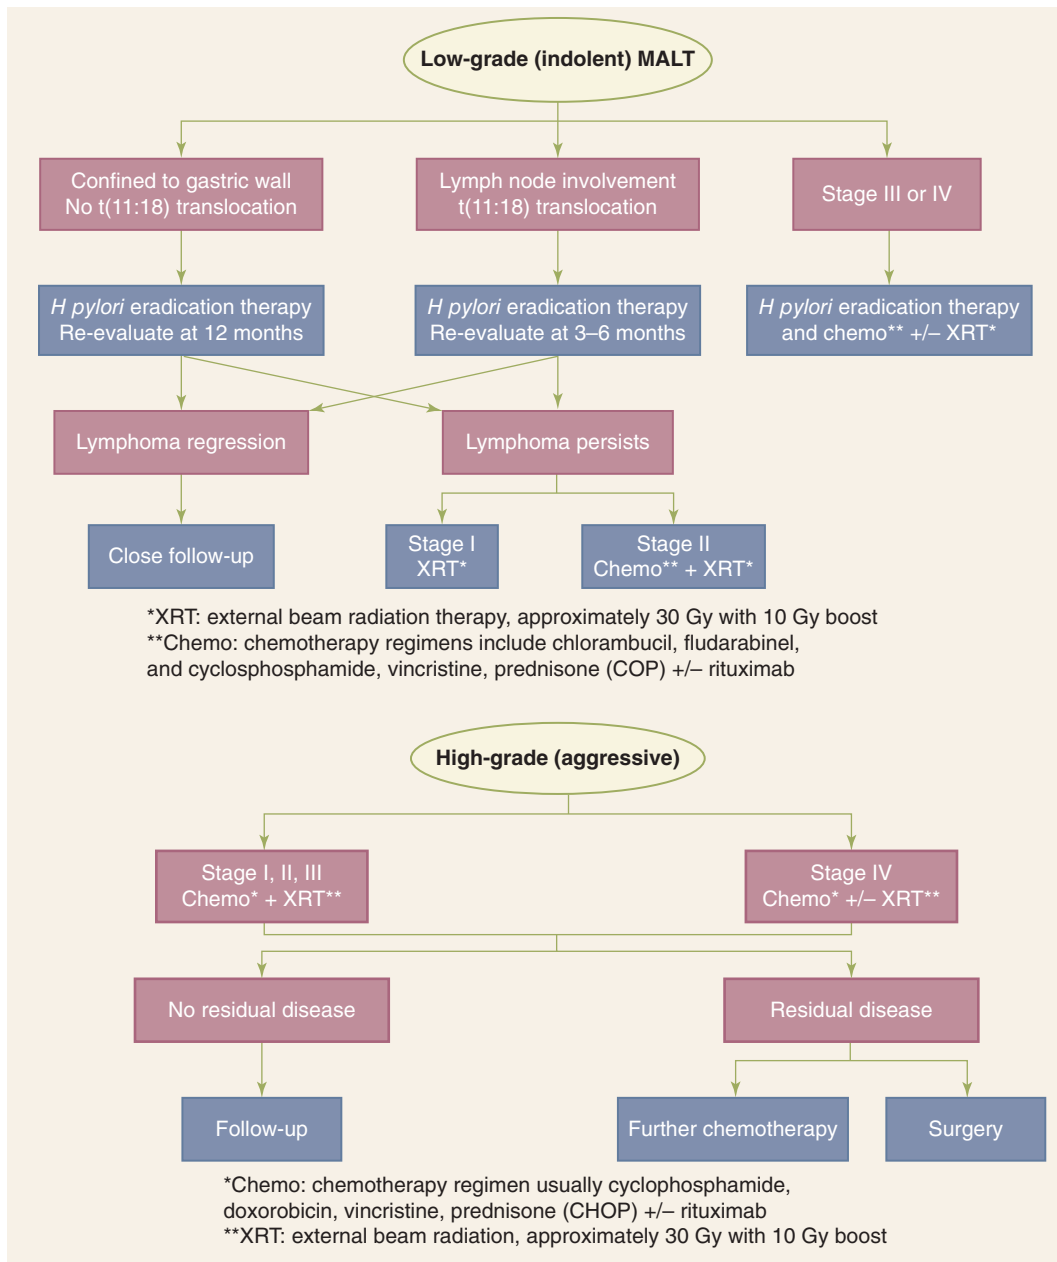

Figure 26-58. Algorithm for the treatment of gastric lymphoma. MALT = mucosa-associated lymphoid tissue. (Reproduced with permission from Yoon SS, Coit DG, Portlock CS, et al. *The diminishing role of surgery in the treatment of gastric lymphoma*, Ann Surg. 2004 Jul;240(1):28-37.)

True invasion of adjacent structures by the primary tumor is occasionally seen with larger more aggressive lesions. If safe, en bloc resection of involved surrounding organs is appropriate to remove all tumor.

The risk of tumor recurrence or metastasis behavior has been stratified into four groups according to the tumor size and mitotic count.¹¹⁰ Very low risk is defined by size <2 cm and <5 mitoses/50 HPF (high-power field). Low risk is defined by size 2 to 5 cm and <5 mitoses/50 HPF. Intermediate risk is defined by size <5 cm and 6 to 10 mitoses/50 HPF or size 5 to 10 cm and >5 mitoses/50 HPF. High risk is defined by size >5 cm and >5 mitoses/50 HPF, size >10 cm regardless of mitotic rate or >10 mitoses/50 HPF regardless of size. As mentioned, stomach lesions are associated with lower risk than are tumors in other locations. Classification based on tumor location, size, and mitotic rate have been proposed to evaluate the risk of

recurrence and metastasis and role for adjuvant therapy.¹⁸⁸ In an effort to further refine risk stratification, a number of nomograms have been introduced incorporating tumor features. These tools draw upon and are subject to the limitations of the institutional data from which they are derived, but they are sometimes helpful in counseling patients.

Mutations in the oncodriver c-kit and PDGFRA are present in a majority of GISTs. This has been exploited through the use of imatinib (Gleevec), a tyrosine kinase inhibitor. Several clinical trials in a metastatic disease setting demonstrated marked improvements in median survival from 9 months to greater than 5 years.¹⁸⁹ These striking results not only established imatinib as the primary therapy for metastatic GIST, but they also compelled broader efforts to target solid tumors with small molecule inhibitors. Notably, up to 50% of treated patients develop resistance to imatinib by 2 years, and several

second-line agents have been utilized for patients with refractory disease, most notable sunitinib.

The efficacy of imatinib as adjuvant therapy for high risk GIST has been demonstrated in two randomized clinical trials, ACOSOG Z9001 and SSG XVIII.^{190,191} The former trial randomized patients to 1 year of adjuvant imatinib or placebo and showed an improvement in recurrence-free survival with imatinib. The latter trial demonstrated an overall survival advantage with 3 years compared to 1 year of therapy. Imatinib is now recommended in high risk groups as an adjuvant therapy, for three years or longer. Preoperative therapy with imatinib may be indicated in selected patients with larger lesions that may be more difficult to completely resect or require multivisceral resection.

Molecular profiling has been embraced with growing recognition that specific tumor subtypes are insensitive to imatinib. Patients with PDGFRA D842V mutations, for example, do not respond to imatinib.¹⁹² Management of metastatic GIST is principally medical, but surgery has a selected role. An algorithm for the treatment of patients with metastatic GIST is shown in Fig. 26-59.

Gastric Neuroendocrine Tumors^{193,194}

Compared to neuroendocrine tumors of the midgut and hindgut, neuroendocrine tumors of the stomach are rare. Gastric neuroendocrine tumors comprise about 1% of all neuroendocrine tumors and less than 2% of gastric neoplasms. They arise from gastric enterochromaffin-like (ECL) cells and may have malignant potential. The apparent incidence of gastric neuroendocrine tumors is increasing, perhaps related to increased detection or the increasing use of acid suppressive medication. The latter may cause hypergastrinemia, and gastrin has a recognized trophic effect on gastric ECL cells.

Nomenclature remains a point of confusion; carcinoid and well-differentiated neuroendocrine tumor (NET) are synonymous according to WHO classification.

Gastric neuroendocrine tumors are classified into one of three different types. Type I is the most common, accounting for about 75% of cases. Type I lesions occur in patients with chronic hypergastrinemia secondary to pernicious anemia or atrophic gastritis. These lesions occur more frequently in women, are often multiple and small, and have low malignant potential (<5% metastasize). The role of long-term acid suppression with resultant hypergastrinemia in the pathogenesis of type I gastric carcinoids is unclear. Type II gastric neuroendocrine tumors are associated with MEN1 and ZES. These lesions also tend to be small and multiple, but they have a somewhat higher malignant potential than type I lesions (10% metastasize). Type II lesions are more common in the setting of MEN1; they are quite uncommon in patients with sporadic ZES. The constellation of gastric acidity, hypergastrinemia, and gastric neuroendocrine tumors suggests gastrinoma until proven otherwise. Type III gastric neuroendocrine tumors are sporadic. They are most often solitary (usually >2 cm) and occur more commonly in men. They are not associated with hypergastrinemia. Most patients have regional nodal or distant metastases at the time of diagnosis, and some present with symptoms of carcinoid syndrome.

Gastric neuroendocrine tumors are usually diagnosed with endoscopy and biopsy. The type can be determined based upon clinical context, patient history, the presence or absence of atrophic gastric mucosa, gastric pH and gastrin level. Some tumors are submucosal and may be quite small. They are often confused with heterotopic pancreas or small leiomyomas. Biopsy may be difficult because of the submucosal location, and EUS can be helpful in defining the size and depth of the lesion. Plasma

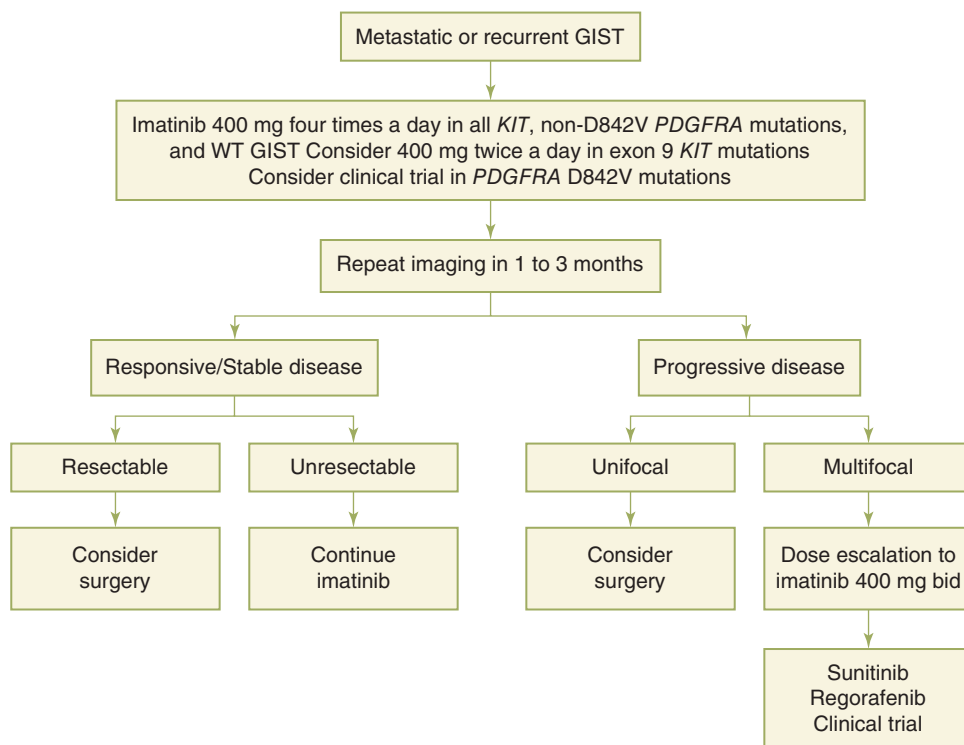

Figure 26-59. Algorithm for the treatment of malignant gastrointestinal stromal tumor. (Reproduced with permission from Balachandran VP, DeMatteo RP: *Gastrointestinal stromal tumors: who should get imatinib and for how long?* *Adv Surg.* 2014;48:165-183.)

chromogranin A levels are frequently elevated. CT scan and octreotide or gallium dotatate scans are useful for staging.

Type I and II patients with numerous diminutive lesions can be followed with serial endoscopy. Small lesions confined to the mucosa (typically type I or type II lesions) less than 1 cm may be treated endoscopically with EMR if there are only a few lesions (<5). Occasionally a slightly larger lesion (1–2 cm) necessitate local surgical excision. Larger lesions and type III lesions should be removed by D1 or D2 gastrectomy. Antrectomy to mitigate gastric secretion in type I patients with refractory growing lesions was invoked as a viable treatment strategy in the past, but it is rarely indicated.

Survival is excellent for node-negative patients (>90% 5-year survival); node-positive patients have a 50% 5-year survival. Gastrinoma should be resected if located in patients with type II carcinoid. The 5-year survival for patients with type I gastric carcinoid is close to 100%; for patients with type III lesions, the 5-year survival is less than 50%. Somatostatin analogue therapy may delay progression of metastatic disease. Surgical debulking may have a role in selected patients with limited metastatic disease.

BENIGN GASTRIC NEOPLASMS

Leiomyoma

The typical leiomyoma is submucosal and firm. If ulcerated, it has an umbilicated appearance and may bleed. Histologically, these lesions appear to be of smooth muscle origin. Lesions <2 cm are usually asymptomatic and benign. Larger lesions may cause symptoms such as bleeding, obstruction, or pain. Asymptomatic lesions <2 cm may be carefully observed or enucleated if fine-needle aspiration and immune markers confirm smooth muscle tumor; larger lesions and symptomatic lesions should be removed by wedge resection (often possible laparoscopically). When lesions thought to be leiomyoma are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

Lipoma

Lipomas are benign submucosal fatty tumors that are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically, they have a characteristic appearance; there also is a characteristic appearance on EUS. Excision is unnecessary unless the patient is symptomatic.

Gastroparesis

Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying, and motor and sensory abnormalities (e.g., functional dyspepsia). Surgically relevant secondary disorders of gastric motility (e.g., dumping, gastric stasis, and Roux syndrome) are discussed under Postgastrectomy Problems. Gastroparesis is the most surgically relevant primary disorder of gastric motility.^{195,196}

Most patients with primary gastroparesis present with nausea, vomiting, bloating, early satiety, and/or abdominal pain. Eighty percent of these patients are women; some are diabetic. Postprandial vomiting significantly complicates the management of blood glucose in the latter group, predisposing to hypoglycemia following preprandial insulin. In patients with gastroparesis, it is important to rule out mechanical gastric outlet obstruction, and small-bowel obstruction. An upper GI series may suggest slow gastric emptying and relative atony,

or it may be normal. EGD may show bezoars or retained food but is frequently normal. Gastric emptying scintigraphy shows delayed solid emptying, and often delayed liquid emptying. Gastroparesis can be a manifestation of a variety of problems (Table 26-22). Medical treatment includes promotility agents, antiemetics, and, perhaps, botulinum injection into the pylorus.

If the diabetic gastroparetic patient is not a candidate for pancreas transplant, both gastrostomy (for decompression) and jejunostomy tubes (for feeding and prevention of hypoglycemia) can be helpful in managing these patients. Other surgical options include implantation of a gastric pacemaker, pyloroplasty or peroral endoscopic pyloromyotomy (particularly in patients responsive to pyloric Botox injection), and gastric resection.¹⁹⁷ Generally, gastric resection should be done only after other therapeutic options have been exhausted.

Massive Upper Gastrointestinal Bleeding

Although there are arbitrary definitions of “massive” upper GI bleeding put forth, perhaps the most practical definition in the current era would be acute GI bleeding proximal to the ligament of Treitz, which requires blood transfusion. In multiple series, the stomach and proximal duodenum are by far the most common sources of pathology associated with this diagnosis.^{109,198}

The most common causes of acute upper GI bleeding in emergency department or hospitalized patients are peptic ulcer, gastritis, Mallory-Weiss syndrome, and esophagogastric varices. Less common causes include benign or malignant neoplasm, angiodysplasia, Dieulafoy's lesion, portal gastropathy, Ménétrier's disease, and watermelon stomach. Arterioenteric fistula should always be considered in the patient who has an aortic graft or who has undergone repair of a visceral artery aneurysm.

The most important issues in the early hospital management of patients with acute upper GI bleeding are resuscitation and risk stratification. Large-bore IV access and Foley catheterization is accomplished, and nasogastric intubation is considered. Risk stratification is essentially accomplished by answering the following questions:

- What is the magnitude and acuity of the hemorrhage? Hypotension, tachycardia, oliguria, low hematocrit, pallor, altered mentation, and/or hematemesis suggest a large blood loss that has occurred over a short period of time. This is a high-risk situation.
- Does the patient have significant chronic disease, particularly lung, liver, kidney, and/or heart disease, which compromises physiologic reserve? If yes, this is a high-risk situation.
- Is the patient anticoagulated, or immunosuppressed? If yes, this is a high-risk situation.
- On endoscopy, is the patient bleeding from varices, or is there active bleeding, or is there a visible vessel, or is there a deep ulcer overlying a large vessel (e.g., posterior duodenal ulcer overlying the gastroduodenal artery)? Could the patient be bleeding from an arterio-enteric fistula? If yes, this is a high-risk situation.

When judged to be low risk, most patients will stop bleeding with supportive treatment and IV PPI. Selected patients may be discharged from the emergency department and managed on an outpatient basis.

If the patient is deemed to be high risk based on one or more of the aforementioned questions, then the following should be done immediately:

- Type and cross-match for transfusion of blood products.
- Admit to ICU or monitored bed in specialized unit.
- Consult surgeon.
- Consult gastroenterologist.
- Start intravenous PPI.
- Perform upper endoscopy within 12 hours, after resuscitation and correction of coagulopathy. Endoscopic hemostasis should be considered in most high-risk patients with acute upper GI bleeding.

Although the surgeon should be involved early in the hospital course of all high-risk patients with acute upper GI bleeding, most of these patients will be adequately managed without operation. Mucosal lesions can usually be controlled with endoscopic hemotherapy and medical management. Occasionally, arteriography can be helpful.¹⁹⁹ Operation for bleeding ulcer is discussed previously (see "Operation for Bleeding Peptic Ulcer" and Fig. 26-43).

Isolated Gastric Varices

Isolated gastric varices are those that occur in the absence of esophageal varices and are classified as type I (fundic) or type II (distal to fundus including proximal duodenum).²⁰⁰

The presence of isolated gastric varices is usually associated with portal hyper-tension or splenic vein thrombosis. Although there is a significant bleeding risk from isolated gastric varices on long-term follow-up, there is no indication for the routine application of prophylactic measures.

Patients with acute upper GI bleeding from isolated gastric varices should be considered high risk. Although data are limited, octreotide and/or vasopressin infusion may decrease bleeding, if tolerated. Balloon tamponade with a Sengstaken-Blakemore tube may provide temporary control of exsanguinating hemorrhage from type isolated gastric varices, but if this is used, endotracheal intubation for airway protection is prudent. Endoscopic treatment with sclerotherapy or varix ligation is less successful than in esophageal varices but should be considered. Interventional radiology should be consulted and balloon-occluded retrograde transvenous obliteration considered. A transjugular intrahepatic portosystemic shunt (TIPSS) may be useful if there is nonsegmental portal hypertension. If the patient has splenic vein thrombosis and left-sided (sinistral) or segmental portal hypertension, splenectomy is quite effective in controlling bleeding from isolated gastric varices. The operative mortality is 5%. Liver transplantation should always be considered in the cirrhotic patient.

Hypertrophic Gastropathy (Ménétrier's Disease)

There are two clinical syndromes characterized by epithelial hyperplasia and giant gastric folds: ZES and Ménétrier's disease. The latter is characteristically associated with protein-losing gastropathy and hypochlorhydria. There are large rugal folds in the proximal stomach, and the antrum is usually spared. Mucosal biopsy shows diffuse hyperplasia of the surface mucus-secreting cells and usually decreased parietal cells (Fig. 26-60). It has recently been suggested that Ménétrier's disease is caused by local overexpression of transforming growth factor- α in the gastric mucosa, which stimulates the epidermal growth factor receptor, a receptor tyrosine kinase, on gastric SECs. This results in the selective expansion of surface mucous cells in the gastric body and fundus. A few patients with this unusual disease have been successfully

Figure 26-60. Mucosal biopsy in Ménétrier's disease. (Reproduced with permission from Ming S-C, Goldman H: Pathology of the Gastrointestinal Tract, 2nd ed. Baltimore, MD: Williams & Wilkins; 1998.)

treated with the epidermal growth factor receptor blocking monoclonal antibody cetuximab.²⁰¹

Most patients with Ménétrier's disease are middle-aged men who present with epigastric pain, weight loss, diarrhea, and hypoproteinemia. There may be an increased risk of gastric cancer. Sometimes, the disease regresses spontaneously. Occasionally it is associated with *H pylori* infection, and the disease improves with helicobacter eradication. Total gastrectomy may be indicated for bleeding, severe hypoproteinemia, or cancer.

Watermelon Stomach (Gastric Antral Vascular Ectasia)

The parallel red stripes atop the mucosal folds of the distal stomach give this rare entity its sobriquet. Histologically, gastric antral vascular ectasia (GAVE) is characterized by dilated mucosal blood vessels that often contain thrombi, in the lamina propria. Mucosal fibromuscular hyperplasia and hyalinization often are present (Fig. 26-61). The histologic appearance can resemble portal hypertensive gastropathy, but the latter usually affects the proximal stomach, whereas watermelon stomach predominantly affects the distal stomach. β -Blockers and nitrates, useful in the treatment of portal hypertensive gastropathy, are ineffective in patients with gastric antral vascular ectasia. Patients with GAVE are usually elderly women with chronic GI blood loss requiring transfusion. Most have an associated autoimmune connective tissue disorder, and at least 25% have chronic liver disease. Nonsurgical treatment options include estrogen and progesterone, and endoscopic treatment with the neodymium yttrium-aluminum garnet (Nd:YAG) laser or argon plasma coagulator.²⁰² Antrectomy may be required to control blood loss, and this operation is quite effective but carries increased morbidity in this elderly patient group. Patients with portal hypertension and antral vascular ectasia should be considered for transjugular intrahepatic portosystemic shunt (TIPSS).

Dieulafoy's Lesion

Dieulafoy's lesion is a congenital arteriovenous malformation characterized by an unusually large tortuous submucosal artery. If this artery is eroded, impressive pulsatile bleeding may occur. To the endoscopist or surgeon, this appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. The lesion typically occurs in middle-aged or

elderly men and may be more common in patients with liver disease.²⁰³ Patients typically present with upper GI bleeding, which may be intermittent, and endoscopy can miss the lesion if it is not actively bleeding. Treatment options include endoscopic hemostatic therapy, angiographic embolization, or operation. At surgery, the lesion may be oversewn or resected.

Bezoars/Diverticula

Bezoars are concretions of indigestible matter that accumulate in the stomach. Trichobezoars are composed of swallowed hair (Fig. 26-62). Phytobezoars are composed of vegetable matter and, in the United States, are usually seen in association with gastroparesis or gastric outlet obstruction. They also are associated with persimmon ingestion. Most commonly, bezoars produce obstructive symptoms, but they may cause ulceration and bleeding. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Treatment options include enzyme therapy (papain, cellulase, or acetylcysteine), endoscopic disruption and removal, or surgical removal.

Gastric diverticula are usually solitary and may be congenital or acquired. Congenital diverticula are true diverticula and contain a full coat of muscularis propria, whereas acquired diverticula (perhaps caused by pulsion) usually have a negligible outer muscle layer. Most gastric diverticula occur in the posterior cardia or fundus (Fig. 26-63) and are usually asymptomatic. However, they can become inflamed and may produce pain or bleeding. Perforation is rare. Asymptomatic diverticula do not require treatment, but symptomatic lesions should be removed. This can often be done laparoscopically.

Foreign Bodies

Ingested foreign bodies are usually asymptomatic. Small coins usually pass through the GI tract without difficulty. Sharp or

Figure 26-63. Upper GI contrast study showing a diverticulum of the stomach. (Used with permission from Marc Levine, MD.)

large objects in the stomach should be removed. This can usually be done endoscopically, with an overtube technique. Recognized dangers include aspiration of the foreign body during removal and rupture of drug-containing bags in “body packers.” Both complications can be fatal. Surgical removal is recommended in body packers who ingest drug parcels for smuggling and in patients with large jagged objects that cannot be safely removed endoscopically. Corrosive objects (i.e., batteries) should be removed promptly usually endoscopically. Ingested magnets should be removed unless they are small and singular and without other ingested metal objects.

Mallory-Weiss Syndrome

The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction.²⁰⁴ It is presumably caused by forceful vomiting and/or retching, and it is commonly seen in alcoholics. It presents with upper GI bleeding, often with hematemesis. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. Other options to control the bleeding include balloon tamponade, angiographic embolization, or selective infusion of vasopressin, systemic vasopressin, and operation. Surgical treatment consists of oversewing the bleeding lesion through a long gastrotomy.

Volvulus

Gastric volvulus is a twist of the stomach that usually occurs in association with a large hiatal hernia. It also can occur in patients with an unusually mobile stomach without hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up (Fig. 26-64C). If the stomach twists around the transverse axis, it is called *mesenteroaxial rotation* (Fig. 26-64A and Fig. 26-64B). Often, volvulus is a chronic condition that can be surprisingly asymptomatic. In these instances, expectant nonoperative management is typically advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients. Symptomatic patients should be considered for operation, especially if the symptoms are severe and/or progressive. Patients may present with symptoms of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Pressure on the lung may produce dyspnea, pressure on the pericardium may produce palpitations, and pressure on the esophagus may produce dysphagia. Symptoms are often relieved with vomiting or passage of a nasogastric tube. Gastric infarction is a surgical emergency, and the patient can be moribund. Gastric necrosis may be extensive or focal. Elective operation for gastric volvulus usually involves reduction of the stomach and gastropexy with or without repair of hiatal hernia. Gastropexy alone should be considered for high-risk patients since it can nearly always be performed laparoscopically and may be surprisingly effective in relieving mechanical symptoms.

GASTROSTOMY

A gastrostomy is performed either for alimentation or for gastric drainage/decompression. Gastrostomy may be done percutaneously, laparoscopically, or via open technique.^{205,206} Currently, percutaneous endoscopic gastrostomy is the most common method used. The open techniques include the Stamm method (Fig. 26-65), the Witzel method (Fig. 26-66), and the Janeway method. The Janeway gastrostomy, designed to create a permanent nondraining gastric stoma that can be intermittently intubated, is more complicated than the other open techniques, and is rarely necessary. By far the most common surgical technique is the Stamm gastrostomy, which can be performed open or laparoscopically.

Complications of gastrostomy include infection, dislodgment, leakage with peritonitis, and aspiration pneumonia. Although gastrostomy tubes usually do prevent tense gastric dilatation, they may not adequately drain the stomach, especially when the patient is bedridden, and they cannot always be relied upon to prevent pulmonary aspiration of gastric contents.

POSTGASTRECTOMY PROBLEMS²⁰⁷

Dumping Syndrome

Dumping is a phenomenon caused by the destruction or bypass of the pyloric sphincter.²⁰⁸ However, other factors undoubtedly play a role because dumping can occur after operations that preserve the pylorus, such as parietal cell vagotomy. Also, an appropriate stimulus may provoke dumping symptoms, even in some patients who have not undergone surgery. Clinically significant dumping occurs in 5% to 10% of patients after pyloroplasty, pyloromyotomy, or gastrectomy, and consists of a constellation of postprandial symptoms ranging in severity from annoying to disabling. The symptoms are thought to be the result of the abrupt delivery of a hyperosmolar load into the small bowel due to ablation of the pylorus or decreased gastric compliance. Typically, 15 to 30 minutes after a meal, the patient becomes diaphoretic, weak, light-headed, and tachycardic. These symptoms may be ameliorated by recumbence or saline infusion. Crampy abdominal pain is not uncommon, and diarrhea often follows. This is referred to as *early dumping* and should be distinguished from postprandial (reactive) hypoglycemia, also called *late dumping*, which usually occurs later (2–3 hours following a meal) and is relieved by the administration of sugar. A variety

Figure 26-66. A through F. Witzel gastrostomy. (Reproduced with permission from Zuidema GD, Yeo CJ: Shackelford's Surgery of the Alimentary Tract, 5th ed. Vol. II. Philadelphia, PA: Elsevier/Saunders; 2002.)

of hormonal aberrations have been observed in early dumping, including increased serum levels of VIP, CCK, neurotensin, peripheral hormone peptide YY, renin-angiotensin-aldosterone, and decreased atrial natriuretic peptide. Late dumping is associated with hypoglycemia and hyperinsulinemia.

Medical therapy for the dumping syndrome consists of dietary modification and somatostatin analogue (octreotide). Often, symptoms improve if the patient avoids liquids during meals. Hyperosmolar liquids (e.g., milk shakes) may be particularly troublesome. There is some evidence that adding dietary fiber compounds at mealtime may improve the syndrome. If dietary manipulation fails, the patient is started on octreotide, 100 µg subcutaneously twice daily. This can be increased up to 500 µg twice daily if necessary. The long-acting depot octreotide preparation is useful. Octreotide not only ameliorates the abnormal hormonal pattern seen in patients with dumping symptoms, but it also promotes restoration of a fasting motility pattern in the small intestine (i.e., restoration of the MMC). The α -glucosidase inhibitor acarbose may be particularly helpful in ameliorating the symptoms of late dumping.

Only a very small percentage of patients with dumping symptoms ultimately require surgery. Most patients improve with time (months and even years), dietary management, and medication. Therefore, the surgeon should not rush to reoperate on the patient with dumping symptoms. Multidisciplinary nonsurgical management must be optimized first. Before reoperation, a period of in-hospital observation is useful to define the severity of the patient's symptoms and patient compliance with prescribed dietary and medical therapy.

The results of remedial operation for dumping are variable and unpredictable. There are a variety of surgical approaches, none of which work consistently well. Additionally, there is not a great deal of experience reported in the literature with any of these methods and long-term follow-up is rare. Patients with disabling refractory dumping after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is patent. The reversed intestinal segment is rarely used today—and rightly so. This operation interposes a 10-cm reversed segment of intestine between the stomach and the proximal small bowel. This slows gastric emptying, but often leads to obstruction, requiring reoperation. Isoperistaltic interposition (Henley loop) has not been successful in ameliorating severe dumping over the long term. The Roux-en-Y gastrojejunostomy is associated with delayed gastric emptying, probably on the basis of disordered motility in the Roux limb. Taking advantage of this disordered physiology, surgeons have used this operation successfully in the management of the dumping syndrome. Although this is probably the procedure of choice in the small group of patients requiring operation for severe dumping following gastric resection, gastric stasis may result, particularly if a large gastric remnant is left. In the presence of significant gastric acid secretion, marginal ulceration is common after both jejunal interposition and Roux-en-Y procedures; thus, concomitant vagotomy and hemigastrectomy should be considered. The theoretical possibility of treating postpyloroplasty dumping with a Roux-en-Y to the proximal duodenum (the duodenal switch, a potentially reversible operation) has not yet been reported (Fig. 26-67). Because pyloric ablation seems to be the dominant factor in the etiology of dumping, it is not surprising that conversion of Billroth II to Billroth I anastomosis has not been successful in the treatment of dumping.

Figure 26-67. Duodenal switch operation. (Reproduced with permission from Hinder RA: *Duodenal switch: a new form of pancreaticobiliary diversion*, *Surg Clin North Am.* 1992 Apr;72(2):487-499.)

Diarrhea

Diarrhea following gastric surgery may be the result of truncal vagotomy, dumping, or malabsorption. Truncal vagotomy is associated with clinically significant diarrhea in 5% to 10% of patients. It occurs soon after surgery and usually is not associated with other symptoms, a fact that helps to distinguish it from dumping. The diarrhea may be a daily occurrence, or there may be significant periods of relatively normal bowel function. The symptoms tend to improve over the months and years after the index operation. The cause of postvagotomy diarrhea is unclear. Possible mechanisms include intestinal dysmotility and accelerated transit, bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth. The latter problem is facilitated by decreased gastric acid secretion and (even small) blind loops. Although bacterial overgrowth can be confirmed with the hydrogen breath test, a simpler test is an empirical trial of oral antibiotics. Some patients with postvagotomy diarrhea respond to cholestyramine, while in others codeine or loperamide may be useful. Octreotide should also be tried. Another theoretical cause of diarrhea following gastric surgery is fat malabsorption due to acid inactivation of pancreatic enzymes or poorly coordinated mixing of food and digestive juices. This can be confirmed with a qualitative test for fecal fat and treated with acid suppression. Postvagotomy diarrhea usually does not respond to treatment with pancreatic enzymes. In the rare patient who is debilitated by postvagotomy diarrhea unresponsive to medical management, operation might be considered, but outcomes can be problematic. The operation of choice is probably a 10-cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz. Another option is the onlay antiperistaltic distal ileal graft. Both operations can cause obstructive symptoms and/or bacterial overgrowth.²⁰⁹

Gastric Stasis^{210,211}

Gastric stasis following surgery on the stomach may be due to a problem with gastric motor function or caused by an obstruction. The gastric motility abnormality could have been preexisting and unrecognized by the operating surgeon. Alternatively,

it may be secondary to deliberate or unintentional vagotomy, or resection of the dominant gastric pacemaker. An obstruction may be mechanical (e.g., anastomotic stricture, efferent limb kink from adhesions or constricting mesocolon, or a proximal small-bowel obstruction) or functional (e.g., retrograde peristalsis in a Roux limb). Gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss.

The evaluation of a patient with suspected postoperative gastric stasis includes EGD, upper GI and small bowel series, gastric emptying scan, and gastric motor testing. Endoscopy shows gastritis and retained food or bezoar. The anastomosis and efferent limb should be evaluated for stricture or narrowing. A dilated efferent limb suggests chronic stasis, either from a motor abnormality (e.g., Roux syndrome) or mechanical small bowel obstruction (e.g., chronic adhesion). If the problem is thought to be primarily a disorder of intrinsic motor function, newer techniques such as EGG and GI manometry should be considered, but chronic distal mechanical obstruction may result in disordered motility in the proximal organ confounding interpretation.

Once mechanical obstruction has been ruled out, medical treatment is successful in most cases of motor dysfunction following previous gastric surgery. This consists of dietary modification and promotility agents. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth, with its attendant symptoms of bloating, flatulence, and diarrhea.

Gastroparesis following V + D may be treated with subtotal gastrectomy but simple loop gastrojejunostomy (GJ) should be tried if previous drainage was pyloroplasty. Billroth II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction after subtotal gastrectomy for gastric stasis, but bile reflux can still occur. Initial operation for gastric stasis is often associated with persistent gastric emptying problems that may subsequently require near-total or total gastrectomy, a nutritionally unattractive option. Delayed gastric emptying following ulcer surgery (V + D or V + A) may represent an anastomotic stricture (often due to recurrent ulcer) or proximal small bowel obstruction. Recurrent ulcer may respond to medical therapy with PPI and abstinence from NSAIDs, aspirin, and smoking. And if necessary, endoscopic dilation is occasionally helpful. However, when associated with symptomatic gastric stasis, reoperation is often necessary. Gastroparesis following subtotal gastric resection is best treated with near-total (95%) or total gastric resection and Roux-en-Y reconstruction. If total gastrectomy is performed, a jejunal reservoir should be considered. Gastric pacing is promising, but it has not achieved widespread clinical usefulness in the treatment of postoperative gastric atony.

Bile Reflux Gastritis and Esophagitis

Most patients who have undergone ablation or resection of the pylorus have bile in the stomach on endoscopic examination, along with some degree of gross or microscopic gastric inflammation. Therefore, attributing postoperative symptoms to bile reflux is problematic because most asymptomatic patients have bile reflux too. However, it is generally accepted that a small subset of patients have bile reflux gastritis syndrome. These patients present with nausea, bilious vomiting, and epigastric pain, and quantitative evidence of excess enterogastric reflux. Curiously, symptoms often develop months or years after the index operation. The differential diagnosis includes afferent or efferent loop obstruction, gastric stasis, and small-bowel

obstruction. Plain abdominal X-rays, upper endoscopy, upper GI series, abdominal CT scan, and gastric emptying scans are helpful in evaluating these possibilities.

Bile reflux may be quantified with gastric analysis or esophageal impedance testing or with scintigraphy (bile reflux scan). Typically, enterogastric reflux is greatest after Billroth II gastrectomy or gastrojejunostomy, and least after vagotomy and pyloroplasty, with Billroth I gastrectomy giving intermediate values. Patients who are well into the abnormal range of bile reflux may be considered for remedial surgery if symptoms are severe. Remedial surgery will eliminate the bile from the vomitus and may improve the patient's pain, but it is quite unusual to render these patients completely asymptomatic, especially if they are narcotic dependent.

Bile reflux gastritis after distal gastric resection may be treated by one of the following options: Roux-en-Y gastrojejunostomy; interposition of a 40-cm isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop); Billroth II gastro jejunostomy with Braun enteroenterostomy; total gastrectomy with Roux esophagojejunostomy. To minimize reflux of bile into the stomach or the esophagus, the Roux limb should be at least 45 cm long (preferably 60 cm). The Braun enteroenterostomy should be placed at a similar distance from the stomach. Excessively long limbs may be associated with obstruction or malabsorption. All of these operations can result in marginal ulceration on the jejunal side of the gastrojejunostomy and thus are combined with a generous distal gastrectomy. If this has already been done at a previous operation, the Roux or Braun operations may be attractively simple. Whether truncal vagotomy should be considered to decrease the risk of marginal ulceration is controversial because acid-suppressing medications may be equally effective. In addition, the benefits of decreased acid secretion following vagotomy may be outweighed by problems with vagotomy-associated dysmotility in the gastric remnant. The Roux operation may be associated with an increased risk of emptying problems compared to the other two options, but controlled data are lacking. Patients with debilitating bile reflux after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is open.

Primary bile reflux gastritis (i.e., no previous operation) is rare, and may be treated with the duodenal switch operation, essentially an end-to-end Roux-en-Y to the proximal duodenum (see Fig. 26-68). The Achilles' heel of this operation is, not surprisingly, marginal ulceration. Thus, it should be combined with highly selective vagotomy, and/or long-term acid suppressive medication.

Bile gastritis or esophagitis is a recognized complication after esophagogastrectomy with or without pyloroplasty. This can be effectively treated by division of the duodenum immediately distal to the pylorus with drainage of the prepyloric antrum into a Roux limb. Preservation of the right gastroepiploic pedicle is important. Proximal subtotal gastrectomy with esophago-antral anastomosis should be avoided, but when performed, the pylorus should be left intact.

Roux Syndrome

A subset of patients who have had distal gastrectomy and Roux-en-Y gastrojejunostomy will have great difficulty with gastric emptying in the absence of mechanical obstruction. These patients present with vomiting, epigastric pain, and weight loss. This clinical scenario has been labeled the

Roux syndrome. Endoscopy may show retained food or bezoars, dilation of the gastric remnant, and/or dilation of the Roux limb. Anastomotic inflammation and stricture from marginal ulceration is a confounding finding. An upper GI series confirms these findings and may show delayed gastric emptying. This is better quantified by a gastric emptying scan, which always shows delayed solid emptying and may show delayed liquid emptying as well.

GI motility testing shows abnormal motility in the Roux limb, with much of the propulsive activity toward, rather than away from, the stomach.²¹² Gastric motility also may be abnormal. Presumably, the disordered motility in the Roux limb occurs in all patients with this operation. Why only a subset develops the Roux syndrome is unclear. Perhaps patients with disordered gastric motility are at most risk. The disorder seems **10►** to be more common in patients with a generous gastric remnant. Truncal vagotomy also has been implicated.

Medical treatment consists of promotility agents. Surgical treatment consists of paring down the gastric remnant. Care should be taken to preserve adequate blood supply to the new gastric pouch. If the left gastric artery is intact, a vertically oriented lesser curvature based pouch (similar to gastric bypass) with excision of the fundus can be considered. If gastric motility is severely disordered, 95% gastrectomy or total gastrectomy should be considered. The Roux limb should be resected if it is dilated and flaccid, unless doing so puts the patient at risk for short bowel.

Gallstones

Gallstone formation following gastric surgery generally is thought to be secondary to vagal denervation of the gallbladder with attendant gallbladder dysmotility and stasis. Although prophylactic cholecystectomy is not justified with most gastric surgery, it should be considered if the gallbladder appears abnormal, especially if subsequent cholecystectomy is likely to be difficult. If preoperative evaluation reveals sludge or gallstones, or if intraoperative evaluation reveals stones, incidental cholecystectomy should be considered.

Weight Loss

Weight loss is common in patients who have had a vagotomy and/or gastric resection. The degree of weight loss tends to parallel the magnitude of the operation. It may be insignificant in the obese but devastating in the asthenic patient. The surgeon should always consider the possible nutritional consequences before performing a gastric resection for benign disease in a thin patient. The causes of weight loss after gastric surgery generally fall into one of two categories: altered dietary intake or malabsorption. If a stool stain for fecal fat is negative, it is likely that decreased caloric intake is the cause. This is the most common cause of weight loss after gastric surgery, and it may be due to small stomach syndrome, postoperative gastroparesis, anorexia due to loss of ghrelin, or self-imposed dietary modification because of dumping and/or diarrhea. Consultation with an experienced dietitian may prove invaluable.

Anemia

Iron absorption takes place primarily in the proximal GI tract, and it is facilitated by an acidic environment. Intrinsic factor, essential for the enteric absorption of vitamin B₁₂, is made by the parietal cells of the stomach. Vitamin B₁₂ bioavailability also is facilitated by an acidic environment. Folate-rich vegetables may be poorly tolerated if gastric emptying is delayed or if

gastric capacity is limited. Since iron, B₁₂, and folate play vital roles in hematopoiesis, it is easy to understand why patients who have had a gastric operation are at risk for anemia. Anemia is the most common metabolic side effect in patients who have had a gastric bypass for morbid obesity. It also occurs in up to one-third of patients who have had a vagotomy and/or gastric resection. Iron deficiency is the most common cause, but vitamin B₁₂ or folate deficiency also occurs, even in patients who have not had total gastrectomy. Of course, patients who have had a total gastrectomy will all develop B₁₂ deficiency without some type of regular nonenteral vitamin B₁₂ administration. Gastric bypass patients should be given oral iron supplements and monitored for iron, B₁₂, and folate deficiency. Patients who have had a vagotomy and/or gastrectomy should be similarly monitored with periodic determination of hematocrit, red blood cell indices, iron and transferrin levels, B₁₂, and folate levels. Marginal nutrient status should be corrected with oral and/or parenteral supplementation.

Bone Disease

Gastric surgery sometimes disturbs calcium and vitamin D metabolism. Calcium absorption occurs primarily in the duodenum, which is bypassed with gastrojejunostomy. Fat malabsorption may occur because of blind loop syndrome and bacterial overgrowth or because of inefficient mixing of food and digestive enzymes. This can significantly affect the absorption of vitamin D, a fat-soluble vitamin. Both abnormalities of calcium and vitamin D metabolism can contribute to metabolic bone disease in patients following gastric surgery. The problems usually manifest as pain and/or fractures many years after the index operation. Musculoskeletal symptoms should prompt a study of bone density. Dietary supplementation of calcium and vitamin D may be useful in preventing these complications. Routine skeletal monitoring of patients at high-risk (e.g., elderly males and females and postmenopausal females) may prove useful in identifying skeletal deterioration that may be slowed or stopped with appropriate treatment after gastric surgery.

LAPAROSCOPIC GASTRIC OPERATIONS

The most common laparoscopic gastric operations performed today are for GERD and obesity. However, all conventional gastric operations can be performed with minimal access techniques.²¹³ Some are more technically challenging (e.g., partial or total gastric resection) are of debatable advantage over conventional open approaches. Certainly, highly selective vagotomy, vagotomy and gastrojejunostomy, and gastrostomy lend themselves to a minimal access approach. Laparoscopic local excision is often feasible for GI stromal tumors, leiomyomas, or gastric diverticula. Difficult to access lesions near the GE junction or pylorus may be removed through an anterior gastrotomy; more recent approaches utilizing transgastric ports or combined laparoscopic and endoscopic approaches show promise in allowing removal of practically any small gastric lesion with limited incisions.

In Japan and Korea, laparoscopic and robotic assisted approaches have been applied increasingly in the management of gastric cancer.^{214,215} Indeed, laparoscopic subtotal gastrectomy has supplanted the traditional open operation as the preferred operation for patients with earlier stage tumors, and laparoscopic total gastrectomy for proximal tumors is performed with regularity and excellent outcomes. The Asian experience

has firmly established the feasibility of safe laparoscopic D2 gastrectomy. Translation of this experience to the United States, however, is not easily accomplished. Studies from Asia suggest that expertise in the laparoscopic approach require upwards of 40 cases, a challenging baseline given the much lower incidence of gastric cancer in the United States.²¹⁶⁻²¹⁹ A more advanced spectrum of disease and higher mean BMI in Western countries are additional barriers to widespread implementation of laparoscopic resection for gastric cancer. Notwithstanding, several high volume centers in the United States have reported excellent outcomes after laparoscopic gastrectomy. As robotic technology that facilitates dissection and anastomosis with articulated instrumentation and enhanced visualization becomes increasingly ubiquitous, the pendulum will likely swing toward increasing utilization of minimal access approaches for all gastric operations.²²⁰

INTRODUCTION

Despite the global pandemic of obesity, there has been little progress in nonsurgical treatment approaches, especially among patients with severe obesity. In addition, the evidence base for bariatric procedures has grown rapidly over the last 10 years, yielding important short- and long-term data on the safety and efficacy of the surgical treatment for obesity and related metabolic disorders. Therefore, the approach for patients considering bariatric and metabolic surgery has now shifted to a well-informed and shared decision-making process as there are significant tradeoffs between the potential risks and benefits of these procedures.¹

History

During the 1950s, operations were first performed to treat severe hyperlipidemia with associated obesity.² These were ileocolic bypass operations to limit absorption and were associated with severe nutritional complications and liver failure postoperatively. A more modest jejunoileal bypass was performed next, also a malabsorptive operation, but it bypassed only a portion of the small intestine. Complications after this procedure included

severe diarrhea, electrolyte disturbances, protein-calorie malnutrition, renal stones, and liver failure.

In 1969, Mason and Ito performed the first gastric bypass, describing a loop of jejunum connected to a transverse proximal gastric pouch.³ Bile reflux esophagitis was severe postoperatively, causing Griffin and colleagues to describe the Roux-en-Y modification of the gastric bypass in 1977.⁴ The gastric pouch was also altered from transverse to vertical using the upper lesser curvature at this time (Fig. 27-1).

In 1980, Mason⁵ first performed the vertical banded gastroplasty (VBG), which was a restrictive procedure using a stapled proximal gastric pouch of the upper lesser curvature of the stomach with a restrictive band for its outlet to the rest of the stomach. This operation produced excellent initial weight loss (50% of excess weight or more) with low morbidity and mortality. It rapidly became the most commonly performed bariatric operation in the United States during the 1980s. However, by the early 1990s, it became clear that patients who underwent VBG modified their diets to high-calorie soft foods and liquids and some regained weight.⁶ A significant incidence of stenosis at the cuff and staple line

Key Points

- 1▶ Sixty-five percent of the world’s population live in countries where overweight and obesity are linked to more deaths than underweight and malnutrition. Obesity is the second leading cause of preventable death in adults in the United States.
- 2▶ There is an ongoing major shift in procedure utilization with the sleeve gastrectomy and Roux-en-Y gastric bypass being the two most common procedures, worldwide.
- 3▶ The former classification of bariatric operations as either “restrictive” or “malabsorptive” is being replaced by knowledge from investigation into the more basic physiologic and metabolic mechanisms responsible for the effects of bariatric surgery.
- 4▶ Patients who develop a bowel obstruction after laparoscopic gastric bypass require surgical and not conservative therapy due to the high incidence of internal hernias and the potential for bowel infarction.
- 5▶ Malabsorptive operations are highly effective in producing durable weight loss and metabolic improvements but have higher surgical complication rates and considerable nutritional side effects. Patients undergoing such procedures require complete follow-up and appropriate nutritional supplements.
- 6▶ Large, longer-term observational studies of bariatric surgery have shown durable weight loss, diabetes remission, lipid improvements, and improved survival with bariatric surgery. Still unclear are specific pre- and postoperative predictors of those outcomes, long-term complications, microvascular and macrovascular events, mental health outcomes, and costs.
- 7▶ High quality data have clearly established that bariatric procedures are more effective than medical or lifestyle interventions for inducing weight loss and initial remission of type 2 diabetes, even in less obese patients. Randomized clinical trials showed greater weight loss and type 2 diabetes mellitus remission following bariatric surgery compared with nonsurgical treatments.
- 8▶ The incidence of complications after bariatric surgery varies from 4% to over 25% and depends on the duration of follow-up, the definition of complication used, the type of bariatric procedure performed, and individual patient characteristics.
- 9▶ Emerging areas in bariatric surgery include the use of intermediate weight loss devices, adolescent bariatric surgery, and the increase in the need for revision and conversion bariatric procedures.

disruptions was also problematic.⁷ Long-term weight loss was poor,⁸ and by the 1990s in the United States, Roux-en-Y gastric bypass (RYGB) became the procedure of choice for bariatric surgery.

In the meantime, in Italy Scopinaro had developed and popularized the biliopancreatic diversion (BPD) in the early 1980s.⁹ This procedure was also modified to include duodenal switch (DS),¹⁰ the only major malabsorptive operation currently in use.

The laparoscopic approach to bariatric surgery became available in the 1990s, and Belachew performed the first laparoscopic adjustable gastric banding (LAGB) operation in 1994.¹¹ Wittgrove and Clark performed the first laparoscopic RYGB the same year.¹² LAGB was commonly performed in Europe and Australia during the late 1990s, and in 2001 it was approved for use in the United States. Sleeve gastrectomy (SG) as a primary bariatric operation has grown rapidly in use since 2008.

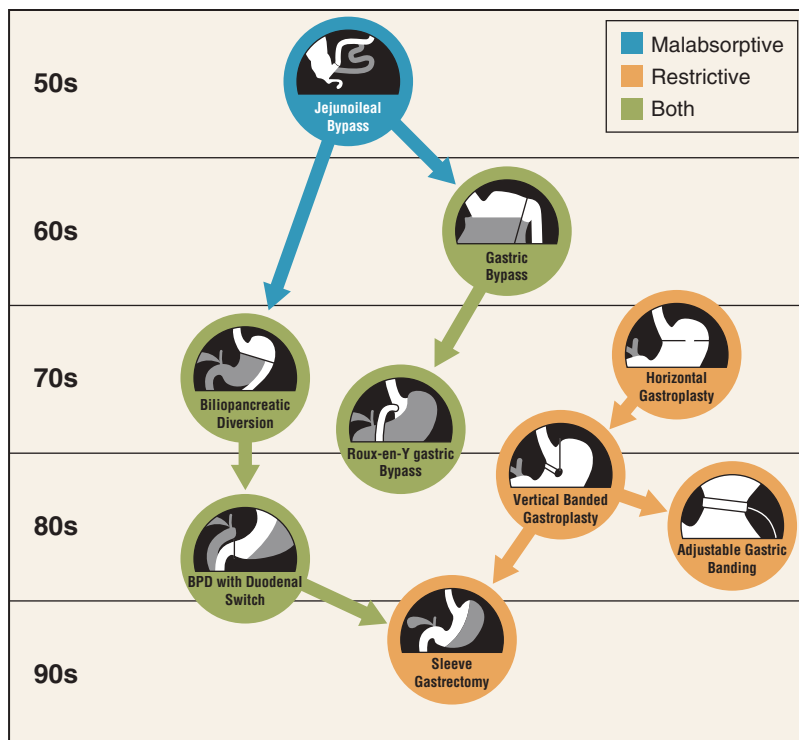

Figure 27-1. History of bariatric surgery. (Reproduced with permission from Arterburn DE, Courcoulas AP: Bariatric surgery for obesity and metabolic conditions in adults, BMJ. 2014 Aug 27;349:g3961.)

State of the Field

There has been an ongoing major shift in bariatric procedures both in the United States and worldwide¹³ with the rapid adoption of the laparoscopic sleeve gastrectomy and the simultaneous decreasing utilization of the laparoscopic adjustable gastric banding procedure (Fig. 27-2). International trends in the utilization of bariatric surgical procedures have also been published. These show that the total number of bariatric surgical procedures performed in 2014 was 579,517. The three most commonly performed procedures in the world were SG at 46%, followed by RYGB (40%), and LAGB (7%). The annual percentage changes from 2013 show an increased utilization of SG and a decreased use of RYGB in the United States, Canada, Europe, and Asia and Pacific countries. In Central and South America, however, the use of SG decreased, and RYGB was most commonly used.¹⁴

Extension of the indication from bariatric surgery for weight loss to *metabolic surgery* to treat type 2 diabetes (T2DM) even in patients with less than severe obesity has been another more recent development, driven by the availability of more level 1 data.^{15,16}

Also, considerable effort is now being devoted to the study of the basic physiologic mechanisms underlying weight loss and, perhaps more importantly, the resolution of comorbid medical problems associated with obesity. Despite the classic “restrictive” and “malabsorptive” anatomic conceptualizations of bariatric surgical procedures (see Fig. 27-1), there is much ongoing research in animal and human models towards understanding the specific underlying mechanisms of action, which may be more physiologic in nature.¹⁷ Some of the potential candidates for the mechanisms of action of bariatric procedures include

alterations in ghrelin, leptin, glucagon-like peptide-1 (GLP-1), cholecystokinin, peptide YY (PYY), gut microbiota, and bile acids. In the future, bariatric procedures will not be described by anatomic surgical similarities but by how they affect key physiological variables, which will provide greater mechanistic insight into how the procedures actually work.

THE DISEASE OF OBESITY

Overview

Worldwide obesity has more than doubled since 1980. In 2014, 39% of adults age 18 years and over (38% of men and 40% of women) were overweight, and 13% of the world’s adult population (11% of men and 15% of women) were obese. In 2014, an estimated 41 million children under the age of 5 years were overweight or obese.¹⁸ Overweight and obesity are now on the rise in low- and middle-income countries, particularly in urban settings. Currently, 65% of the world’s population live in countries where overweight and obesity are linked to more deaths than underweight and malnutrition. Obesity is the second leading cause of preventable death in adults in the United States, after tobacco use.¹⁹

The degrees of obesity are defined by body mass index (BMI = weight [kg]/height [m]²), which correlates body weight with height. The World Health Organization international classification of overweight and obesity is shown in Table 27-1. It should be noted that for Asian populations, classifications remain the same as the international classification, but the public health action points for interventions are set at a lower BMI threshold. For children, age needs to be considered when defining overweight and obesity, so for children age 5 to 19 years,

Figure 27-2. Changes in bariatric procedure utilization. (Reproduced with permission from Reames BN, Finks JF, Bacal D, et al: *Changes in bariatric surgery procedure use in Michigan, 2006-2013*, JAMA. 2014 Sep 3;312(9):959-961.)

Table 27-1

The international classification of adult overweight and obesity according to body mass index (BMI)

CLASSIFICATION	BMI (kg/m ²)	
	PRINCIPAL CUTOFF POINTS	ADDITIONAL CUTOFF POINTS ^a
Normal range	18.50–24.99	18.50–22.99 23.00–24.99
Overweight	≥25.00	≥25.00
Preobese	25.00–29.99	25.00–27.49 27.50–29.99
Obese	≥30.00	≥30.00
Obese class I	30.00–34.99	30.00–32.49 32.50–34.99
Obese class II	35.00–39.99	35.00–37.49 37.50–39.99
Obese class III	≥40.00	≥40.00

^aFor Asian populations, classifications remain the same as the international classification, but public health action points for interventions are set at 23, 27.5, 32.5, and 37.5 kg/m². Data from WHO, 1995, WHO, 2000 and WHO 2004.

overweight is BMI-for-age greater than 1 standard deviation above the World Health Organization (WHO) growth reference median, and obesity is greater than 2 standard deviations above the WHO growth reference median.

The fundamental cause of obesity and overweight is an energy imbalance between calories consumed and calories expended. Globally, there has been an increased intake of energy-dense foods that are high in fat and a decrease in physical inactivity due to the increasingly sedentary nature of many forms of work, changing modes of transportation, and increasing urbanization. These changes in dietary and physical activity patterns are the result of both societal and environmental changes associated with development. There is also a dearth of supportive policies to counteract these forces in sectors such as health, agriculture, transport, urban planning, environment, food processing, marketing, and education. Obesity as a disease was recognized by the American Medical Association in 2013. It is multifactorial in its etiology, and the components of the disease likely include a combination of both environmental and genetic factors.

U.S. Prevalence of Obesity

According to the 2013–2014 National Health and Nutrition Examination Survey (NHANES) data, in the United States the overall age-adjusted prevalence of obesity was 37.7% (95% confidence interval [CI], 35.8–39.7%); among men, it was 35.0% (95% CI, 32.8–37.3%); and among women, it was 40.4% (95% CI, 37.6–43.3%). The corresponding prevalence of class III obesity overall was 7.7% (95% CI, 6.2–9.3%); among men, it was 5.5% (95% CI, 4.0–7.2%); and among women, it was 9.9% (95% CI, 7.5–12.3%). Changes over the decade from 2005 through 2014, adjusted for age, race, smoking status, and education, showed significantly increasing trends among women for overall obesity and for class III obesity, but not among men.²⁰

For children in the United States, obesity is defined as a BMI at or above the sex-specific 95th percentile, and extreme obesity is defined as a BMI at or above 120% of the sex-specific 95th percentile on the U.S. Centers for Disease Control and Prevention (CDC) BMI-for-age growth charts. In the most recent NHANES study of U.S. children and adolescents age 2 to 19 years, the prevalence of obesity from 2011 to 2014 was 17.0%, and extreme obesity was 5.8%.²¹

Causes of Obesity

Both genetic and environmental factors contribute to the development of obesity. Not everyone exposed to the prevailing environment becomes obese, suggesting that genetic mechanisms are operating at the individual level. Estimates vary, but twin, family, and adoption studies show that the rate of heritability of BMI is high, ranging from 40% to 70%.^{22,23} Eleven rare and monogenic forms of obesity are now recognized, including a deficiency of the leptin and melanocortin-4 receptors, which are expressed in the hypothalamus and are involved in regulating energy homeostasis.²⁴ Heterozygous mutations in the melanocortin-4 receptor gene are currently the most common cause of monogenic obesity, causative in 2% to 5% of children with severe obesity.

Genes and environment interact in a complex process that regulates energy balance and weight. Reducing food intake or increasing physical activity leads to a negative energy balance and a cascade of compensatory adaptive mechanisms that

preserve vital functions and are associated with reductions in resting energy expenditure, food preoccupation, and many other changes that depend on the amount and duration of caloric restriction. There is also a counterregulatory increase in appetite and food intake that limits the degree of expected weight loss that is associated with interventions such as exercise programs.²²

Individuals with obesity have excessive adipose cells, both in size and number. The number of such cells often is determined early in life; adult-onset obesity is largely a product of increase in adipose cell size. Weight gain results from increase in both adipose cell size and number. Adipose tissue may be deposited in large quantities in the subcutaneous layer of the abdominal wall or the viscera. Generally, males tend to have central visceral fat distribution, whereas females more often have a peripheral fat distribution. Central or visceral fat distribution is associated with metabolic diseases such as diabetes, hypertension, and the metabolic syndrome.

Concurrent Medical and Social Problems

Raised BMI is a major risk factor for diseases such as cardiovascular disease (mainly heart disease and stroke), which were the leading cause of death in 2012, diabetes, osteoarthritis, some cancers (including endometrial, breast, ovarian, prostate, liver, gallbladder, kidney, and colon).¹⁸ The risk for these conditions increases with increases in BMI. Childhood obesity is associated with a higher chance of obesity, premature death, and disability in adulthood. In addition to increased future risks, children with obesity experience sleep apnea, increased risk of fractures, hypertension, early markers of cardiovascular disease, insulin resistance, and psychological effects.

The severely obese patient typically presents with multiple chronic and weight-related problems or comorbidities/comorbid conditions. These include degenerative joint disease, low back pain, hypertension, obstructive sleep apnea, gastroesophageal reflux disease (GERD), cholelithiasis, T2DM, dyslipidemia, asthma, hypoventilation syndrome of obesity, right-sided heart failure, migraine headaches, pseudotumor cerebri, venous stasis ulcers, deep venous thrombosis (DVT), fungal skin rashes, skin abscesses, stress urinary incontinence, infertility, dysmenorrhea, depression, and large abdominal wall hernias.

There are anatomical, metabolic, and physiological effects of obesity through which this excess adiposity leads to disease risk factors and chronic diseases themselves (Fig. 27-3).²² Subcutaneous adipose tissue holds most of the stored lipid at a variety of anatomical sites while visceral adipose tissue is a smaller storage compartment with omental and mesenteric fat mechanically linked to some of the metabolic disturbances and adverse consequences outcomes associated with obesity.^{25,26} Adipose tissue surrounds and compresses the renal parenchyma and may contribute to the hypertension frequently observed in patients who are obese.²⁷ Obesity is frequently accompanied by an increase in pharyngeal soft tissues, which can lead to obstructive sleep apnea.²⁸ Excess adiposity also imposes a significant mechanical load on joints, making it a risk factor for the development of osteoarthritis.²⁹ An increase in intraabdominal pressure likely accounts for the elevated risks of gastroesophageal reflux disease (GERD), Barrett's esophagus, and esophageal adenocarcinoma among those with obesity.³⁰ Chronic overactivity of the sympathetic nervous system is present in some patients with obesity and may contribute to pathophysiological processes, including high blood pressure.²⁷ Obesity is also associated with an increased prevalence of mood, anxiety, and other psychiatric disorders, especially

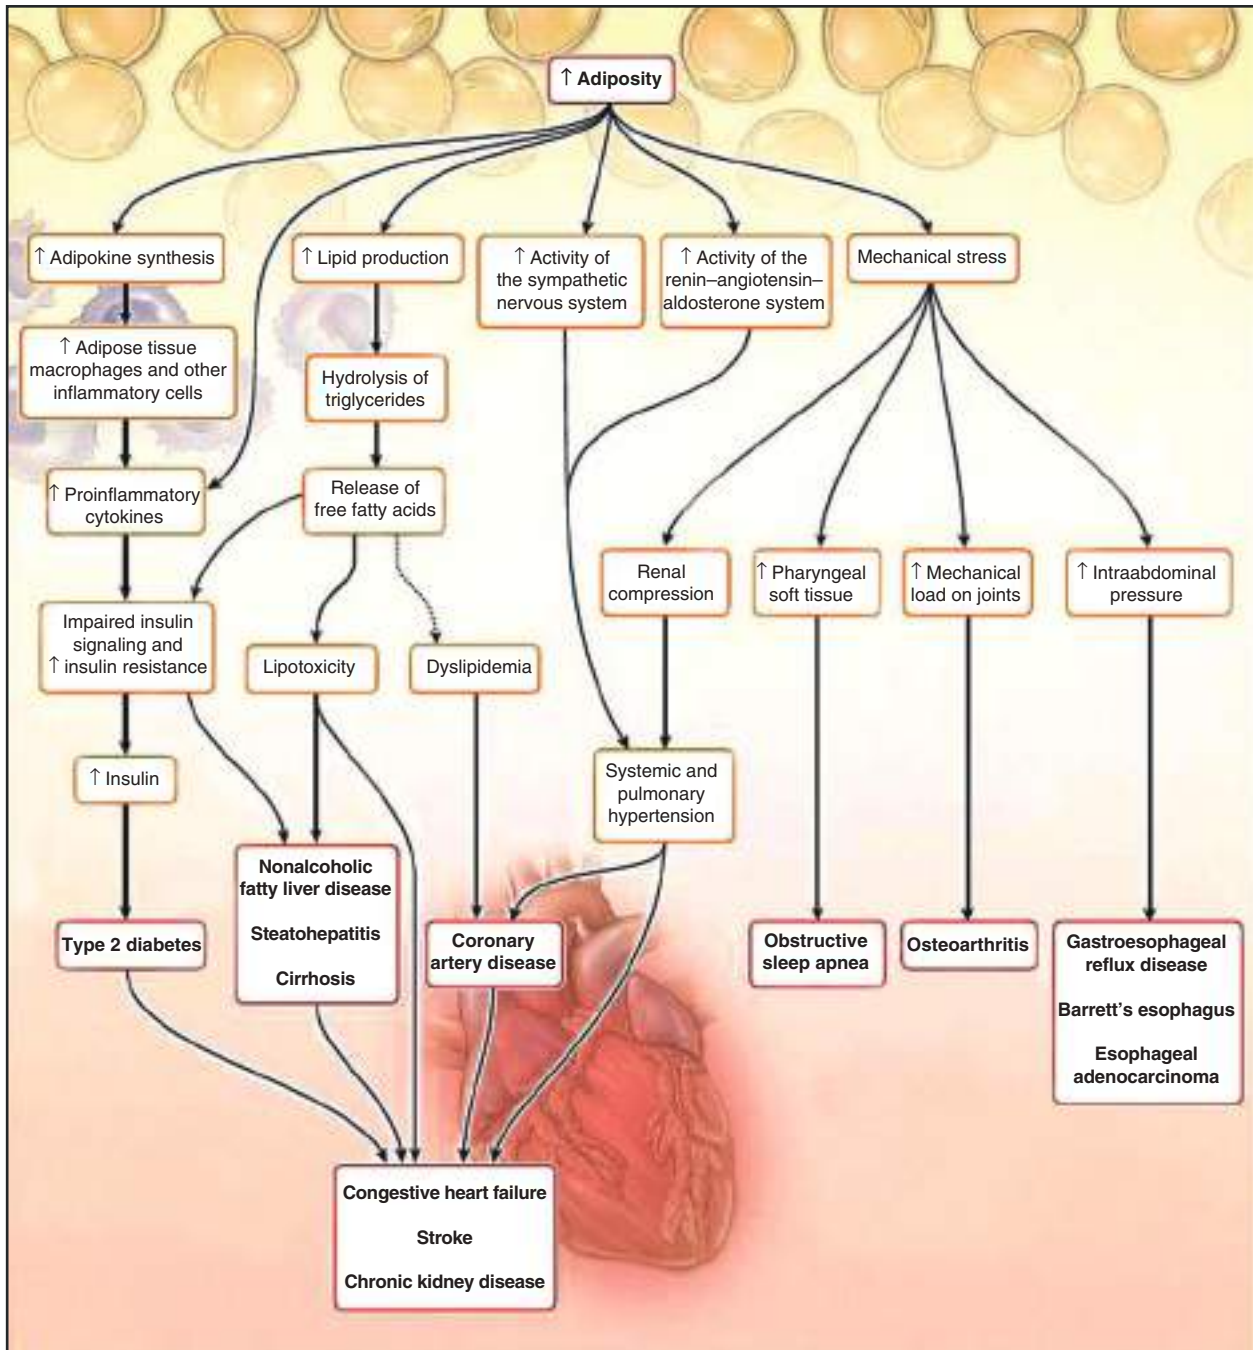

Figure 27-3. Pathways through which obesity leads to major risk factors and common chronic diseases. Common chronic diseases are shown in red boxes. The dashed arrows indicate an indirect association. (Reproduced with permission from Heymsfield SB, Wadden TA: *Mechanisms, Pathophysiology, and Management of Obesity*, N Engl J Med. 2017 Jan 19;376(3):254-266.)

among persons with severe obesity and in those seeking bariatric surgery.³¹⁻³³ Decreased quality of life also results due to severe obesity. Most patients seeking surgical treatment of severe obesity do so because of the medical issues they face from comorbid conditions or the decreased quality of life they are experiencing as a result of severe obesity.

MEDICAL MANAGEMENT OF OBESITY

Treatments should be aligned with the severity of obesity, associated comorbid conditions, and the individual's functional limitations. There are guidelines available to evaluate an individual's health risks and potential treatment options.^{34,35} Three

main treatment options exist with sufficient evidence-based support: lifestyle intervention, pharmacotherapy, and bariatric surgery.

Lifestyle Intervention

Lifestyle interventions designed to modify eating behaviors and physical activity are the first option for weight management, given their low cost and low risk.³⁵ Behavioral therapy, the core of any lifestyle intervention, provides patients with techniques for adopting dietary and activity recommendations. Among these recommendations are regular recording of food intake, physical activity, and weight. Patients review their progress approximately weekly with a trained interventionist

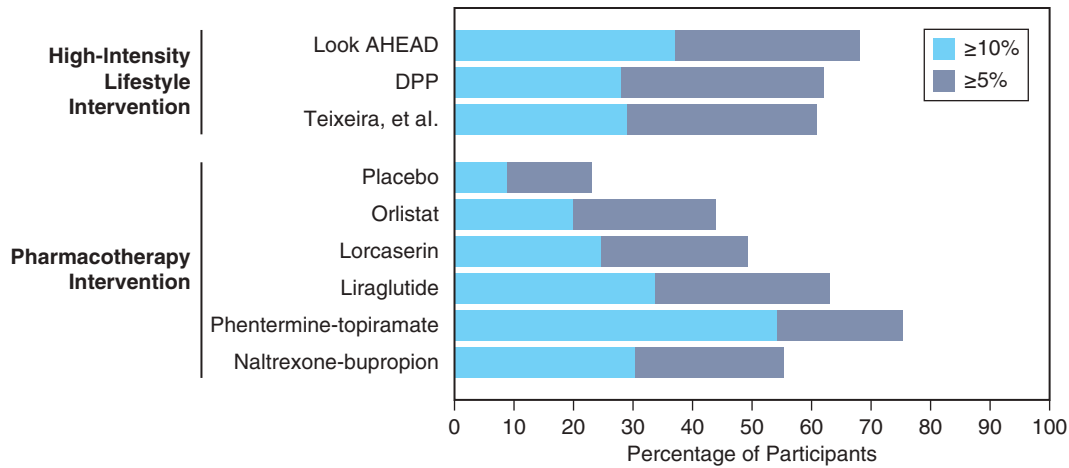

Figure 27-4. ²²Percent weight loss at 1 year with intensive lifestyle interventions or pharmacotherapy combined with lower level lifestyle. Shown are the percentages of participants in randomized, controlled trials who had weight loss of at least 5% or at least 10% of their initial weight at 1 year after intensive lifestyle intervention or pharmacotherapy that typically was combined with lower-intensity lifestyle. Percentages shown are cumulative; the percentage of participants who lost at least 5% of their initial weight includes the percentage who lost at least 10%. Additional data on the percentage of participants with weight loss at 1 year of at least 15% of their initial weight were available for the Look AHEAD³⁶ study (16%), the DPP³⁹ trial (11%), liraglutide⁴⁰ (14%), phentermine–topiramate (32%), and naltrexone–bupropion (14%). (*Reproduced with permission from Heymsfield SB, Wadden TA: Mechanisms, Pathophysiology, and Management of Obesity, N Engl J Med. 2017 Jan 19;376(3):254-266.*)

who provides support and encouragement, help setting goals, and problem-solving instructions.³⁵ This type of comprehensive program results in a mean weight loss of 5% to 8%, and approximately 60% to 65% of patients lose 5% or more of initial weight. The Look AHEAD study randomized 5145 adults with obesity to either an intensive lifestyle intervention (ILI) or to a diabetes support group and education group (DSE) to assess the impact on weight loss, T2DM, and cardiovascular outcomes. At 1 year, the intensive intervention group lost an average of 8.6% initial weight compared to 0.7% in the support and education group. As shown in Fig. 27-4, 68% of participants in the Look AHEAD study lost at least 5% of their initial weight, and 37% of these participants lost at least 10%. Also at 1 year, participants undergoing the more intensive program experienced improved cardiovascular risk factors and glycemic control.³⁶

At 4 years, participants in the intensive intervention group experienced more weight loss (−6.15% ILI compared to −0.88% DSE), better glycemic control, fitness, and an improvement in cardiovascular risk factors.³⁷ Nevertheless, the beneficial clinical effects of the improved weight loss achieved with intensive lifestyle intervention did not reduce morbidity and mortality associated with cardiovascular disease after 9.6 years when the Look AHEAD study was stopped due to futility for that primary endpoint.³⁸ Figure 27-4 shows a comparison of several lifestyle intervention trials (Look AHEAD, the Diabetes Prevention Program [DPP] trial,³⁹ and the trial reported by Teixeira et al⁴⁰) for >5% and >10% weight loss outcomes. These trials, specifically, were selected because they were judged to be good quality by the Guidelines (2013) for the Management of Overweight and Obesity in Adults and because the trial data were reported as categorical weight loss. Categorical weight loss data from the DPP trial were provided by the DPP Research Group to the authors of the review.²²

In summary, multidisciplinary lifestyle intervention and weight-management programs are viable and potentially cost-effective treatment options in overweight or obese patients with or without T2DM. Such approaches, however, often fail to achieve durable weight loss of more than 5% to 10%, so they are not effective enough for the severely obese. Importantly,

lifestyle and medical approaches do not appear to improve cardiovascular outcomes in studies so far. Thus, further research is needed to evaluate the role for current medical and lifestyle therapeutic regimens for obesity and T2DM, including comparisons to surgical interventions. Certainly, and at the very least, these approaches are important adjuncts to bariatric surgery.

Pharmacotherapy

Medications may be considered as an adjunct to lifestyle modification in adults who have a BMI of 30 or higher or a BMI of 27 to 29 with at least one obesity-related condition.⁴¹ Pharmacotherapy and lifestyle intervention together lead to additive weight losses and should be used together and may also be helpful in facilitating the maintenance of reduced weight.^{34,41,42} Phentermine, the most widely prescribed weight-management medication in the United States, is a sympathomimetic amine that was approved by the FDA in 1959 for short-term use of fewer than 3 months long.⁴¹ There are now five newer FDA-approved medications for long-term weight management that include three single drugs and two combination drugs. In 1-year pivotal trials, total weight losses for the three single therapies (orlistat, lorcaserin, and liraglutide), the effects of which are mediated by different mechanisms, ranged from 5.8% to 8.8% of initial body weight.^{41,43-45} The two combination medications (phentermine–topiramate and naltrexone–bupropion) include drugs that act on neural weight-loss mechanisms.^{46,47} In 1-year pivotal trials, total weight loss for these combination drugs ranged from 6.4% to 9.8% of initial body weight.

These medications, when prescribed with lifestyle interventions, produce *additional weight loss relative to placebo* ranging from approximately 3% of initial weight for orlistat and lorcaserin to 9% for the higher-dose phentermine plus topiramate–extended release at 1 year. The proportion of patients achieving clinically meaningful (at least 5%) weight loss ranges from 37% to 47% for lorcaserin, 35% to 73% for orlistat, and 67% to 70% for higher-dose phentermine plus topiramate–extended release. All three of these medications produce greater improvements in cardiometabolic risk factors than placebo,

but none has been shown to reduce cardiovascular morbidity or mortality. There is limited data for the long-term safety and efficacy of these medications, and some of these drugs may increase heart rate⁴³ or attenuate expected blood pressure reductions.⁴⁷ In addition, completed trials of hard cardiovascular disease outcomes (heart attack and stroke) in patients treated with these medications have yet to be published, except in the case of liraglutide.⁴³ Figure 27-4 shows a comparison of weight loss outcomes for these medications. The median percentages of participants who had a weight loss of at least 5% or 10% with each of five medications approved for long-term weight management are from a meta-analysis by Khera et al.⁴⁸

In summary, medications approved for long-term obesity treatment, when used as an adjunct to lifestyle intervention, lead to greater mean weight loss and an increased likelihood of achieving clinically meaningful 1-year weight loss compared to placebo.⁴² Yet weight loss medications are underutilized, likely due to several factors. First, patients are often disappointed by moderate weight loss. Second, there are requirements to pay a substantial portion of costs, which may lead to short-term rather than longer-term use. Third, there remain concerns about medication safety. Finally, weight regain is common after termination of drug treatment, which is discouraging to both patients and their providers.^{22,42}

Barriers to Treatment

Only a small fraction of patients for whom these medical treatments or bariatric surgery are indicated actually pursue and receive them. Past studies have estimated that 1% or fewer of those people with severe obesity who could consider bariatric surgery ever do so. Barriers to general obesity care include the slow recognition among providers that obesity requires long-term management, inadequate physician training in nutrition and obesity, limited reimbursement for the full range of treatments, lack of more effective and accessible lifestyle programs, and limited referrals of patients with severe obesity to experienced surgeons.²² Lack of knowledge about the more recent outcomes of bariatric surgery may also play a contributing role.

CANDIDATES FOR BARIATRIC SURGERY

Indications

There has been significant procedure evolution over the last  several years indicating an ongoing major shift in bariatric procedures both in the United States and worldwide¹³ (Fig. 27-5). According to a 2016 report from the American Society of Metabolic and Bariatric Surgery (ASMBS), the two most common procedures in the United States are RYGB and SG, accounting for approximately 25% to 30% and 50% to 60%, respectively, of annual cases.^{49,50} The utilization of LAGB has declined dramatically to under 10% of cases, and the malabsorptive procedure BPD with or without DS is utilized in less than 1% to 2% of cases (see Fig. 27-2). All of these procedures were defined by the Centers for Medicare & Medicaid Services (CMS) as standard approved procedures, noting that SG coverage is based on the discretion of regional carriers throughout the United States.

The indications for performing bariatric surgery in class II and class III obesity still remain as described in the National Institutes of Health (NIH) Consensus Conference of 1991, and a summary of the broad selection criteria are shown in Table 27-2.⁵¹ In 2016, the second Diabetes Surgery Summit (DSS-II) published guidelines indicating that metabolic surgery

should also be considered for patients with T2DM and BMI of 30 to 34.9 kg/m² (class I obesity) if blood sugar is inadequately controlled despite optimal medication treatment.¹⁶ In addition, these guidelines recommended that the BMI threshold for *metabolic surgery* (surgery for diabetes as the indication) should be reduced by 2.5 kg/m² for Asian populations at risk.

The NIH criteria for bariatric surgery do not set guidelines or limits for age, and surgical practice varies widely. The pediatric obesity epidemic is both increasing and also driving the adult epidemic, and a growing proportion of younger patients are potentially eligible for bariatric surgery. For young patients, there are concerns about assent to surgery and compliance with and adherence to postoperative lifestyle changes, but there are also some emerging data that suggest intervening earlier in the disease process may lead to improved reversal of comorbid conditions compared to adults.⁵² In addition, there is a longer period of postoperative benefit in terms of improved quality of life and prevention of or reduction in the emotional, social, and physical consequences of obesity (see “Bariatric Procedures in Adolescents”). Alternatively, older patients are more likely to have more numerous and debilitating comorbid conditions and thus have an immediate benefit in quality of life but not necessarily enhanced longevity. There is also some concern that recovery from potential complications is impaired in patients over the age of 65. Most studies in older patients have focused on RYGB and older restrictive procedures with limited follow-up. The results of more recent studies in older patients are generally equivocal in terms of any increased risk of morbidity and mortality or any difference in weight outcomes compared to younger adults.⁵³⁻⁵⁵ One study has shown that the older patient population, especially those few patients older than age 70 undergoing bariatric surgery, did have an increased risk of mortality and morbidity after RYGB.⁵⁶ Also, a 2016 study from the Utah Obesity group found that RYGB is protective against mortality even for older patients and also reduces the age-related increase in mortality observed in severely obese individuals not undergoing surgery.⁵⁷

Contraindications

Medical issues that preclude patients from being good surgical candidates include American Society of Anesthesiologists (ASA) class IV disease of a nature that makes surgical therapy extraordinarily high risk. Psychological instability or the inability to understand the implications of the proposed operation and what changes will result from it in terms of the patient's lifestyle are also contraindications. Known and documented active drug or alcohol addiction is a contraindication to surgery (see Table 27-2). Tobacco use should be completely avoided by bariatric patients at all times, and smoking cessation should occur 6 weeks prior to surgery. After surgery smoking increases risks of poor wound healing, anastomotic ulcers, and impaired health.⁵⁸ A poorly controlled eating disorder, especially bulimia, is also a contraindication to surgery. Nonambulatory status is a relative contraindication to surgery and is associated with increased surgical risk,⁵⁹ especially if the obesity is so severe that the patient cannot normally do self-care or would not likely be able to do so after surgery. In addition to excessive morbidity, the placement of these individuals in care facilities postoperatively for recovery is often impossible due to their size and limitations of physical ability. Finally, lack of sufficient social support or an extremely poor or unsupportive home environment can be contraindications to surgical care, since such environmental factors are important to optimize outcomes once discharged from the hospital.

Bariatric surgery procedure evolution. **A.** Horizontal gastroplasty; **B.** vertical banded gastroplasty; **C.** Roux-en-Y gastric bypass; **D.** transected Roux-en-Y gastric bypass; **E.** gastric band; **F.** biliopancreatic diversion; **G.** biliopancreatic diversion with duodenal switch; **H.** vertical sleeve gastrectomy. Table 27-2

Patient selection criteria for bariatric surgery

FACTOR	CRITERIA
Weight (adults)	BMI ≥ 40 kg/m ² with no comorbid conditions BMI ≥ 35 kg/m ² with obesity-associated comorbidity
Weight loss history	Failure of previous nonsurgical attempts at weight reduction, including nonprofessional programs
Commitment	Expectation that patient will adhere to postoperative care Follow-up visits with physician(s) and team members Recommended medical management, including use of dietary supplements Instructions regarding any recommended procedures or tests
Contraindications/exclusions	Prohibitive surgical risk, ASA IV Reversible endocrine or other disorders that can cause obesity Current drug or alcohol misuse Uncontrolled, severe psychiatric illness Uncontrolled, severe bulimia Lack of comprehension of risks, benefits, expected outcomes, alternatives, and lifestyle changes

Data from Mechanick JI, Youdim A, Jones DB, et al: Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2013 update: cosponsored by American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic & Bariatric Surgery, *Obesity (Silver Spring)*. 2013 Mar;21 Suppl 1:S1-S27.

MECHANISM OF ACTION OF BARIATRIC AND METABOLIC SURGERY

Overview

There is not yet a clear understanding as to how various bariatric procedures exert their effects on weight loss, metabolism, and glycemic control. Much effort is currently being devoted to gaining a better understanding of these specific mechanisms. A review of what is known from published animal and human studies about mechanisms related the three most common surgical procedures is shown in Fig. 27-6.¹⁷ A few interim, summary statements can be drawn from this available data. First, neither LRYGB nor SG can be thought of as primarily “restrictive procedures,” and there are changes in behavior and physiology that likely help to maintain the new reduced body weight that are not observed after nonsurgically induced weight loss. LAGB appears to be more dependent on gastric restriction as both the behavioral changes and changes in gut hormone secretion are much less dramatic. Second, both LRYGB and SG are associated with metabolic improvements that are different from those that are caused by weight loss alone, and these mechanisms remain under current active study. For LAGB, the metabolic effects are mostly due to the impact of the resulting weight loss. This growing understanding of the physiology of these procedures points away from the older, classic

anatomic classifications of “restrictive” versus “malabsorptive” procedures. This new conceptual approach has important implications for future studies of how bariatric surgery exerts its effects. Earlier hypotheses for the mechanism of action of LRYGB have been classified into either the “foregut hypothesis” or “hindgut hypothesis.”⁶⁰ The foregut hypothesis states that improvements after LRYGB come from the bypassing of the upper small intestine that results in the reduction of nutrient-dependent hormonal actions that would normally impair glucose tolerance.⁶¹ The hindgut hypothesis states instead that the key events are the result of more rapid delivery of nutrients to the distal small intestine causing effects such as increased GLP-1/PYY secretion and the ileal brake.⁶² Now, the more recently recognized and common metabolic effects of SG and LRYGB may indicate directions for study away from this foregut/hindgut distinction, as the SG does not bypass the foregut or induce nutrients further down in the intestine.

Mechanisms of Bariatric Surgery (Weight Loss)

Certainly, one component mechanism by which RYGB produces weight loss is related to reduced caloric intake and malabsorption brought about by a smaller gastric volume and bypass of the proximal small bowel, so weight loss following LAGB and SG may be explained, at least in part and early on, by gastric restriction⁶³ and resulting reduced food intake. Aside from anatomic changes induced by surgery, there are also changes in physiology that may affect food preferences and energy expenditure. Gastric emptying and insulin sensitivity increases following RYGB and SG.⁶³ Functional magnetic resonance imaging has demonstrated a decreased neuronal activation of the food reward-related centers in response to high-calorie foods following RYGB.⁶⁴ Neural signaling may be altered and stretch sensitive vagal endings in the new pouch and Roux limb, resulting in a feeling of early satiety.⁶⁵ Hormonal changes are also evident, and in a number of studies looking at the effect of RYGB on ghrelin levels, results are conflicting. Changes in intestinal microbiota is another area of active study.⁶⁶ Individuals with obesity have different gut flora compared to nonobese subjects. The Firmicutes (mainly *Lactobacillus* and *Clostridium* species) to Bacteroidetes ratio (*Bacteroides* or *Prevotella* species) is elevated in obese subjects. Following gastric bypass, the Firmicutes group decrease while *Bacteroides/Prevotella* increase at 3 and 6 months intervals.⁶⁷ Bacteria transplant provides some of the benefits of gastric bypass surgery without the surgery.⁶⁸ It has also been shown that administering oral lactobacillus post-RYGB leads to increased weight loss; this indicates benefits of changing gut microbiota to induce weight loss.⁶⁹

Serum bile acid levels also increase following gastric bypass.⁷⁰ Gastric bypass diverts undiluted bile acids to the distal bowel. Bile acids activate protein-coupled receptor TGR5 present in L cells responsible for GLP-1 secretion. They also activate FXR (farnesoid-X receptor) in the jejunum, which regulates lipid and glucose metabolism.⁷¹ Furthermore, bile acids lead to rapid clearance of triglycerides.⁷² Bariatric surgery alters bile acid enterohepatic circulation in favor of weight loss and resolution of nonalcoholic steatohepatitis (NASH).⁷³ Ryan et al demonstrated in a study on mice that the therapeutic value of SG is not limited to mechanical restriction but to an increase in circulating bile acids and associated changes to gut microbiota.⁷⁴ Hollanda et al studied two cohorts of patients: those who lost more than 50% of their excess weight compared to those who did not. This group suggested that ghrelin and GLP-1 may be mediators of successful weight loss as those levels increased, while PYY and GLP-2,

	LRYGB	LAGB	SG
			
Lipid	Elevated HDL Reduced triglycerides Reduced total cholesterol, LDL	Elevated HDL Reduction in triglycerides not as dramatic as LRYGB or SG	Elevated HDL Reduced triglycerides
Glucose homeostasis	Improved fasting blood glucose and insulin sensitivity, prior to weight loss	Improvements are slower and not as dramatic as after SG or LRYGB	Improved fasting blood glucose and insulin sensitivity, prior to weight loss
Role of gastric restriction	Has not yet been directly tested	Failure of band leads to less gastric restriction and less weight loss	Gastric restriction is not the critical factor preventing hyperphagia
Gastric emptying	Few published studies	No overall change in gastric emptying rate; Emptying rate of proximal pouch created by band is enhanced	Most papers show increase
Energy expenditure	Controversial	Not reported	Unchanged, but only reported in one study
Leptin	Circulating leptin levels lower than expected for body weight Changes to leptin sensitivity not tested	Plasma leptin reduced, as expected for body weight; Changes to leptin sensitivity not tested	Circulating leptin levels lower than expected for body weight; Body weight changes not driven by changes to leptin sensitivity
Ghrelin	Reduced total ghrelin; Controversial, but no change in acyl-ghrelin levels	Increased circulating ghrelin	Reduced total ghrelin; Controversial, but no change in acyl-ghrelin levels
CCK	No change	No change	Not measured
GLP=1 (postprandial)	Weight loss-independent postprandial increase	Increased circulating GLP-1 but much less than RYGB or SG	Weight loss-independent increase comparable to LRYGB
PYY (postprandial)	Increased postprandial PYY levels; Reduced body weight loss in PYY knockout mice	No change	Increased postprandial PYY levels, comparable to levels after LRYGB
Bile acids	Increased plasma bile acids	Not reported	Increased plasma bile acids
Diet change	Decreased fat intake, more fruits and vegetables	Decrease bread intake and increase in caloric liquids; Greater fat intake and fewer fruits/vegetables than RYGB	Decreased fat intake, similar to LRYGB
Food Intolerance	Some dumping syndrome, usually well-tolerated	More persistent and problematic than LRYGB; Mainly vomiting	Little or none

Figure 27-6. Mechanisms of effect: comparison of LRYGB, LAGB, and SG. (Reproduced with permission from Stefater MA, Wilson-Pérez HE, Chambers AP, et al: All bariatric surgeries are not created equal: insights from mechanistic comparisons, *Endocr Rev.* 2012 Aug;33(4):595-622.)

gut mass and hypertrophy (citrulline), and the bile acid effect on fibroblast growth factor-19 (FGF-19) appear to have no effect on weight loss.⁷⁵ In summary, there exists a complex relationship between dietary changes, bile flow changes, altered hormonal milieu and the gut microbiota that is not yet completely well characterized as it relates to weight loss after bariatric surgery.

Mechanisms of Metabolic Surgery (Diabetes Improvement)

Understanding the basic mechanism(s) of diabetes improvement following bariatric surgery is an important area of intensive study. Recently published data on worldwide trends in diabetes indicate that the number of adults with diabetes has increased from 108 million in 1980 to 422 million in 2014,⁷⁶ the majority with T2DM. In the United States, diabetes is the number two cause of hospitalizations in adults age 18 years or older, accounting for approximately 11% of all hospital admissions. With no medical cure, the natural course of diabetes is characterized by progressive β -cell failure and development of microvascular and macrovascular complications, leading to renal failure, blindness, amputation, and death due to cardiovascular disease (CVD). Bariatric surgery has been renamed *metabolic surgery* for T2DM treatment and has emerged as an effective tool for control of hyperglycemia.⁷⁷⁻⁸⁶

More than 20 years ago Pories et al found that bariatric surgery rapidly normalized blood glucose levels in people with obesity and T2DM, and 10 years later the majority remained disease free.⁸⁷ He suggested that caloric restriction played a role but that there were likely other factors such as proximal intestinal nutrient exclusion, rapid distal gut nutrient delivery, and the role of gut hormones that would require further investigation. The findings of T2DM improvement and remission after bariatric surgery have now been widely replicated by others, and there is evidence that bariatric surgery prevents or delays incident cases of T2DM. Much work has been done to investigate these specific physiological mechanisms underlying the beneficial glycemic effects of bariatric surgery, but they remain incompletely understood. Candidate hypotheses include changes in bile acid metabolism, nutrient sensing and glucose utilization, intestinal adaptation, incretins, possible anti-incretin(s), and the intestinal microbiome. These physiologic and molecular changes lead to reduced hepatic glucose production, increased glucose uptake in tissues, improved insulin sensitivity, and enhanced β -cell function. A schematic of these potential mechanisms of improved glycemic control is shown in Fig. 27-7.

It is likely that several of these individual factors, acting together and with different impact based on the specific surgical procedure, are responsible for postoperative glycemic improvement. Work in this area is actively ongoing, and genomic, metabolomic, and gut microbiome studies will likely enhance the understanding of these changes. This may potentially lead to identifying novel pathways and potential therapeutic targets to replace bariatric procedures by equally effective, but less invasive, new treatments for obesity-related T2DM. In other words, understanding mechanisms of glycemic improvement after bariatric surgery may allow for the development of treatments to “bypass the bypass.”⁸⁸

PREOPERATIVE ISSUES

Preoperative Preparation

Patient selection for surgery should be based on a multidisciplinary team approach. All patients should undergo preoperative

evaluation for obesity-related comorbidities and causes of obesity, with special attention directed to factors that could affect candidacy for bariatric surgery⁸⁹ (Table 27-3).

The preoperative assessment of the patient for bariatric surgery must include input from the nutritionist as an important independent evaluation. Careful assessment of the patient’s eating habits, knowledge, self-awareness, and insight are important. An estimation of the patient’s motivation to change eating habits is important. The nutritionist should have at least one assessment session with the patient and an educational session preoperatively once the decision to proceed with surgery has been determined. The operation to be performed requires specific nutritional counseling and education. Psychological assessment is required by most programs and many insurance carriers with a goal of identifying potential contraindications to surgical intervention, such as poorly controlled psychiatric illness or active substance abuse, and identifying strategies to help with long-term weight management.⁹⁰ There are published recommendations regarding the content of a mental health evaluation for bariatric surgery,⁹¹⁻⁹³ but no consensus guidelines have been published. These evaluations are carried out by interview and questionnaires, which rely on clinical interviews including tests of personality or psychopathological conditions.⁹⁴ More comprehensive evaluations also assess bariatric surgery knowledge, weight history, lifestyle habits, and potential barriers.^{91,92} Psychological assessment in clinical practice may be inaccurate compared to independent evaluations for research purposes, as patients present themselves in the most favorable light in order to gain access to surgery.⁹⁵

Obstructive sleep apnea (OSA) is prevalent in over 90% of bariatric surgery candidates with approximately one-third undiagnosed.⁹⁶⁻¹⁰¹ The Epworth Sleepiness Scale, a standard set of questions evaluating daytime sleepiness, is often used as a screening tool for OSA.³⁸ As OSA is associated with increased risk of mortality¹⁰² (and in bariatric surgery patients, with adverse outcomes),⁵⁹ routine preoperative screening with polysomnography should be considered.¹⁰³ In addition, standard preoperative management of obese patients with OSA using continuous positive airway pressure (CPAP) is recommended.¹⁰⁴ Asthma and hypoventilation syndrome of obesity are other significant pulmonary diseases often requiring preoperative management. Hypoventilation syndrome of obesity is defined as resting arterial partial pressure of oxygen less than 55 mmHg and partial pressure of carbon dioxide greater than 47 mmHg, with accompanying pulmonary hypertension and polycythemia. Pulmonary consultation is indicated for patients with hypoventilation syndrome. Postoperative intensive care unit hospitalization, rarely used after bariatric surgery, may be indicated for these patients.

Preoperative weight loss can reduce liver volume/size and may help improve the technical aspects of surgery in those people with extreme central obesity and an enlarged liver, and it is sometimes utilized as a practice-specific recommendation or requirement. Ten percent total body weight loss (TBWL) with energy-restricted diets has been associated with a reduction in hepatic volume,¹⁰⁵ variable perceived and measured improved facility in operative technique,^{106,107} variable effects on short-term¹⁰⁸⁻¹¹² complication rates, and weight loss. Cirrhosis¹¹³ has been associated with poor outcomes following bariatric surgery, including progression to liver transplantation.¹¹⁴

Preoperative glycemic control should be optimized using diet, physical activity, and medications, as needed. Reasonable targets for preoperative glycemic control include a hemoglobin A1c value of 6.5% to 7.0% or less, a fasting blood glucose

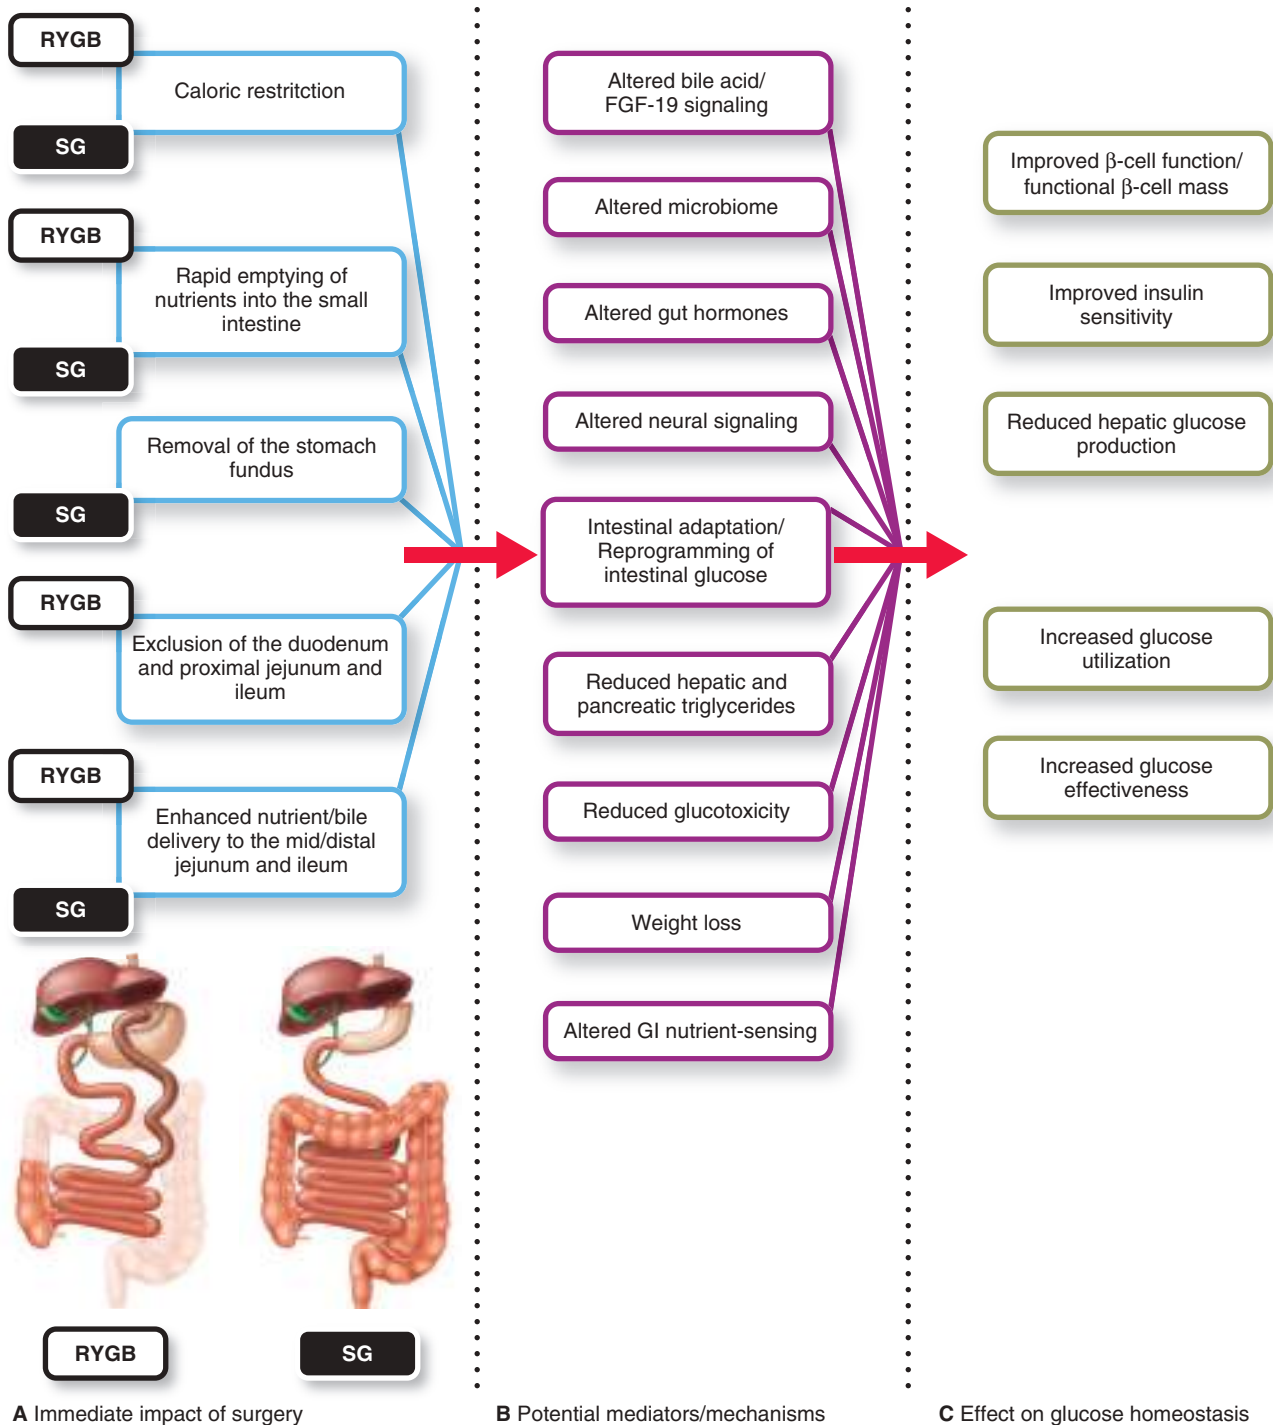

Figure 27-7. Schematic of potential mechanisms of improved glycemic control after LRYGB and SG. **A.** Immediate effects of RYGB and SG due to anatomical changes. **B.** Potential mediators/mechanisms involved. Cross talk occurs among these factors. **C.** Effects on glucose homeostasis. (Reproduced with permission from Batterham RL, Cummings DE: *Mechanisms of Diabetes Improvement Following Bariatric/Metabolic Surgery*, *Diabetes Care*. 2016 Jun;39(6):893-901.)

level of ≤ 110 mg/dL, and a 2-hour postprandial blood glucose concentration of ≤ 140 mg/dL.¹¹⁵ More liberal preoperative targets with higher A1c should be considered in patients with advanced comorbid conditions or long-standing diabetes where lower targets are not attainable. For patients with active GERD on medication, a preoperative screening upper endoscopy to rule out Barrett's esophagus and to rule out intrinsic lesions of the stomach or duodenum is recommended. This is especially true for patients planning LRYGB, where the distal stomach

and duodenum will be precluded from easy inspection postoperatively. In addition, the presence of Barrett's esophagus is a contraindication to SG, which is a reflux-inducing operation. The presence of a hiatal hernia detected on preoperative esophagogastroduodenoscopy will alert the surgeon for the need to perform intraoperative repair.

Patients with a history of DVT or cor pulmonale should undergo a diagnostic evaluation for DVT. A prophylactic vena caval filter may present a greater risk than benefit in patients

Table 27-3

Preoperative checklist for bariatric surgery

- Complete for History & Physical (H&P) (obesity-related comorbidities, causes of obesity, weight/BMI, weight loss history, commitment, and exclusions related to surgical risk)
- Routine labs (including fasting blood glucose and lipid panel, kidney function, liver profile, lipid profile, urine analysis, prothrombin time/INR, blood type, CBC)
- Nutrient screening with iron studies, B₁₂ and folic acid (RBC folate, homocysteine, methylmalonic acid optional), and 25-vitamin D (vitamins A and E optional); consider more extensive testing in patients undergoing malabsorptive procedures based on symptoms and risks
- Cardiopulmonary evaluation with sleep apnea screening (ECG, CXR, echocardiography if cardiac disease or pulmonary hypertension suspected; DVT evaluation if clinically indicated)
- GI evaluation (*H pylori* screening in high-prevalence areas; gallbladder evaluation and upper endoscopy if clinically indicated)
- Endocrine evaluation (A1c with suspected or diagnosed prediabetes or diabetes); TSH with symptoms or increased risk of thyroid disease; androgens with PCOS suspicion (total/bioavailable testosterone, DHEAS, D4-androstenedione); screening for Cushing's syndrome if clinically suspected (1 mg overnight dexamethasone test, 24-hour urinary free cortisol, 11 PM salivary cortisol)
- Clinical nutrition evaluation by registered dietician
- Psychosocial-behavioral evaluation
- Document medical necessity for bariatric surgery
- Informed consent
- Provide relevant financial information
- Continue efforts for preoperative weight loss
- Optimize glycemic control
- Pregnancy counseling
- Smoking cessation counseling
- Verify cancer screening by primary care physician

with a history of prior pulmonary embolism (PE) or DVT given the risks of filter-related complications including thrombosis. The overall risk of venous thromboembolism (VTE) after surgery is 0.42%, and over 70% of these events occur after hospital discharge, most within 30 days after surgery.¹¹⁶ The risk of VTE is greater in patients undergoing RYGB than in those undergoing LAGB and is more frequent following open surgery. Patients with a VTE event tend to be male, older, and have higher BMIs; they are also more likely to have a history of VTE.¹¹⁶ The risk of VTE is greater in patients with an inferior vena cava filter (hazard ratio [HR] 7.66, 95% CI 4.55–12.91),¹¹⁶ and there is evidence suggesting that prophylactic inferior vena caval (IVC) filter placement before bariatric surgery does not prevent PE and may lead to additional morbidity, which may outweigh its use.^{117,118}

Candidates for bariatric surgery should avoid pregnancy preoperatively and for 12 to 18 months postoperatively and

women who become pregnant after bariatric surgery should be counseled and monitored for appropriate weight gain, nutritional supplementation, and for fetal health.¹¹⁹ All women of reproductive age should be counseled on contraceptive choices following bariatric surgery as utilization, absorption, and effectiveness are inconsistent.^{120,121} Patients should be provided with educational materials and access to preoperative educational sessions. Multimedia tools for patient education and consent show promise for improving understanding.¹²²⁻¹²⁴ There should be a thorough and dynamic consent discussion regarding the risks and benefits, procedural options, and the need for long-term follow-up and vitamin supplementation (including costs required to maintain appropriate follow-up). Consent should include the experience of the surgeon with the specific procedure and whether the program participates in national quality improvement initiatives and certification.

Anesthesiology Issues

Two major challenges that face the anesthesiologist when performing a general anesthetic for the severely obese patient are vascular access and airway management. Fiberoptic laryngoscopy is often used for the most difficult class IV or even class III airways should standard laryngoscopy be determined to provide an inadequate view. Videotelescopic intubation systems are successfully used as well. Significant preoxygenation for 3 minutes or longer prior to intubation is used for the severely obese patient to provide a longer safe duration for intubation should difficulties be encountered. However, desaturation must be immediately addressed with reestablishment of oxygenated ventilation because this patient group does not tolerate any prolonged desaturation without potential adverse cardiopulmonary consequences.

The anesthesiologist must also manage alterations in cardiopulmonary function from the use of a pneumoperitoneum during laparoscopic bariatric procedures. These include the effects of carbon dioxide absorption on required minute ventilation, the potential for bradyarrhythmias, and the potential for decreased systemic pH with longer procedures in patients with preexisting cardiopulmonary disease. Arterial monitoring of the latter group of patients may be necessary by the anesthesiology team, and a radial arterial line is standard for such patients.¹²⁵ Drug pharmacokinetics differ in severely obese patients as well. Changes in volume of distribution include smaller-than-normal fraction of total body water, greater adipose tissue content, altered protein binding, and increased blood volume. Possible changes in renal function and hepatic function must be considered when administering drugs. Specific anesthetic drug metabolic alterations in the severely obese include a larger volume distribution of thiopentone, resulting in a prolonged effect of the drug. Calculation of the dosage should be done by lean body weight. Benzodiazepines also exhibit a prolonged elimination phase, causing prolongation of their effects. Increased pseudocholinesterase activity is present in the severely obese patient, requiring increased dosages of pancuronium. Enflurane metabolism is increased over the average-sized person, requiring a lower dosage of this agent.

Enhanced Recovery After Surgery

Enhanced recovery after surgery (ERAS) protocols have been initiated in bariatric surgery and have demonstrated promise to decrease surgical morbidity. Additionally, a recent meta-analysis has identified a significant decrease in length of stay (standard mean difference = -2.40 [-33.89, -0.89], *P* = 0.002).¹²⁶ In 2016, the ERAS Society published evidence-based guidelines

for perioperative care in bariatric surgery.¹²⁷ The guidelines include recommendations in preoperative, intraoperative, and postoperative care. These include shorter acting and lower absorption anesthetic agents and opioid minimization as important intraoperative recommendations.

Special Equipment and Infrastructure

The special needs of the bariatric patient and program extend from the entry to the hospital and clinic, to the operating room, and throughout the inpatient and outpatient experience. The program needs infrastructure and support at all levels including support staff, physicians and surgeons, administrators, program directors, psychologists, and nutritionists. The physical plant needs to include extra-wide doorways, special seating, a scale that weighs up to 800 lb (363 kg), larger patient gowns, large blood pressure cuffs, and floor-mounted toilets. In the operating room, the table must accommodate 600 to 800 lb (272 to 363 kg) and must position in steep reverse Trendelenburg position. Larger lower extremity compression devices, extra padding, safety belts, and a footboard are required. An angled (30° or 45°) telescope, extra-long graspers and staplers, and a liver retractor system are all standard equipment. Staff sensitivity training for the care of the obese as well as regular education about the complications of bariatric surgery are program requirements.

BARIATRIC SURGICAL PROCEDURES

VBG shown in Figs. 27-1 and 27-5, although still listed as one of the approved operations for the surgical treatment of severe obesity based on the NIH Consensus Conference of 1991,⁵¹ is not currently performed due to poor long-term weight loss and technical complications, so it is of historic interest only, and the surgical technique will not be described here.⁸ The other procedures described in this section will be articulated using a laparoscopic approach as that is the dominant method. RYGB, BPD, and DS may still be performed by some surgeons using an open approach, but this has now become the exception. In this text LRYGB will refer specifically to RYGB performed by the laparoscopic approach, while RYGB will indicate procedures performed by the open approach or by both approaches as is the case for many studies of outcomes. Minimization of the morbidity of the open incision, especially incisional hernias and wound complications, as well as earlier hospital discharge and lower 30-day complication rates have all been clearly shown to favor using a laparoscopic approach when feasible.¹²⁸⁻¹³⁰ Laparoscopy begins with the safe creation of a pneumoperitoneum, often a difficult step in the bariatric patient. A tracheostomy hook can be inserted through a trocar-sized incision to elevate the fascia in the left subcostal region to facilitate the insertion of a Veress needle into an appropriate location for pneumoperitoneum creation. The use of a Hasson approach for creating a pneumoperitoneum in the bariatric population may be limited by the thick body wall. In the patient with an extremely thick body wall, extra-long trocar ports can be used for laparoscopic surgery. The pneumoperitoneum pressure that is used when performing bariatric surgical procedures is generally in the 15 to 18 mmHg range. A high-flow insufflator is mandatory to maintain the pneumoperitoneum for adequate and safe visualization.

When an open surgical approach is used for any of these procedures, an upper midline incision with table mounted retractors is the most commonly used approach. The robotic approach to bariatric procedures is also now utilized with purported

advantages of reduction of the use of the open technique, improved surgical, length of stay, cost outcomes, and potentially improving ergonomics and resultant surgeon fatigue and injury. A meta-analysis involving 27 studies and over 25,000 patients concluded that there were no significant differences between robotic bariatric surgery and laparoscopic bariatric surgery with respect to overall complications, length of stay, reoperation, conversion, and mortality.¹³¹ Another study utilizing University Consortium data demonstrated no difference in hospital mortality, major complications, readmissions, or length of stay between the robotic and laparoscopic approach.¹³² In both studies, robotic surgery did increase significantly operative time and hospital costs (>20%) compared to laparoscopic approaches. As yet, larger prospective cohort studies and/or randomized trials have not yet been published, so the role of this technique is still to be defined and further studies are needed.^{133,134}

Laparoscopic Roux-en-Y Gastric Bypass

Background and Patient Selection. Figure 27-8 depicts the configuration of the LRYGB. It is an appropriate operation for consideration for most patients eligible for bariatric surgery. Relative contraindications specifically for LRYGB include previous gastric surgery, previous antireflux surgery, severe iron deficiency anemia, distal gastric or duodenal lesions that require ongoing future surveillance, and Barrett's esophagus with severe

Figure 27-8. Configuration of laparoscopic gastric bypass. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

dysplasia. The major feature of the operation is a proximal gastric pouch of small size (<20 mL) that is totally separated from the distal residual stomach. A Roux limb of proximal jejunum is brought up and anastomosed to the pouch. The pathway of that limb can be anterior to the colon and stomach, posterior to both, or posterior to the colon and anterior to the stomach. The length of the biliopancreatic limb from the ligament of Treitz to the distal enteroenterostomy is 20 to 50 cm, and the length of the Roux limb is 75 to 150 cm.

Creating the proximal gastric pouch by totally dividing it from the distal stomach is superior to simply stapling and partitioning the stomach, since the latter is associated with a high incidence of staple line breakdown.¹³⁵ The size of the proximal gastric pouch must be small to create adequate restriction and should be based on the lesser curvature of the stomach to prevent dilation over time. Length of the Roux limb was associated with higher short-term weight loss for longer length limbs,¹³⁶ but this difference becomes less meaningful on long-term follow-up and has not been demonstrated in more recent studies.¹³⁷ Gastric pouch size and caliber of the gastrojejunostomy have not, in any studies, been shown to be related to weight loss. The gastrojejunal anastomosis can be constructed in a variety of ways, including hand sewn techniques and linear and circular staplers. Smaller diameter circular staplers are associated with a higher incidence of postoperative stenosis, and linear stapling is associated with a lower incidence of stenosis compared to circular stapling.^{138,139}

Technique. The operation generally is performed using five ports plus a liver retractor as shown in Fig. 27-9. Both the surgeon, who stands on the patient's right, and the first assistant, who stands on the patient's left, have two ports for instruments. The telescope requires a port, usually in the supraumbilical region. The assistant's ports are in the left subcostal and flank areas, while the surgeon may have both ports in the right upper quadrant or one on each side of the camera. Division of the proximal jejunum at 40 to 50 cm distal to the ligament of Treitz is performed with the linear stapler, using a vascular stapler cartridge. Further division of the mesentery at that location is performed either with the stapler or harmonic scalpel, such that adequate mobilization of the Roux limb is achieved. A Penrose drain or a marking suture is placed on the proximal Roux limb for identification and facilitation of advancement to the

Figure 27-9. Port scheme for laparoscopic gastric bypass. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

gastric pouch (Fig. 27-10). The length of the Roux limb (usually 100–150 cm) to be created is measured. A jejunojejunostomy is then created to the proximal end of the biliopancreatic limb at the previously determined location along the Roux limb. A side-to-side stapled anastomosis is performed (Fig. 27-11). Either single- or double-fired staple technique (the latter using a stapler

Figure 27-10. Creating Roux limb during laparoscopic gastric bypass.

Figure 27-11. Enteroenterostomy of laparoscopic Roux-en-Y gastric bypass.

fired in each direction) is used. The stapler defect is optimally closed with sutures but can be closed with a stapler if great care is taken not to narrow the lumen of the alimentary tract at this location. Once the stapler defect is closed, the mesenteric defect is then also closed with running permanent suture.

Passage of the Roux limb toward the stomach is now performed. If an antecolic route is to be used, the end of the Roux limb is brought up so as to confirm its ability to reach the stomach (Fig. 27-12). If a retrocolic route is to be used, a defect is made in the transverse colon mesentery just to the left and slightly above the ligament of Treitz. The proximal end of the Roux limb is placed into the retrogastric space. The left lobe of the liver is now retracted using any one of several retractor types. The patient is moved to a reverse Trendelenburg position. The harmonic scalpel divides the peritoneum in the area of the angle of His, and then it is used to open an area along the lesser curvature of the stomach approximately 3 cm down from

the gastroesophageal junction. Another approach for creating access to the lesser curvature of the stomach is to use a white or gray load (vascular load) of the stapler and divide the lesser curvature vessels up to the surface of the stomach. Then a blue load of the stapler is fired one time transversely from the lesser curvature side partially across the stomach, followed by multiple subsequent firings of the stapler upward in the direction of the angle of His, to completely separate the proximal gastric pouch from the remainder of the stomach (Fig. 27-13). Optionally, use of an Ewald tube passed by the anesthesiologist and maneuvered to lie against the lesser curvature of the proximal stomach can help calibrate the pouch size.

Once the pouch is created, the Roux limb is brought up to the proximal gastric pouch. For the linear stapled anastomosis, the proximal end of the Roux limb is aligned with the distal gastric pouch end, and the sides of the organs are sutured together to maintain their side-by-side position. A stapler is introduced through a gastrotomy and an enterotomy for the two legs of the stapler, and the anastomosis is created (Fig. 27-14). The stapler defect is closed with sutures and often reinforced with a second

layer of sutures. The gastrojejunostomy may be tested for security by using either methylene blue injected under pressure through the Ewald tube or a flexible upper endoscopy intraoperatively to test for air leakage from the anastomosis. The final

step of the operation involves suture closure of all mesenteric defects using permanent suture.

Alternatively, a completely hand-sewn gastrojejunostomy can be created using two layers of absorbable suture to anastomose an approximately 1-cm gastrotomy and enterotomy. The circular anastomosis technique is another approach to complete the gastrojejunostomy and is also a particularly useful technique for “salvage” anastomosis if the gastric pouch is very small and/or high. This is done through placement of the anvil of the stapler through the anterior wall of the proximal gastric pouch. This is accomplished by pulling the anvil transorally via an endoscopically placed guidewire (Fig. 27-15), making a gastrotomy in the pouch that is later closed, or making a gastrotomy in the lower stomach before completing gastric division to create the pouch, allowing the anvil to be placed into the lumen of the stomach and then be brought through the anterior stomach in an area that is subsequently included in the proximal gastric pouch (Fig. 27-16).

Procedure-Specific Complications. Mortality after LRYGB is now consistently less than 0.5% in most large reported series. Data from several national data sets/studies find a mortality rate of approximately 0.3%, 0.14%, and 0.2% at 30 days overall.^{59,140} Overall morbidity after LRYGB has also been low. In the Longitudinal Assessment of Bariatric Surgery (LABS) study, a composite endpoint including death, deep-vein thrombosis or venous thromboembolism, reintervention, or failure to be discharged by 30 days after surgery occurred in 4.8% of those who had undergone LRYGB.⁵⁹ In the national database of the ASMBS, morbidity alone was 14.87% for 30,864 gastric bypass procedures.¹⁴¹ Complications that do occur after LRYGB include a 0.3% incidence of anastomotic leak,¹⁴² 0.33%

incidence of venous thromboembolism,¹⁴³ a 3% to 5% incidence of wound infections or problems,¹⁴⁰ a 3% to 15% incidence of marginal ulcers,¹⁴⁴ an approximately 7% incidence of bowel obstruction,¹⁴⁵ a 4% incidence of postoperative transfusion,¹⁴⁶ and a 1% to 19% incidence of anastomotic stenosis,¹³⁹ based on the type of anastomosis created. Postoperative nutritional complications after LRYGB include a 66% incidence of iron deficiency, a 5% incidence of iron deficiency anemia, a 50% incidence of vitamin B₁₂ deficiency,¹⁴⁷ and an at least 15% incidence of vitamin D deficiency,¹⁴⁸ which usually is present preoperatively. Both early and late dumping occur in an

unspecified number of postoperative cases, as the symptoms are difficult to document and overlap with other problems such as hypoglycemia.

Several complications that are specific to LRYGB must be emphasized. One of the most important is small bowel obstruction. This complication must be treated differently than in the average general surgery patient, whose complication is usually from adhesions and often will resolve with conservative, nonoperative therapy. Patients who have had LRYGB who present with obstructive symptoms generally require surgical therapy on an emergent basis. This is because the etiology of the bowel obstruction after LRYGB is often an internal hernia from inadequate or nonclosure of the mesenteric defects by the surgeon at the time of operation. Thus, treatment for these patients differs from most patients with small bowel obstruction. One of the most important points of this chapter is to emphasize to general surgeons to be aware of the need to emergently operate on patients after LRYGB who present with small bowel obstruction. Currently, centers that perform small bowel transplantation are seeing patient referral for that procedure after small bowel obstruction after LRYGB, where patients developed infarction of most of the bowel from an internal hernia and have short gut syndrome.¹⁴⁹ Other patients, for whom surgery is delayed and the bowel infarcts, do not survive. When the surgeon does encounter bowel obstruction after LRYGB, he or she can expect to see proximally dilated bowel. Cutoff of passage of contrast on CT scan at the enteroenterostomy is particularly suggestive of this diagnosis (Fig. 27-17). The surgical treatment of this particular problem can, if addressed early in the course of the obstruction, be treated laparoscopically. The surgeon must place a trocar for the telescope low enough in the abdomen to adequately survey most of the small intestine. The cecum and terminal ileum are identified, and the bowel is followed retrograde from the terminal ileum to determine the anatomy. Often much of the small bowel is herniated through a mesenteric defect, and only this technique allows the surgeon to reliably identify the bowel and decompress it appropriately. If the bowel is viable,

Figure 27-17. Obstruction of contrast at enteroenterostomy with small bowel obstruction from internal hernia after laparoscopic Roux-en-Y gastric bypass.

suturing the mesenteric defect is all that is needed for treatment. It should be emphasized that either an antecolic or retrocolic placement of the Roux limb can result in this complication, as internal hernias can arise from either approach.

Marginal ulcers are another complication relatively specific to LRYGB. The patient presents with pain in the epigastric region that is not altered by eating. Diagnosis is by endoscopy. Treatment is medical with proton pump inhibitors, which are effective in 90% of cases. Only those with a gastrogastic fistula to the distal stomach, severe stenosis of the lumen of the gastrojejunostomy, or acute perforation require surgical therapy. Treatment of a perforated marginal ulcer is a laparoscopic Graham patch. Stenosis of the gastrojejunostomy has been reduced by the use of the linear stapling technique.¹³⁸ Stenosis symptoms usually appear from 6 to 12 weeks postoperatively, but less commonly can occur later. Diagnosis is by upper endoscopy. Treatment is circumferential balloon dilatation. Resolution normally occurs with one to two treatments. Less than 10% of patients require reoperation, and those are almost always associated with concurrent marginal ulcers.¹⁵⁰

In the immediate postoperative period, anastomotic leak is the single serious complication after RYGB, either open or laparoscopic. Careful vigilance and a high index of suspicion for this problem are important since its presentation may be insidious and the patient's demise, if untreated, may be sudden and complete. Tachycardia, tachypnea, fever, and oliguria are the most common symptoms that should arouse suspicion for this problem. The treatment is surgical, except in rare circumstances where a drain is already in place, no hemodynamic or clinical deterioration is present, and the leak is contained.¹⁵¹ Usual surgical treatment involves repair as feasible, drainage, and creation of a reliable feeding access through a distal Stamm gastrostomy.

In the first few hours or day after surgery, hematemesis indicates bleeding from the gastrojejunostomy unless proven otherwise. The dangers to the patient include aspiration, life-threatening hemorrhage, or more commonly intraluminal hematoma of the Roux limb and enteroenterostomy, which then causes an obstruction of the biliopancreatic limb leading to distal gastric staple line rupture.¹⁵² In fact, any obstructive symptoms in the first few weeks after surgery or any signs of obstruction of the biliopancreatic limb on postoperative swallow studies due to stenosis of the enteroenterostomy require immediate surgical intervention to prevent rupture of the distal gastric staple line. Some reports show that percutaneous decompression of the distal stomach can help to ameliorate the problem,¹⁵³ but operative therapy to decompress the stomach and treat the obstruction is first-line therapy.

Laparoscopic Sleeve Gastrectomy

Background and Patient Selection. SG was originally introduced as the first of a two-stage operative treatment for patients with super obesity (BMI >60 kg/m²).^{154,155} Its currently utilization is as a primary single-stage operation, but the possibility of a second-stage treatment remains, especially for the super obese patients, depending on the effectiveness of it as the primary operation. In addition, patients who have longstanding severe GERD may not be good candidates for SG as GERD is worsened by the anatomical configuration of the SG. Barrett's esophagus is also a contraindication for performing SG, since the potential for future esophageal dysplasia and the need for an available intact stomach for esophageal reconstruction outweigh the potential advantages of the procedure.

Figure 27-18. Port scheme for laparoscopic sleeve gastrectomy.

Technique. The patient is positioned supine, with foot support to allow reverse Trendelenburg positioning. The surgeon stands to the patient's right along with the camera driver, while the assistant stands to the patient's left. Port placement may vary, but a recommended port placement schema is shown in Fig. 27-18. The 15-mm port, helpful for removal of the stomach, is located in either the camera (just to the patient's left of the umbilicus) or surgeon's right hand (right upper quadrant near the midline) location. The other of these ports is a 12-mm port. The assistant has two 5-mm ports available in the left upper quadrant laterally, and the surgeon's left-hand port is a 5-mm port more lateral and superior in the right upper quadrant. A liver retractor is placed in the epigastric region.

The operation begins by devascularizing the greater curvature of the stomach, beginning 3 to 5 cm proximal to the pylorus. The division of all vessels adjacent to the greater curvature is continued up to the left crus of the diaphragm. A complete mobilization of the fundus in this area and division of posterior fibrous attachments to the antrum and body of the stomach are then performed such that the stomach is attached solely by the lesser curvature blood supply and the pyloric and esophageal regions. Stapled division of the stomach now follows. The first firing of the stapler occurs from the point of devascularization of the greater curvature at an angle pointing toward a point about 2 cm lateral to the incisura. The antrum of the stomach is at its thickest here, and so it is important to be certain the stapler load used is sufficiently large enough to allow good approximation and closure of the divided stomach. Two staple firings are performed, which takes the gastric division to past the incisura. After the first staple firing, some surgeons will engage the anesthesiologist to pass a 32- to 40-French bougie and position it along the lesser curvature of the stomach. This bougie then serves as a guide for further gastric division. Alternatively, some surgeons will insert the endoscope instead of the bougie as a guide for gastric division. It can also be used to test for air leaks, bleeding, or obstruction as it is withdrawn after gastric division. Dividing the stomach adjacent to the bougie or endoscope will produce the desired diameter of the gastric sleeve. It is most important not to narrow the stomach lumen at the incisura. During the second and third firing of the stapler to divide the stomach, it is critical to confirm by visualization of both the anterior and posterior surfaces of the stomach that the incisura area is not narrowed. By the third firing of the stapler, usually the angle of the gastric division is now pointed directly toward the angle of His, parallel to the bougie (Fig. 27-19).

Figure 27-19. Performing sleeve gastrectomy. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

At this point, changing staple loads to lower staple height is advisable.

Once the stomach is completely divided up to the angle of His, the staple line is inspected for hemostasis and integrity. Some surgeons will reinforce the staple line with a buttress material, while others will invaginate the staple line with a running serosa to serosa suture. Some surgeons will exchange the bougie at this point for a 32-French Ewald tube and perform a methylene blue leak test. Alternatively, if an endoscope is used, it is withdrawn with insufflation, and the staple line is inspected for air leaks while submerged in saline. The specimen is removed through the 15-mm trocar site, usually with only slight enlargement of the site. Figure 27-20 shows the completed operation. Controversy still exists as to the optimal size of the bougie used during the procedure and the relative utility of methods used to oversee or reinforce the staple line.

Procedure-Specific Complications. The major factor unique to SG is that it creates a high-pressure gastric tube. This increased intraluminal pressure places the staple line at risk for leakage and increased risk for GERD. As noted previously, controversy exists about both bougie size and staple line reinforcement/oversew as they relate to clinical outcomes. One summary of the literature shows that the stenosis rate is lower if a 40-French bougie is used, and the leak rate may also be lower without compromising weight loss.¹⁵⁶ However, individual institutional experiences with smaller-sized bougies have shown the potential for good weight loss and no increased incidence of stenosis.¹⁵⁷ Another controversial area is that of staple line reinforcement with staple buttressing material or reinforcement with oversewing.¹⁵⁸ The overall bleeding rate for the staple line after SG is generally cited as about 2% in collected series.¹⁵⁹ There have been no studies that have shown a definitive decrease in this bleeding rate with the use of buttress materials; however, a panel of experts has voiced support for a decreased incidence of bleeding from the staple line if buttress material is used.¹⁵⁸

Figure 27-20. Completed sleeve gastrectomy. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

One meta-analysis did show that there is evidence to suggest buttress materials may decrease the staple line leak rate.¹⁶⁰ Other prospective randomized studies have failed to show a benefit of buttress materials for leak prevention.¹⁶¹ A more recent study of over 180,000 SG procedures in the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) national database showed that staple line reinforcement cases were associated with higher leak rates (0.96% vs. 0.65%, odds ratio [OR] 1.20 95% CI 1.00–1.43) and lower bleeding rates (0.75% vs. 1.00%, OR 0.74 95% CI 0.63–0.86) compared to no reinforcement, at the patient level.¹⁶² At this time, there is no preponderance of data to support one approach as being superior to others for *both* staple line bleeding or leak rates. Given this state of the literature, a surgeon should consider the risks, benefits, and costs of these surgical techniques and utilize those that, in their hands, minimize morbidity while maximizing clinical outcomes.

If there is a relative obstruction or stenosis of the sleeve, which most often occurs at the incisura because of narrowing there during formation of the sleeve, pressure above the level of the obstruction will be even more elevated and create an increased risk for staple line leak. Leaks of the proximal staple line are the most frequent type seen after SG and often are felt to be related to increased intraluminal pressure distally. They may also be related to stapling too close to the angle of His, with resultant instability of the tissue directly adjacent to the esophagus in this area. It is important not to staple too close to the angle of His during the final stapling division portion of the stomach so as to not further weaken the staple line in this area. Proximal staple line leaks may also present as late leaks, 6 weeks to months following the procedure. Late leaks are rare

following other bariatric procedures, but are seen with SG, and index of suspicion should remain high.

Distal staple line leaks are different from proximal staple line leaks and are usually associated with earlier presentation and related to mechanical failure of the staple line to securely approximate the thicker distal gastric tissue. These leaks are more amenable to successful repair with a reoperation, whereas proximal leaks may not improve with oversewing at a reoperation unless the mechanics of the relative distal obstruction and high intraluminal pressure of the sleeve are also treated. Endoscopic intervention to dilate stenotic areas as well may be beneficial in the setting of a stenosis with or without a proximal leak. Care must be taken by the endoscopist to not excessively dilate the tract beyond the original size of the bougie used. Another factor that may influence stenosis at the incisura is that there may be a relative twisting of the stomach at this location, with the antrum being partially twisted away from the upper portion of the sleeve. Endoscopic treatment can help straighten and markedly alleviate the obstruction in such cases. Thus, relatively early endoscopic intervention is appropriate in the patient with a stenosis at the incisura. One study has shown that endoscopic dilation is usually successful in treating stenosis after SG, with a mean of 1.6 dilatations being done an average of 48 days postoperatively.¹⁶³

The patient with the proximal gastric staple line leak because of mechanical factors may experience persistence of the leak for months. Nonsurgical treatment with drainage and stenting can be used initially. Some now advocate for conversion of the patient with a longstanding leak after SG to a RYGB to provide a low-pressure anastomosis above the site of the stenosis.^{164,165} Similarly, persistent stenosis of the sleeve despite conservative therapy and endoscopic dilatation also is an indication for conversion to RYGB.

Laparoscopic Adjustable Gastric Banding

Background and Patient Selection. LAGB involves placement of an inflatable silicone ring around the proximal stomach. The band is attached to a reservoir system that allows adjustment of the tightness of the band. This reservoir system is accessed through a subcutaneously placed port, similar in concept to ports used for chemotherapy via central venous catheters. Figure 27-21 shows the LAGB apparatus in place. Patients who have had previous upper gastric surgery, such as a Nissen fundoplication, and those with severe GERD are relatively poor candidates for LAGB due to altered proximal gastric anatomy interfering with proper band placement or worsening of GERD symptoms. Two major types of bands have been used for this procedure. The original Lap-Band has been used most frequently. The Swedish Band, remarketed as the Realize Band in the United States, is slightly wider and larger in circumference than the Lap-Band but is no longer being manufactured. The port systems have differences as to profile and methods of attachment to the fascia.

Technique. Port placement for LAGB has varied among surgeons. Usually some combination of two ports for the surgeon's hands, one or two for the assistant, a port for the telescope, and a liver retractor site are needed. With the patient placed in reverse Trendelenburg position, the procedure begins with division of the peritoneum at the angle of His and then division of the gastrohepatic ligament in its avascular area (the *pars flaccida*) to expose the base of the right crus of the diaphragm. If a hiatal hernia is present, it must be repaired at this point, using a

Figure 27-21. Laparoscopic adjustable band overall scheme. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

standard posterior esophageal dissection to expose the crura and perform suture repair. A grasper is inserted along the base of the anterior surface of the diaphragmatic crura, from right to left, emerging at the angle of His in the area of the divided peritoneum (Fig. 27-22). The device is then used to pull the band

Figure 27-22. Grasper being passed through under stomach to grasp tubing during placement. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

underneath the posterior surface of the gastroesophageal junction. This technique, by passing the band through some fibrous tissue in this plane, serves to anchor the band more securely posteriorly. During the initial years of band placement, a retrogastric location of the posterior half of the band in the free space of the lesser sac caused an unacceptably high incidence of slippage and prolapse of the band. The adoption of the *pars flaccida* technique decreased the incidence of such slippage.¹⁶⁶

Once the band is passed around the proximal stomach, it is locked into its ring configuration through its own self-locking mechanism. This involves the tubing end being passed through the orifice of the buckle for the Lap-Band and the suture on the end of the flanged end of the band site being passed through for the Realize Band. Once the band is securely locked in place, the buckle portion of the band is located on the lesser curvature of the stomach (Fig. 27-23A,B). Now the anterior surface of the fundus and proximal stomach is imbricated over the band using several sutures (Fig. 27-24). The tubing of the band system is brought out through the desired site for placement of the port portion of the system. Usually this is a trocar site near the upper abdomen or xiphoid region to place the port most superficially such that it can be palpated postoperatively. The port is secured

to the anterior abdominal wall fascia. Access to the port for subsequent addition of fluid to the band system is percutaneously achieved using a Huber or noncutting type needle. The band is initially placed empty of fluid, except priming, in most circumstances.

Procedure-Specific Complications. The complications that may occur after LAGB include gastric prolapse, band slippage, band erosion, and port and tubing complications. In addition, failure to lose clinically significant weight is more common following this procedure compared to others. Acute gastric prolapse is the most common emergent complication that requires reoperation after LAGB. Acute, severe pain with immediate dysphagia, vomiting, and inability to take oral food or liquid is the typical presentation. Vomiting may predispose or exacerbate this problem. Either anterior or posterior prolapse may occur.¹⁶⁷ The initial evaluation for prolapse involves obtaining a plain film radiograph. If the band is in a horizontal position instead of its normal oblique position, prolapse must be strongly suspected. Initial treatment for an acute or chronic prolapse is to remove all the fluid from the system. This often allows reduction of the prolapse and resolution of symptoms. If symptoms do not resolve after this, an upper gastrointestinal (UGI) series

A

B

Figure 27-24. Stomach imbricated over band.

is indicated, and if prolapse persists, then reoperation laparoscopically to reduce the prolapse and resuture the band in place is indicated. Chronic gastric prolapse is more subtle. The band retains its normal oblique angle, but there is symmetric dilation of the gastric pouch above the band. These are initially managed with fluid removal and monitoring of symptoms. Follow-up evaluation can be performed in 4 to 8 weeks, and if the chronic prolapse resolves on UGI, slow refilling of the band may begin.

Band erosion is uncommon, reported in 1% to 2% of most series. The patient usually develops either a port site infection or systemic fever and a low-grade abdominal inflammatory sepsis. Endoscopy can be diagnostic, visualizing the white band material within the stomach. The presence of otherwise unexplained free air on computed tomography (CT) scan should alert the surgeon to this diagnosis as well. Laparoscopic removal of the band is indicated, with repair of the gastric perforation. Often the perforation is already sealed by an inflammatory process, but if not, appropriate management of a gastric perforation must be followed.¹⁶⁷

Port and tubing problems occur in at least 5% to 15% of patients undergoing LAGB. These require revision of the port/tubing system due to perforation, leaking, or kinking of the tubing or turning of the port such that access to the surface of the port for adding fluid is precluded. Usually a procedure under local anesthesia is all that is required to repair or realign the tubing or port. The incidence of band removal for patient dissatisfaction or lack of weight loss has been difficult to assess completely, but this number is increasing annually. Angrisani et al¹⁶⁸ reported a 40.9% incidence of band removal after 10-year follow-up. In the Longitudinal Assessment of Bariatric Surgery (LABS) study, 18 subsequent reoperations occurred for every 100 participants with LAGB who were followed up for 3 years.¹⁶⁹ Overall, these numbers are expected to increase as follow-up increases.

Biliopancreatic Diversion and Duodenal Switch

Background and Patient Selection. BPD was first described by, and remains championed by, Scopinaro in Italy.⁹ The operation, which is shown in Fig. 27-25, involves resection of the distal half to two-thirds of the stomach and creation of an alimentary tract of the most distal 200 cm of ileum, which is anastomosed to the stomach. The biliopancreatic limb is

anastomosed to the alimentary tract at approximately 100 cm proximal to the ileocecal valve. This operation is limited in its utilization due to both technical difficulty and the significant percentage of nutritional complications that arise postoperatively.

One early problem with BPD was the development of a high incidence of marginal ulcers postoperatively. Hess and

Figure 27-25. Diagram of biliopancreatic diversion. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

Figure 27-26. Diagram of duodenal switch. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All Rights Reserved.)

Hess¹⁰ and Marceau and colleagues¹⁷⁰ separately described the adaptation of the DS operation, originally proposed by DeMeester and colleagues¹⁷¹ for treatment of bile reflux gastritis, to replace the gastric portion of the BPD. This procedure was originally called BPD with DS. For ease of description, it is now simply called the duodenal switch (DS) (Fig. 27-26). Currently, BPD and DS represent together less than 1% to 2% of bariatric operations performed in the United States. Patients who undergo either BPD or DS must be prepared for the consequences of a malabsorptive operation. Frequent and large-quantity bowel movement after any large amount of oral intake is common. Also, patients must agree to close follow-up and a large number of vitamin and mineral supplements to avoid nutritional problems. Given the increased incidence of postoperative nutritional and other complications, BPD and DS usually are recommended only for patients who have higher BMIs or for patients who have failed another operation for weight loss or metabolic control. Contraindications to the procedure include geographic distance from the surgeon, lack of financial means to afford supplements, and preexisting calcium, iron, or other nutrient deficiencies.

Technique. The technique for BPD and DS is the same for the open and the laparoscopic approach, and they are very technically challenging operations.¹⁷² The BPD operation begins with performance of a distal subtotal gastrectomy with a residual 200-mL gastric pouch. The terminal ileum is identified and divided 250 cm proximal to the ileocecal valve. The distal end of that divided ileum is then anastomosed to the stomach, creating a 2- to 3-cm stoma. The proximal end of the ileum is then anastomosed side-to-side to the terminal ileum

approximately 100 cm proximal to the ileocecal valve. Prophylactic cholecystectomy is performed due to the high incidence of gallstone formation with the malabsorption of bile salts.

The DS procedure differs from the BPD procedure only in the proximal gut portion of the operation. Instead of a distal gastrectomy, resection of all the stomach except for a narrow lesser curvature tube of the stomach (SG) is performed. The diameter of this tube is calibrated with a bougie of 32- to 40-French size. The duodenum is then divided in its first portion, leaving an approximately 2-cm length of duodenum intact beyond the pylorus. This end of the duodenum is then anastomosed to the distal 250 cm of ileum. This anastomosis is often done in an end-to-end fashion with a circular stapler. This is the most difficult portion of the DS procedure, and leak rates are slightly higher than with other anastomoses. The distal bowel configuration and cholecystectomy are similar to BPD.

Procedure-Specific Complications. Complications that occur after BPD include those seen after RYGB, where intestinal anastomoses and gastric division create potential problems with bleeding and leakage. Scopinaro and colleagues¹⁷³ reported GI obstruction in 1.2%, wound infections in 1.2%, and marginal ulcers in 2.8% of patients. However, others found the incidence of marginal ulcer to be higher after BPD, leading to the adoption of the DS. Preservation of the pylorus reduces the incidence of dumping (poorly quantitated in most series) after BPD. The duodenoileostomy of DS also has a very low rate of stomal ulcer, unlike the gastroileostomy of BPD.

Nutritional complications are by far the most frequent and concerning after both of these operations, particularly on long-term follow-up. Scopinaro and colleagues¹⁷³ reported a protein malnutrition rate of 7%, iron deficiency anemia rate of less than 5%, and bone demineralization at 5 years of 53%. Other problems that may arise include alopecia from inadequate protein absorption, night blindness from a lack of vitamin A, and gallstones if the gallbladder is not removed. However, of all these nutritional complications, protein-calorie malnutrition is the most severe and life-threatening. When it is diagnosed, the treatment is parenteral nutrition. Two episodes of required parenteral nutrition are usually considered adequate indication to lengthen the “common channel” of ileum—the ileum between the ileoileostomy of the biliopancreatic limb to the alimentary tract and the ileocecal valve. The amount of length that the surgeon should increase the common channel is poorly documented.

Investigational Bariatric Procedures

There is continuous evolution of the approaches to and procedures for bariatric surgery. The goals of this dynamic process are to minimize risk, reduce invasiveness, and maximize clinical effectiveness. This same benefit-risk approach/paradigm has also been adopted by the FDA for the design of clinical trials for obesity devices to help facilitate product development and approval.¹⁷⁴ In the past, a variety of medical devices to assist with weight reduction have been studied, but only a few have been commercially available. In 2012, to address the need for more intermediate treatment options with devices, the FDA initiated a new paradigm based on a benefit-risk determination to suggest appropriate levels of benefit for devices with different risk levels. In other words, it became more feasible to trial less invasive obesity treatment devices, as the threshold for weight loss was lower if the risk of the device or procedure was lower as well. Since that time, several new devices have been approved. These *intermediate devices* are intended to provide

tools in the middle of the spectrum of care between lifestyle modification and bariatric surgery and are offered to people with BMIs between 30 and 40 kg/m².

The vagus nerve is known to play a role in satiety, metabolism, and autonomic control in the upper gastrointestinal tract. Studies have been conducted to determine the efficacy of vagal nerve block therapy with a treatment device that consistently delivers at least 12 hours of therapy a day and a sham control device that has no possibility of delivering therapy. A laparoscopic abdominal procedure is performed to attach two electrodes to the anterior and posterior vagal trunks at the level of the gastroesophageal junction. Customized electrodes are placed around the nerves and then secured with sutures. These electrodes are then connected to a transcutaneously rechargeable neuroregulator placed in a subcutaneous pocket on the thoracic side wall. Published results show modest weight loss in the vagal nerve blockade group of 9.2% compared to 6.0% TBWL in the sham group at 12 months and 8.8% and 3.8% TBWL in vagal nerve blockade and sham groups, respectively, at 18 months.^{175,176} More weight loss was sustained through 18 months in the vagal blockade group, and the device was shown to be safe, as there was a low rate of serious complications.

Endoscopically placed intragastric balloons (IGBs) are once again an option for overweight and obese patients with a BMI greater than 27 kg/m². The original Garren-Edwards bubble (GEB) from the late 1980s was an endoscopically placed and removed balloon filled with 220 mL of air that was left in the stomach for 3 months. Adverse events related to the GEB reported in the medical literature included small-bowel obstruction secondary to unplanned deflation, gastric ulcers with GI hemorrhage, and gastric perforation, so its use was abandoned. A multidisciplinary conference that followed recommended that future IGBs should (a) be effective at promoting weight loss, (b) be filled with liquid (not air), (c) be capable of adjustment to various sizes, (d) have a smooth surface with low ulcerogenic and obstructive potential, (e) contain a radiopaque marker, and (f) be constructed of durable materials.¹⁷⁷

Newer IGBs have undergone evaluation and approval by the FDA. These include both a single and a double lumen balloon, both placed endoscopically and filled with saline.^{178,179} Results from these two pivotal trials show weight losses of 7.6% and 10.2% TBWL at 6 months in the device group that exceeded weight loss in the control or sham groups. There were some early removals in 9% to 18% of subjects for failure to tolerate symptoms, early deflations without migration in 6%, and gastric ulcers in 10%. The precise role for these devices is yet to be determined, and they must be paired with a diet and exercise plan to maximize effectiveness. Repeat or sequential balloon therapy may be effective in enhancing and sustaining weight loss, and it is being studied in Europe. Finally, ensuring proper follow-up is important to reduce adverse events related to ulcers, spontaneous deflation, or migration of the balloon.

An endoscopically placed percutaneous gastrostomy tube is approved for weight loss. It facilitates drainage of approximately 30% of the calories consumed in a meal, in conjunction with lifestyle counseling. In a randomized trial, participants lost 12.1% ± 9.6% TBWL compared to 3.5% ± 6.0% TBWL in the lifestyle-only control group. The most frequent complication was abdominal pain and discomfort in the perioperative period and peristomal granulation tissue and peristomal irritation in the postoperative period. Serious adverse events were reported in 3.6% of participants in the device group.¹⁸⁰

A duodenal-jejunal bypass liner is an endoscopic device that mimics the duodenal-jejunal exclusion component of an RYGB and is undergoing trials in the United States. Prior studies assessing the efficacy of the DJBL have shown modest weight loss and improvements in glycemic control. There are associated adverse events of migration, obstruction, and epigastric pain. One study demonstrated a high (29%) early device removal rate due to these events.¹⁸¹ A more recent meta-analysis showed that the DJBL was associated with significant mean differences in TBWL for the device (12.6%) compared with lifestyle modification. The mean differences in glycated hemoglobin and fasting plasma glucose among subjects with T2DM in this meta-analysis did not reach statistical significance.¹⁸²

Various endoscopic and endoluminal procedures are also being utilized as less invasive approaches for bariatric surgical procedures. These include procedures to decrease gastric pouch size and to limit gastrojejunostomy anastomotic size after “failed” LRYGB.¹⁸³ Overall, reports have been disappointing for effectiveness. Gastric plication is also being approached both laparoscopically and endoscopically to mimic results of an SG but without requiring stapling or gastric resection. Further studies with long-term safety and efficacy data are required before these investigational procedures can be considered for routine clinical use.

FOLLOW-UP AND POSTOPERATIVE CARE

Postoperative follow-up is required following bariatric surgery to detect and treat postoperative short- and longer-term complications. Weight regain, internal hernias, ulcerations, and important nutrient deficiencies can occur years after bariatric surgery. These specific problems are detailed in the “Procedure-Specific Complications” and overall “Complications” sections. The frequency of follow-up varies by surgical procedure and to some extent by surgical practice, but continues, hopefully, for life. Postoperative follow-up is defined as short-term (0–2 years), medium (2–5 years), and long term (≥5 years). Recommendations are that at least 75% of patients are followed for 5 years for LAGB, SG, and LRYGB operations, and 90% are followed closely for 5 years and longer if they have malabsorptive operations (BPD and DS). Although a clinical follow-up system may be in place, it still requires patient compliance, which is generally low for long-term follow-up. In a systematic review, Puzifferri et al also identified that less than 3% of bariatric studies included >80% long-term follow-up.¹⁸⁴ Vigorous efforts can help to improve follow-up, but these require significant staffing and funding. In the NIH-funded prospective, longitudinal bariatric study, more complete follow-up data and weight measurements were obtained for 79% of RYGB patients in the longer term with the use of these resources.¹⁶⁹

The goals of short-term follow-up are to maximize care of the patient in the postoperative period; assist in adjustment to new eating, exercise, and lifestyle patterns; be on the alert for and treat postoperative complications; and recommend measures to limit such complications. The goals of long-term follow-up are similar, but focus more on weight regain, the management of comorbid condition relapse, and the emergence of recurrent depression, substance and alcohol misuse, and nutritional complications. Vitamin and mineral supplements must be taken regularly for life, including oral supplements for iron, calcium, and vitamin B₁₂ and a multivitamin. Evidence indicates that vitamin and mineral deficiencies, including deficiencies of

calcium, vitamin D, iron, zinc, and copper, are common after bariatric surgery.¹⁸⁵ Guidelines suggest screening patients for iron, vitamin B₁₂, folic acid, and vitamin D deficiencies *preoperatively*, as well.⁸⁹ Patients should also be given daily nutritional supplementation postoperatively, including two adult multivitamin plus mineral supplements (each containing 18 mg of iron, 400 to 800 µg of folic acid, and 50 mg of thiamine), 1200 to 1500 mg of elemental calcium (1800 to 2400 mg for BPD/DS), at least 3000 IU of vitamin D, and vitamin B₁₂, the dose of which varies by route of administration. In addition, all patients should undergo annual screening for specific deficiencies (Table 27-4).

Objective data that should be obtained after all bariatric operations include weight loss, change in BMI, resolution or improvement in medical comorbidities, and any complications that occur. Assessment of quality of life can help gauge efficacy as well, with the Short Form-36 (SF36) questionnaire being one frequently used example. In a retrospective review based on the bariatric outcomes longitudinal database (BOLD) dataset by Spaniolas et al, the effect of postoperative follow-up

on 12-month weight loss was studied in 51,081 patients. Complete follow-up was independently associated with excess weight loss ≥50% and total weight loss ≥30%.¹⁸⁶ To identify the relationship between regular follow-up and resolution of comorbidities, the same group studied a cohort of 46,381 patients (31% RYGB patients) who had minimum of 12-month follow-up. After adjusting for baseline characteristics, the group determined that complete follow-up in the first year after RYGB was independently associated with a higher rate of improvement or remission of comorbid conditions (T2DM, hypertension, and dyslipidemia).¹⁸⁷ Frequent and protocolized band adjustments and postoperative support individual/group sessions were shown to be important for longer-term outcomes following LAGB.¹⁸⁸ Finally, the 12-month postoperative visit, which coincides with the plateauing of weight loss for most procedures, presents an opportunity to intervene while bariatric surgery patients are still engaged. Engaging patients and the use of technology to maintain contact with a medical provider are important tools to maintain follow-up after bariatric surgery.

Table 27-4

Recommended postoperative nutritional monitoring

RECOMMENDATION	LAGB	SG	LRYGB	BPD/DS
Bone density (DXA) ^a at 2 years	Yes	Yes	Yes	Yes
24 hour urinary calcium excretion at 6 months and annually	Yes	Yes	Yes	Yes
Vitamin B ₁₂ annually (methylmalonic acid and homocysteine optional) then every 3–6 months if supplemented	Yes	Yes	Yes	Yes
Folic acid (red blood cell folic acid optional), iron studies, vitamin D, intact parathyroid hormone	No	No	Yes	Yes
Vitamin A initially and every 6–12 months thereafter	No	No	Optional	Yes
Copper, zinc, and selenium evaluation with specific findings	No	No	Yes	Yes
Thiamine evaluation with specific findings	Yes	Yes	Yes	Yes

^aDXA = dual energy X-ray absorptiometry; LAGB = laparoscopic adjustable gastric banding; SG = sleeve gastrectomy; LRYGB = laparoscopic Roux-en-Y gastric bypass; BPD/DS = biliopancreatic diversion with duodenal switch.

Data from Mechanick JI, Youdim A, Jones DB, et al: Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2013 update: cosponsored by American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic & Bariatric Surgery, *Obesity (Silver Spring)*. 2013 Mar;21 Suppl 1:S1-S27.

RESULTS OF BARIATRIC SURGERY

Short-Term Outcomes

The short-term (1–2 year) outcomes for bariatric surgical procedures are shown in Table 27-5, which summarizes of the majority of the literature from 2009 to 2017. Average 30-day mortality is low (<1.0%) for all procedures except BPD/DS. Mortality after LRYGB is now consistently less than 0.3% to 0.5% in most large reported series.^{59,140} Morbidity varies by procedure, but it is the lowest for LAGB, followed by SG and then LRYGB, and highest for the malabsorptive procedure BPD/DS. In the Longitudinal Assessment of Bariatric Surgery (LABS) study, a composite endpoint including death, deep-vein thrombosis or venous thromboembolism, reintervention, or failure to be discharged by 30 days after surgery occurred in 4.8% of those who had undergone LRYGB.⁵⁹ Short-term results of the SG have been reported from large national databases. These data show that SG is positioned between LAGB and LRYGB for efficacy of weight loss and resolution of comorbid medical problems and for morbidity and mortality.¹⁴⁰ Few longer-term results with SG have been published.^{189,190}

In the past, large institutional series of LAGB results have been published from centers in Europe and Australia, showing better results for weight loss than those that have been observed in the United States (13–22% TBWL) (see Table 27-5). Weight loss results with BPD or DS are both excellent and comparable but come with higher surgical morbidity. The results from malabsorptive procedures are also very durable for the small percentage of people who undergo them. One 18-year follow-up study after BPD showed a mean excess weight loss of 70% persisting for that duration of time.¹⁷³ Although most of the results of BPD or DS are after open operations, one report of laparoscopic DS at an experienced center showed that for 40 patients with an average BMI of 60 kg/m² the mean hospital stay was 4 days, average operation room time was 3.5 hours, and mean excess weight loss at 9 months was 58%.¹⁹¹ Buchwald and colleagues showed that the average weight loss after BPD and DS in the literature was over 70%, with a mortality rate of 1.1%, a complication rate of 27% to 33%, and a nutritional complication rate of 40% to 77%.¹⁹² (see Table 27-5).

Table 27-5

Short-term bariatric surgical outcomes

OUTCOME ^a	ALL	SURGICAL PROCEDURE			
		LRYGB	SG	LAGB	BPD/DS
% Mortality 30-day	<1.0%	0.3–0.5%	0.11%	0.05%	1.1%
% Morbidity 30-day	NA, depends on procedure	12–21%	3–6%	2–4%	27–33%
% Total body weight loss (TBWL)	NA, depends on procedure	31–36%	25–30%	13–22%	36–38%
% Excess body weight loss (EBWL)	NA, depends on procedure	48–77% (mean, 68%)	49–81%	29–50%	>70%
% Diabetes remission	77%	60–80%	60%	35%	75%
% Dyslipidemia ^b remission	70%	63–91%	72–82%	78%	80%
% Hypertension remission	62%	61–81%	60–92%	43%	60%, few reports
% Sleep apnea remission ^c	84%	80%	80%	68%	80%

^aOutcomes are the averages found in the literature at 1 to 2 years postoperatively, unless otherwise noted.

^bDenotes any component lipid remission.

^cDenotes clinical remission as repeat sleep studies are uncommonly performed.

Further detail on surgical morbidity for each procedure is addressed in both the “Procedure-Specific Complications” and overall “Complications” sections.

Effectiveness of Bariatric Surgery Compared to Nonsurgical Treatment

The following section summarizes important findings of studies that compare bariatric procedures with nonsurgical management of obesity. The results of these studies concerning remission from T2DM will be discussed in more detail in “Results of Surgery for Diabetes.” A systematic review and meta-analysis by Gloy summarized all randomized controlled trials (RCTs) that compared bariatric surgery with nonsurgical treatments for obesity.¹⁹³ The review analyzed 11 trials comprising nearly 800 people with a BMI of 30 to 52. These studies generally focused on cohorts with T2DM and 1 to 2 years of follow-up. They provided good evidence of the effectiveness of bariatric procedures, including LRYGB,^{78–80} LAGB,^{77,194} BPD,⁷⁹ and SG.⁷⁸ These procedures resulted in greater short-term (1–2 years) weight loss (mean difference –26 kg; 95% CI –31 to –21; $P < 0.001$) and greater remission of T2DM (complete case analysis relative risk of remission: 22.1, 3.2–154.3; $P = 0.002$; conservative analysis: 5.3, 1.8–15.8; $P = 0.003$) compared with various nonsurgical treatments.^{77–80,194} After this meta-analysis, two additional RCTs were published that show similar short-term results for both weight loss and T2DM.^{83,84}

In addition, serum triglycerides and high-density lipoproteins were significantly reduced by bariatric procedures, but blood pressure and other lipoproteins were not (although some studies showed reduced medication use for these conditions).¹⁹³ The Gloy review also noted a lack of evidence from RCTs beyond 2 years for mortality, cardiovascular diseases, and adverse events. Another systematic review by Maggard-Gibbons focused on weight loss and glycemic control in class I obese (BMI 30–34.9) adults with T2DM and identified three RCTs with results similar to those seen in class II (BMI 35–39.9) and severely obese populations. However, the review also noted a lack of longer-term studies in people with class I obesity.¹⁹⁵

Longer-Term Studies

A summary of studies with long-term outcomes are shown in **6▶** Table 27-6. The following section describes these studies and other larger studies that have contributed data to the growing body of evidence with respect to some short-term and now much longer-term outcomes.

Swedish Obese Subjects Study. Much of what is currently known about the long-term results of bariatric surgery come from the Swedish Obese Subjects (SOS) study, which was initiated in 1987 as a prospective trial of 2010 subjects undergoing bariatric surgery compared to a usual care control group ($n = 2037$) that were matched on 18 clinical and demographic variables. The most common bariatric procedure performed in SOS was the VBG (68%), followed by gastric banding (19%), and RYGB (13%). Follow-up rates are high and reported at 99% for some endpoints (including mortality). The SOS investigators have published widely on health outcomes beyond 10 years and up to 20 years, including: weight loss, mortality, T2DM remission and incidence, cardiovascular events, incident cancer, psychosocial outcomes, and health care use and costs. Weight loss among surgical subjects in SOS was greater than in control subjects (mean changes in body weight at 2, 10, 15, and 20 years were –23%, –17%, –16%, and –18% in the surgery group and 0%, 1%, –1%, and –1% in the control group). After 15 years, the mean percent weight loss by procedure type was 27 + 12% for RYGB, 18 + 11% for VBG, and 13 + 14% for gastric banding.

The SOS study also showed major improvements in obesity-related comorbidities. In the surgical group, there was a 72% remission of T2DM after 2 years (OR for remission: 8.4) and 36% durable remission after 10 years (OR for remission: 3.5). In spite of the considerable relapse of T2DM over time, bariatric surgery was associated with a lower incidence of myocardial infarction and other T2DM complications. The SOS study demonstrated that bariatric surgery also reduced the risk of incident T2DM by 96%, 84%, and 78% after 2, 10, and 15 years among subjects without the condition at baseline. The SOS study also

ourcoulas AP, Yanovski SZ2, Bonds D, et al: Long-term outcomes of bariatric surgery: a National Institutes of Health symposium, *JAMA Surg.* 2014 Dec;149(12):1323-1329.

found that bariatric surgery was associated with a reduced incidence of fatal or nonfatal cancer among women but not in men. Finally, at 16 years follow-up, surgery was associated with a 29% lower risk of death (the primary endpoint of the study) from any cause compared to usual care, with the most common causes of death being cancer and myocardial infarction¹⁹⁶⁻²⁰¹ (see Table 27-6).

Utah Obesity Studies. Another important long-term observational study performed in Utah from 1984 to 2002 included 7925 people who had undergone RYGB and 7925 weight, age, and sex matched controls. This study showed a 40% reduction in all-cause mortality (hazard ratio 0.60, 0.45 to 0.67; $P < 0.001$) and a 49% (0.51, 0.36 to 0.73; $P < 0.001$) and 92% (0.08, 0.01 to 0.47; $P = 0.005$) reduction in death from cardiovascular disease and death related to T2DM, respectively, at an average of 7.1 years later.²⁰²

A separate ongoing prospective Utah Obesity Study involving over 400 RYGB cases and two nonrandomized, matched control groups—each with over 400 and 300 severely obese subjects (one group were people seeking surgery that did not undergo operation; the other was a population-based severely obese control group)—has found that the surgery group lost 27.7% of their initial body weight compared to 0.2% weight gain in control group 1 (surgery seekers), and 0% change in control group 2 (population-based control) at 6 years. Diabetes was in remission in 62% of RYGB patients and only 8% and 6% in each of the control groups, while incident T2DM was observed in 2% of RYGB patients and in 17% and 15% of the control groups at 6 years.²⁰³ The 12-year follow-up results were also recently published and showed long-term durability of weight loss and effective remission and prevention of T2DM, hypertension, and dyslipidemia after RYGB.²⁰⁴ Follow-up rates in this study were high at over 90% at 12 years. The mean percent change from baseline in body weight in the RYGB group was -26.9% at 12 years compared to -2.0% and 0.9% in each of the two control groups. There was remission of T2DM in 43 of 84 patients (51%) at 12 years. The OR for the incidence of T2DM at 12 years was 0.08 (95% CI, 0.03–0.24) for the RYGB group versus control group 1 and 0.09 (95% CI, 0.03–0.29) for the RYGB group versus control group 2 ($P < 0.001$ for both comparisons). The RYGB group had higher remission rates and lower incidence rates of hypertension and dyslipidemia than did control group 1 ($P < 0.05$ for all comparisons) (see Table 27-6).

Veteran's Administration Study. A retrospective observational study involving 847 U.S. veterans who were older and more high risk than in typical bariatric studies, found no significant association between bariatric surgery and survival compared to usual care at mean 6.7 years follow-up.²⁰⁵ When matched to control subjects, the outpatient, inpatient, and total expenditures were higher for bariatric surgical cases in the 3 years leading up to the procedure and then went back to the lower cost levels of nonsurgical controls in 3 years after the procedure. The conclusion from this study was that bariatric surgery did not appear to be associated with reduced health care expenditures 3 years after the procedure.²⁰⁶

In a follow-up retrospective cohort study, 2500 U.S. veterans (74% men) who underwent bariatric surgery (74% gastric bypass, 15% sleeve gastrectomy, 10% adjustable gastric banding, and 1% other) were matched to 7462 control patients. The primary outcome was all-cause mortality. In this study, surgical patients ($n = 2500$) had a mean age of 52 years and

a mean BMI of 47. Matched control patients ($n = 7462$) had a mean age of 53 years and a mean BMI of 46. At the end of the 14-year study period, there were a total of 263 deaths in the surgical group (mean follow-up, 6.9 years) and 1277 deaths in the matched control group (mean follow-up, 6.6 years). Mortality rates were 2.4% at 1 year, 6.4% at 5 years, and 13.8% at 10 years for surgical patients; for matched control patients, 1.7% at 1 year, 10.4% at 5 years, and 23.9% at 10 years. So, in this later study, there was significantly lower all-cause mortality at longer follow-up.²⁰⁷

Ten-year weight change in 1787 veterans who underwent RYGB compared to controls, and separately, 4-year weight change in veterans who underwent RYGB ($n = 1785$), SG ($n = 379$), and AGB ($n = 246$) were reported. Patients undergoing RYGB lost 21% more of their baseline weight at 10 years than nonsurgical matches. A total of 405 of 564 patients undergoing RYGB (71.8%) had more than 20% weight loss, and 224 of 564 (39.7%) had more than 30% weight loss at 10 years compared with 134 of 1247 (10.8%) and 48 of 1247 (3.9%), respectively, for nonsurgical matches. At 4 years, patients undergoing LRYGB lost 27.5% of their baseline weight, patients undergoing LAGB lost 10.6%, and patients undergoing SG lost 17.8%. Patients undergoing RYGB lost 16.9% more of their baseline weight than patients undergoing AGB and 9.7% more than patients undergoing SG²⁰⁸ (see Table 27-6).

The Longitudinal Assessment of Bariatric Surgery Study. The Longitudinal Assessment of Bariatric Surgery (LABS-1) study, a multicenter observational surgical cohort, prospectively assessed 30-day safety among 4776 severely obese patients who underwent a first bariatric surgical procedure (25% AGB, 62% laparoscopic RYGB, 9% open RYGB, and 3% another procedure) between 2005 and 2007.⁵⁹ The 30-day mortality in the LABS study was 0.3% for all procedures with a major adverse outcome rate (a predefined composite endpoint that included death, venous thromboembolism, reintervention [percutaneous, endoscopic, or operative], or failure to be discharged from the hospital in 30 days) of 4.1%. These results did vary by procedure and approach, with no mortality in the 1198 patients who had undergone LAGB, 0.2% of the 2975 patients who had undergone LRYGB, and 2.1% of the 437 patients who had undergone open RYGB. Similarly, the rate of adverse outcomes (morbidity) occurred in 4.1% of patients overall; 1.0% for LAGB, 4.8% for LRYGB, and 7.8% for open RYGB.⁵⁹ The Longitudinal Assessment of Bariatric Surgery (LABS-2) study is another large prospective multicenter observational bariatric cohort study that was not randomized and did not include a nonsurgical control group. LABS-2 assessed weight change and comorbid conditions in 2458 participants (1738 RYGB—both open and laparoscopic, 610 LAGB, and 110 other procedures) recruited between 2005 and 2009 who were followed for 7 years.^{169,209} At baseline, 33% had diabetes, 63% had dyslipidemia, and 68% had hypertension. In the LABS-2 cohort, median weight change was 31.5% for RYGB and 15.9% for adjustable gastric banding after 3 years, with much variability in response to each surgical treatment. Remission of T2DM was noted in 67% and 28% of those who had undergone RYGB and LAGB, respectively. The incidence of T2DM was 0.9% and 3.2%, respectively, over the 3 years¹⁶⁹ (see Table 27-6). LABS-2 looked at both pre- and postoperative predictors of weight change and found that very few of many baseline variables studied (Black race, T2DM) were associated

with 3-year weight change, and the effects were small overall. Postoperatively, for RYGB only, three behaviors explained most of the variability (16%) in 3-year weight change: weekly self-weighing, continuing to eat when feeling full more than once a week, and eating continuously during the day. If a person started weekly self-weighing, stopped eating when feeling full, and stopped eating continuously during the day, they lost 14% more weight than those who made no positive changes (38.8% vs. 24.6% TBWL).^{210,211}

At 7 years of follow-up, in LABS, data completeness for weight was high (83%), and the median weight change was 28.4% for RYGB and 14.9% for LAGB. Weight regain between years 3 and 7 was 3.9% of baseline weight for RYGB and 1.4% for LAGB, but 75% of RYGB participants maintained at least 20% total body weight loss, and 50% of LAGB participants maintained at least 16% through 7 years. Remission of T2DM was reported in 60.2% of RYGB cases and 20.3% for LAGB. Mortality was reported as 3.7 per 700 person-years for RYGB and 2.7 per 700 person years for LAGB, i.e., number of events if 100 people were followed for 7 years. Reoperations were also much more common after LAGB compared to RYGB at 7 years (see Table 27-6).

HMO Research Network. Arterburn and colleagues have leveraged the integrated health network system to study bariatric outcomes using the electronic health/medical record. They studied clinical predictors of diabetes remission and relapse among patients undergoing gastric bypass. Theirs was a retrospective cohort study of adults with uncontrolled or medication-controlled T2DM who underwent gastric bypass in three integrated health care delivery systems in the United States. Remission and relapse events were defined by diabetes medication use and clinical laboratory measures of glycemic control. Of 4434 adults with T2DM who underwent RYGB, 68.2% (95% CI, 66% and 70%) experienced an initial complete diabetes remission within 5 years after surgery. Among these, 35.1% (95% CI, 32% and 38%) relapsed back to T2DM within 5 years. The median duration of their remission was 8.3 years. Predictors of incomplete remission and relapse were poor preoperative glycemic control, insulin use, and longer diabetes duration²¹² (see Table 27-6).

In a second study, they compared rates of diabetes remission, relapse, and all-cause mortality at 2 years between severely obese adults with T2DM who underwent bariatric surgery or received usual medical care. There were 1395 adults with T2DM who had bariatric surgery and 62,322 who did not. Most procedures were RYGB (72.0% laparoscopic; 8.2% open); 4.4% were gastric banding, 2.4% were sleeve gastrectomy, and 13.2% were other procedures. At 2 years, bariatric subjects experienced significantly higher diabetes remission rates (73.7% [95% CI: 70.6, 76.5]) compared to nonsurgical subjects (6.9% [95% CI: 6.9, 7.1]). Age, site, duration of diabetes, hemoglobin A1c level, and intensity of diabetes medication treatment were significantly associated with remission. Bariatric subjects also experienced lower relapse rates than nonsurgical subjects (adjusted HR: 0.19; 95% CI: 0.15–0.23) with no higher risk of death (adjusted HR: 0.54; 95% CI: 0.22–1.30) (see Table 27-6).²¹³ This group also studied short-term comparative effectiveness outcomes between procedures (LRYGB and LAGB) and found that LRYGB resulted in much greater weight loss than LAGB but had a higher risk of short-term complications and long-term subsequent hospitalizations.²¹⁴

Michigan Bariatric Surgery Collaborative. The Michigan Bariatric Surgery Collaborative is a statewide consortium of hospitals and surgeons that maintains an externally audited prospective clinical registry. The comparative effectiveness of SG, LRYGB, and LAGB procedures was studied in this dataset. Nearly 3000 SG patients with equal numbers of RYGB and LAGB patients were matched on 23 baseline characteristics. Outcomes assessed included 30-day complications, weight loss, quality of life, and comorbid remission up to 3 years after bariatric surgery. Overall complication rates for SG (6.3%) were significantly lower than for RYGB (10%) but higher than for LAGB (2.4%). Serious complication rates were similar for SG (2.4%) and LRYGB (2.5%) but higher than for LAGB (1.0%). Excess body weight loss at 1 year was 13% lower for SG (60%) than for RYGB (69%), but was 77% higher for SG than for LAGB (34%). Remission of comorbid conditions was similar between SG and LRYGB²¹⁵ (see Table 27-6).

This group also developed a risk prediction model for serious 30-day complications after bariatric surgery. Overall, 2.5% of patients experienced a serious complication. Significant risk factors included prior venous thromboembolism (OR 1.90, CI 1.41–2.54); mobility limitations (OR 1.61, CI 1.23–2.13); coronary artery disease (OR 1.53, CI 1.17–2.02); age over 50 (OR 1.38, CI 1.18–1.61); pulmonary disease (OR 1.37, CI 1.15–1.64); male gender (OR 1.26, CI 1.06–1.50); smoking history (OR 1.20, CI 1.02–1.40); and procedure type.²¹⁶ Further, to assess the relationship between IVC filter insertion and complications while controlling for differences in baseline patient characteristics and medical venous thromboembolism prophylaxis, this group published an additional study, and 35,477 patients from 32 hospitals in Michigan were included. Patients receiving IVC filters had higher rates of pulmonary embolism, deep vein thrombosis, venous thromboembolism, serious complications, and death.²¹⁷

Recently, this group has also been evaluating the effect of surgical skill and operative technique on complications following bariatric surgery.^{218,219}

Other Studies

Metabolic and Bariatric Surgery Quality Improvement Program (MBSAQIP). This is a prospective, multi-institutional, national database that has been used to compare SG to RYGB and LAGB. The study from 2011 was short term and compared 30-day, 6-month, and 1-year outcomes including morbidity and mortality, readmissions, and reoperations as well as reduction in BMI and weight-related comorbid conditions. The findings were that SG has higher risk-adjusted morbidity, readmission and reoperation/intervention rates compared to LAGB, but lower reoperation/intervention rates compared to RYGB either laparoscopic or open. There were no differences in mortality. Reduction in BMI and most of the weight-related comorbidities after SG was also between LAGB and RYGB rates.¹⁴⁰

A later study addressed the impact of various SG techniques on short-term (30-day) outcomes. Using the MBSAQIP data registry, 189,477 SG operations that were performed at over 700 centers in the United States were analyzed. Cases in which staple line reinforcement was used were associated with higher leak rates and lower bleeding rates. Bougie size ≥ 38 French was associated with significantly lower leak rates compared to < 38 French.¹⁶² Longer-term data will eventually be available from this national dataset, but the completeness of follow-up has not yet been determined.

Geisinger Health System. This is an electronic medical record database in a large rural integrated health system. They

have published long-term results (7–12 years) of the percentage of TBWL and preoperative predictors for LRYGB in approximately 700 patients. Over 200 preoperative clinical factors were studied. At a median of 9.3 postoperative years following surgery, the mean (SD) percentage TBWL was 22.5% (13.1%). Preoperative insulin use, history of smoking, and use of 12 or more medications before surgery were associated with greater long-term weight loss; 6.8%, 2.8%, and 3.1%, respectively. Preoperative hyperlipidemia, older age, and higher body mass index were associated with poorer long-term weight loss (−2.8%, −8.8%, and −4.1%, respectively). Again, there were only a few preoperative clinical factors associated with differences in long-term weight loss after RYGB.²²⁰

This group also developed a method to predict the probability of T2DM remission after RYGB surgery on the basis of preoperative clinical criteria in a retrospective cohort study. Over 200 clinical variables were used to identify independent predictors of remission within 5 years and to produce a score (DiaRem) to assess this likelihood. Records were available for 690 patients in the primary cohort, of whom 463 (63%) had achieved partial or complete T2DM remission. Four preoperative clinical variables were included in the final model: insulin use, age, HbA1c concentration, and type of antidiabetic drugs. The DiaRem score was developed from that, and it ranges from 0 to 22 with the proportion of patients achieving remission being highest for the lowest scores.²²¹

Comparisons Between Procedures

There have been many systematic reviews of bariatric surgery attempting to summarize and quantify differences in the efficacy and safety of the different surgical procedures. A major challenge in summarizing this literature from the last 10 years is the fact that no single randomized trial has included all of the most common procedures (RYGB, LAGB, SG, and BPD/DS), so inference must be made through pooled analysis of data from many disparate randomized and non-randomized studies of bariatric surgery with different lengths and completeness of follow-up. There are also no studies that have examined differences in long-term survival, incident cardiovascular events, and quality of life across bariatric procedures.¹ Still one of the most comprehensive systematic reviews by Buchwald included 136 studies and a total of 22,094 bariatric patients. Only 5 of the included studies were randomized trials (28 non-RCTs and 101 uncontrolled case series) and the review did not include any data on the SG procedure, so will need to be updated. This review found a strong trend towards different weight loss outcomes across procedures: weighted mean percentage of excess weight loss (%EWL) 50% for LAGB; 68% for RYGB; 69% for VBG; and 72% for BPD/DS. The rate of T2DM remission also appeared to differ across procedures: 48% for LAGB; 84% for RYGB; 72% for VBG; and 99% for BPD/DS. A similar pattern of disease remission was observed for dyslipidemia, hypertension, and obstructive sleep apnea, with the greatest rates of remission observed among BPD/DS patients, followed by RYGB patients, with the least disease remission among LAGB patients.¹⁹²

There is still ongoing debate regarding the comparative effectiveness of the three most common procedures currently in use: LRYGB, SG, and LAGB. Several other systematic reviews have concluded that LRYGB is more effective for weight loss than LAGB; however, there have been only two small RCTs with follow-up at 4 and 5 years addressing this issue specifically.^{65,222,223} There is evolving data from a number of smaller RCTs to examine differences between LRYGB,

LAGB, and SG for comorbidity improvement (addressed in “Results of Surgery for Diabetes”), but systematic reviews of nonrandomized studies indicate greater remission of T2DM, dyslipidemia, hypertension, and sleep apnea with LRYGB compared to LAGB. Two recent systematic reviews have compared the outcomes of the SG with other procedures.^{224,225} One review identified 15 RCTs involving 1191 patients. The percent excess body weight loss (%EBWL) ranged from 49% to 81% for SG, from 62% to 94% for LRYGB, and from 29% to 48% for LAGB, with a follow-up ranging from 6 months to 3 years. The T2DM remission rate ranged from 27% to 75% for SG vs. 42% to 93% for RYGB. The second review only compared SG to RYGB and identified 6 RCTs and two nonrandomized controlled studies with follow-up ranging from 3 months to 2 years. They found that LRYGB achieved significantly greater improvement in BMI than SG (1.8 kg/m²) and greater improvements in metabolic factors. Longer-term comparative effectiveness data on SG are still needed, but the effectiveness of the SG procedure, again, appears to be positioned between the LRYGB and LAGB procedures.

Resolution of Specific Comorbid Conditions

Bariatric surgery can improve and induce remission of many obesity-related comorbid conditions. Nevertheless, the remission rates can decline over time due to relapse of disease, and as follow-up lengthens, complete and more longer-term follow-up data is needed in some areas.

Cardiovascular Disease. A recent systematic review of long-term cardiovascular risk factor reduction after bariatric surgery involved 73 studies and 19,543 subjects with a mean age of 42 years; 76% of subjects were female, and 44%, 24%, and 44% had baseline hypertension, diabetes, and hyperlipidemia, respectively.²²⁶ At a mean follow-up of 57.8 months, the average excess weight loss for all bariatric procedures was 54%, and remission/improvement was 63% for hypertension, 73% for T2DM, and 65% for hyperlipidemia. Echocardiographic results from 713 subjects showed statistically significant improvements in hemodynamics. There are no long-term RCTs comparing bariatric surgery with nonsurgical medical treatment of obesity that specifically evaluate cardiovascular endpoints and cardiovascular mortality. However, 12 cohort-matched studies comparing bariatric surgery with nonsurgical controls have been reviewed.²²⁷ Collectively, all but two of these studies support a reduced cardiovascular event rate and all-cause mortality rate conferred by bariatric surgery. Of these studies, the Swedish Obesity Subjects (SOS) study still has the longest outcomes.

Gastroesophageal Reflux Disease. Patients with obesity and GERD have a higher chance of failing to obtain symptomatic relief from standard antireflux surgery. The recurrence of symptoms is higher, likely due to a higher incidence of wrap herniation into the mediastinum and other mechanical failure of the fundoplication, which in turn is likely affected by the increased intra-abdominal pressure of the obese condition. The patient with a BMI over 35 kg/m² who has GERD has a better chance of symptom improvement by undergoing LRYGB, which is effective for the treatment of GERD.^{228,229} LRYGB creates such a small gastric pouch that it has a very limited volume for acid production. LAGB may worsen or may improve GERD but to a considerably lesser extent than RYGB. A prospective analysis of 558 consecutive SG ($n = 200$) and LRYGB ($n = 358$) patients demonstrated significantly improved subjective GERD symptoms in the bypass cohort when compared to the SG patients at

1 year.²³⁰ Studies show that SG can increase GERD symptoms postoperatively.

Obstructive Sleep Apnea. A systematic review of 13,900 patients (69 studies) showed significant improvement or resolution of sleep apnea in more than 75% of bariatric surgery patients.²³¹ Comparison of outcomes between procedures demonstrated the most benefit with BPD and RYGB and the least with LAGB. However, a randomized control trial comparing the effect of medical and surgical weight loss (LAGB) on sleep apnea found no significant difference in apnea events despite major differences in weight loss. The findings suggested that much of the improvement achieved was in the mild to moderate weight loss range, with little benefit of further weight loss.²³²

Asthma. Another pulmonary symptom that commonly occurs in severely obese patients is asthma. Dixon and colleagues²³³ studied 23 asthmatic patients who underwent bariatric surgery and found a significant improvement in asthma control (e.g., forced expiratory volume in 1 second, forced vital capacity), asthma-related quality of life, and responsiveness to methacholine. Boulet and colleagues²³⁴ found similar results in their cohort of 12 patients with asthma who experienced significant weight loss after bariatric surgery.

Nonalcoholic Fatty Liver Disease. Nonalcoholic Fatty Liver Disease (NAFLD) is a metabolically related problem associated with obesity. The disease is a spectrum of liver abnormalities including steatosis, steatohepatitis, fibrosis, and cirrhosis of the liver. It is estimated that 20% of U.S. adults have NAFLD, largely because of the high incidence of obesity. NAFLD is present in an estimated 85% of patients with severe obesity.²³⁵ Although further research is needed to accurately assess the role of bariatric surgery as a potential treatment for NAFLD, there are some reports that support its use. A systematic review of the available literature found many retrospective and prospective observational cohort studies, but no RCTs or case-control series.²³⁶

Musculoskeletal Disease. Degenerative joint disease and low back pain are among the most common complaints and associated comorbid problems in the severely obese population. A prospective cohort of 50 obese females age 20 to 74 years were followed for 1 year after LRYGB using the timed-get-up-and-go (TGUG) and health survey SF-36.²³⁷ The results showed a significant improvement in musculoskeletal function and likely enhanced ability to progress in rehabilitation. Patients with osteoarthritis of the neck, shoulder, spine, hip, knee, ankle, wrist, and hand have been shown to have improved or resolved joint pain after bariatric surgery. Reduction in BMI values of 6.2 to 14.7 kg/m² has corresponded with back and knee pain resolution in 5% to 100% of patients, whereas pain severity was reduced in 31% to 94% of patients depending on the joint and study.²³⁸

The LABS-2 Study published data on pain and physical function in over 2200 participants. At year 1, clinically meaningful improvements were shown in 57.6% of participants for bodily pain, 76.5% for physical function, and 59.5% for walk time. Additionally, among participants with severe knee or disability (633), or hip pain or disability (500) at baseline, approximately three-fourths experienced joint-specific improvements in knee pain (77.1%) and in hip function (79.2%). But between year 1 and year 3, rates of improvement significantly decreased for both bodily pain and for physical function.²³⁹

Quality of Life. Few long-term studies have assessed the impact of bariatric surgery on overall quality of life. However, three studies of 6 to 10 years' duration suggest that bariatric procedures are associated with greater improvements in overall and

obesity specific measures of quality of life compared to medical treatment or care.²⁴⁰⁻²⁴² Physical functioning aspects of quality of life seem to be more responsive to bariatric procedures than mental health domains, although more research is needed, especially in patients with less severe (class 1) obesity.

Results of Surgery for Diabetes (Metabolic Surgery)

Based on an abundance of recent observational studies and RCTs, bariatric surgery is increasingly used with the primary intent to treat T2DM or metabolic disease, hence the term *metabolic surgery*.²⁴³ Observational, nonrandomized studies first demonstrated profound improvements in hyperglycemia and other cardiovascular risk factors following metabolic surgery that were followed by RCTs. Resolution or remission of T2DM is typically defined as becoming “nondiabetic” with normal HbA1c, without medications. One meta-analysis (2009) of 19 mostly observational studies ($n = 4,070$ patients) reported an overall T2DM remission rate of 78% after bariatric surgery with 1 to 3 years follow-up.²⁴⁴ The patients all had BMI >35 and generally early/mild T2DM that likely increased remission rates. In the Swedish Obese Subjects study, the remission rate following surgery was 72% at 2 years and 36% at 10 years compared with 21% and 13%, respectively, for the nonsurgical controls ($P < .001$).²⁰¹ Metabolic surgery was also significantly more effective than nonsurgical treatment in preventing new onset cases of T2DM, with a relative risk reduction of 78%.

A more recent systematic review (2012) evaluated long-term cardiovascular risk reduction after bariatric surgery in 73 studies and 19,543 patients.²²⁶ At a mean follow-up of 57.8 months, the average excess weight loss for all procedures was 54%, and rates of remission or improvement were 63% for hypertension, 73% for T2DM, and 65% for hyperlipidemia. Results from 12 cohort-matched, nonrandomized studies comparing bariatric surgery vs. nonsurgical controls demonstrated reduced cardiovascular events and death (30–88% reduction) in patients with and without T2DM.²²⁷ One of these studies involving male veterans, who were mostly at high cardiovascular risk, reported a 42% reduction in mortality at 10 years compared with medical therapy.²⁰⁷ Similarly, in the Swedish Obese Subjects study, the mortality rate from cardiovascular disease in the bariatric surgical group was lower than for control patients (adjusted hazard ratio, 0.47; $P = .002$).²⁰¹ For patients with T2DM in this study, surgery was associated with a 50% reduction in microvascular complications (41.8 per 1000 person-years for control patients and 20.6 per 1000 person-years in the surgery group; hazard ratio, 0.44; $P < .001$).²⁴⁵ These observational, nonrandomized studies provide evidence that metabolic surgery is superior to medical management alone in improving glycemic control, reducing cardiovascular risk factors, and lowering long-term morbidity and mortality of T2DM, yet supporting RCTs have been lacking until recently.

During the past 10 years, 11 such RCTs have been published including 794 patients in total (Table 27-7).^{16,77-83,85,86,246-253}

▶ These RCTs included obese patients with T2DM ($n = 794$; range 38–150 patients per study) with follow-up from 6 months to 5 years (Fig. 27-27). All common metabolic surgical procedures were represented including LRYGB (9 studies), LAGB (5 studies), SG (2 studies), and BPD (1 study). T2DM severity varied significantly from mild (mean HbA1c 7.7%, <2-year onset, no insulin)^{253,77} to severe (mean HbA1c 9.3%, duration 8.3 years, 48% on insulin).⁷⁸ The BMI ranged from 25 to 53 kg/m², with 11 of 12 studies including patients with BMI <35 kg/m², also called class 1 obesity. Age, sex, and ethnic background were similar,

Table 27-7

Metabolic surgery randomized controlled trials for type 2 diabetes (n = 794)^a

STUDY	BMI (kg/m ²), % OF PATIENTS	DESIGN	NO. OF PATIENTS RANDOMIZED	FOLLOW-UP (MONTHS)	REMISSION CRITERIA*	OUTCOME (REMISSION OR CHANGE IN HbA _{1c})
Dixon ⁷⁷	<35, 22%	LAGB vs. control	60	24	HbA _{1c} <6.2%	73% vs. 13%, P <0.001
Schauer ^{78,246,252}	<35, 36%	RYGB vs. SG vs. control	150	60	HbA _{1c} ≤6.0%	22% vs. 15% vs. 0, P <0.05
Mingrone ^{79,82}	>35, 100%	RYGB vs. BPD vs. control	60	60	HbA _{1c} ≤6.5%	42% vs. 68% vs. 0, P = 0.003
Ikramuddin ^{80,247}	<35, 59%	RYGB vs. control	120	24	HbA _{1c} <6%	44% vs. 9%, P <0.001
Liang ²⁴⁸	<35, 100%	RYGB vs. control	101	12	HbA _{1c} <6.5%**	90% vs. 0 vs. 0, P <0.0001

although three studies^{80,247,248} included a significant number of Asian patients. For most studies, the primary endpoint was remission, defined as an HbA_{1c} target at or below 6.0% to 6.5% without use of diabetes medications.

Overall, these RCTs showed that surgery was significantly more effective than medical treatment in reaching remission and glycemic control ($P < .05$) (Fig. 27-27). The one exception showing no superiority of surgery involved gastric banding and resulted in a diabetes remission for LAGB vs. medical treatment of 33% and 23%, respectively ($P > 0.05$).⁸⁵ Overall, surgery decreased HbA_{1c} by 2% to 3.5%, whereas medical treatment lowered it by 1% to 1.5%, as seen in Fig. 27-28. Most of these studies also showed superiority of surgery over medical treatment in achieving secondary endpoints such as weight loss, remission of metabolic syndrome, reduction in diabetes and cardiovascular medications, and improvement in triglycerides, lipids, and quality of life. Results were mixed in terms of improvements in systolic and diastolic blood pressure or low-density lipoproteins after surgery vs. medical treatment, but many studies did show a corresponding reduction in medication usage.

Although previous guidelines and payer coverage policies had limited metabolic surgery to severely obese patients (BMI ≥35 kg/m²), nearly all RCTs showed that the surgical procedures, especially LRYGB and SG, were equally effective in patients with BMI 30 to 35 kg/m². This is particularly important given that many patients with T2DM have a BMI <35 kg/m². The effect of surgery in these patients with a lower class of obesity is also durable out to at least 5 years.^{243,252}

None of these RCTs were sufficiently powered to detect differences in macrovascular or microvascular complications or death, especially at the relatively short follow-up, and no such differences have been detected thus far. Four of the RCTs from Pittsburgh, Seattle, Boston, and Cleveland have combined their patient populations in a pooled study to assess 10-year outcomes. This study, Alliance of Randomized Trials of Medicine vs. Metabolic Surgery (ARMMS), aims to identify long-term risks and benefits of metabolic surgery.

The evidence, as previously summarized, was the basis for newly established international guidelines on the role of metabolic surgery in treating T2DM. In 2015, the 2nd Diabetes Surgery Summit (DSS-II) Consensus Conference generated

7. Glycemic endpoints of RCTs by length of follow-up. Forest plot of Peto odds ratios (ORs) of main glycemic end points, as defined in each trial, from published RCTs comparing surgery compared with medical/lifestyle treatments for diabetes with data arranged in order of increasing length of follow-up. (Reproduced with permission from Cummings SR, et al. *Metabolic Surgery to Treat Type 2 Diabetes in Patients With a BMI <35 kg/m²*, *Diabetes Care*. 2016 Jun;39(6):924-933.)

guidelines that were endorsed by more than 50 diabetes and medical organizations.¹⁶ The recommendations include patient selection, preoperative evaluation, choice of procedure, postoperative follow-up, and indications for surgery. According to the

DSS-II guidelines, metabolic surgery should be recommended to treat T2DM in patients with class III obesity (BMI ≥40 kg/m²) regardless of glycemic control and in those with class II obesity (BMI 35.0–39.9 kg/m²) when hyperglycemia is inadequately controlled by lifestyle and optimal medical therapy (Fig. 27-29). Surgery should also be considered for patients with T2DM and BMI 30.0 to 34.9 kg/m² if hyperglycemia is inadequately controlled despite optimal treatment with either oral or injectable medications. These BMI thresholds should be reduced by 2.5 kg/m² for Asian patients. The new treatment algorithm from DSS-II incorporates appropriate use of all three treatment modalities: lifestyle intervention, drug therapy, and surgery (see Fig. 27-29).¹⁶ The 2017 Standards of Care for Diabetes from the American Diabetes Association include those key indications in its recommendations for metabolic surgery, as well.

COMPLICATIONS OF BARIATRIC SURGERY

Surgical Complications

None of the surgical procedures are without risks. The perioperative mortality for the average patient is low (<0.5%) and declining, but can vary significantly across subgroups with perioperative mortality rates of 2.0% or higher in some patient populations.¹ The incidence of complications after the various surgical procedures varies from 4% to over 25% and depends on the definition of complication used, the type of bariatric procedure performed, and patient characteristics^{216,254,255} (see Table 27-5).

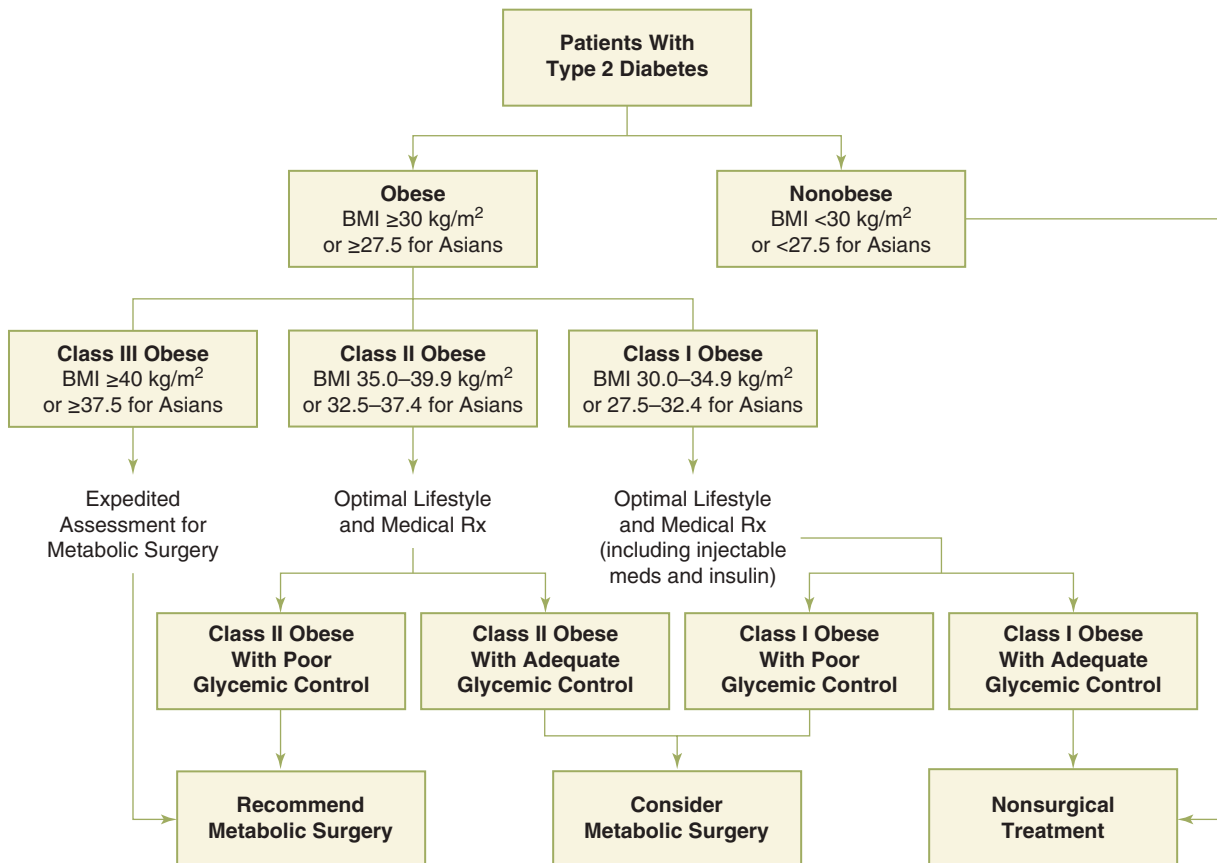

Figure 27-29. Algorithm for the treatment of type 2 diabetes as recommended by the 2nd Diabetes Surgery Summit. (Reproduced with permission from Rubino F, Nathan DM, Eckel RH, et al: *Metabolic Surgery in the Treatment Algorithm for Type 2 Diabetes: A Joint Statement by International Diabetes Organizations*, Diabetes Care. 2016 Jun;39(6):861-877.)

In the 11 RCTs (794 patients) that have compared bariatric surgery to nonsurgical treatment, rates of adverse events were higher among surgical subjects, with follow-up up to 5 years for two of the studies and up to 2 to 3 years for others.^{82,252,256} There were very few cardiovascular events or deaths in either the surgical or the nonsurgical groups, and the most common adverse events after surgery were iron deficiency anemia (15% with intestinal bypass operations) and reoperations (8%). These RCTs were not large enough to compare safety between procedure types, and most of the comparative data on procedure-to-procedure complications has and will come from larger observational studies.

The 30-day mortality in the LABS Study was 0.3% for all procedures with a major adverse outcome rate (a predefined composite endpoint that included; death, venous thromboembolism, reintervention [percutaneous, endoscopic, or operative], or failure to be discharged from the hospital in 30 days) of 4.1%.⁵⁹ Major predictors of an increased risk of complications in LABS were a history of venous thromboembolism, a diagnosis of obstructive sleep apnea, impaired functional status defined as inability to walk 300 feet (91 m), extreme BMI, and undergoing an RYGB by the open technique. Other large observational studies, such as SOS, have shown higher rates of complications, with 14.5% having at least one nonfatal complication over the first 90 days, including pulmonary complications, vomiting, wound infection, hemorrhage, and anastomotic leak. However, the SOS included mostly open and VBG procedures, which are rarely performed today. Despite these older procedures and techniques, the 90-day mortality rate in SOS was low at 0.25%.¹⁹⁶

In a 2007 meta-analysis of 361 studies, mostly nonrandomized observational studies involving over 85,000 patients, Buchwald and colleagues reported important differences in ≤ 30 -day mortality across different laparoscopic bariatric procedures: 0.06% for LAGB; 0.21% for VBG; 0.16% for RYGB; and 1.11% for BPD/DS.²⁵⁷ This review also found significantly higher mortality for open procedures compared with those performed laparoscopically. A U.S. study of over 300,000 patients in 12 states examined in-hospital complications before and after implementation of the CMS national policy restricting insurance coverage for bariatric surgery to “centers of excellence.” The study found no significant differences in complications before and after the policy was implemented, and overall complication rates were 7% to 8% with 3.3% to 3.6% being serious, including a 1% reoperation rate during both time periods.^{1,258} A clinically useful prognostic risk score was also developed and validated in 9382 patients to predict 90-day mortality after LRYGB surgery using five clinical characteristics: BMI ≥ 50 kg/m², male sex, hypertension, known risk factor for pulmonary embolism, and age ≥ 45 years. Patients with 4 to 5 of these characteristics are at much higher risk of death (4.3%) by 90 days than those with 0 to 1 characteristics (0.26%).²⁵⁹⁻²⁶¹ A systematic review of 15 RCTs of SG found no deaths in just under 800 patients but a 9.2% mean complication rate (range 0–18%).²²⁴ In the American College of Surgeons Bariatric Surgery Network database, mortality 30 days after SG was 0.11%, positioning its overall complication profile between that for LAGB (0.05%) and RYGB (0.14%). The 30-day complication rate was similarly positioned at 5.6% for SG, 1.4% LAGB, and 5.9% for RYGB.¹⁴⁰

An established problem now is the frequent rate of reoperation, particularly among LAGB patients. In O’Brien and colleagues’ prospective cohort of 3227 LAGB patients, revisional procedures occurred in 1116 (35%) and were performed for the

following reasons: proximal enlargement (26%), port and tubing problems (21%), and erosion (3.4%). The need for revision due to proximal enlargement decreased dramatically over a 17-year period from 40% to 6.4% as the surgical technique evolved; however, the band was ultimately removed in 5.6% of all individuals.²⁶² Other long-term cohorts suggest that LAGB removal rates may be as high as 50%. The O’Brien systematic review of long-term studies indicates that the rate of revisional surgery for LRYGB may be similar to LAGB (22% revision for LRYGB, range 8% to 38%; 26% revision for LAGB, range of 8% to 60%). However, in the LABS Study, there was a higher rate of revision and reoperation for LAGB as compared to RYGB at both 3 and 7 years of follow-up.¹⁶⁹ In general, more long-term data with more complete follow-up with standardized definitions and reporting of complications are needed to compare reoperation and complication rates of all bariatric procedures.

Nonsurgical Complications

Postgastric bypass hypoglycemia (PGBH) is a relatively uncommon but particularly challenging problem that affects an unknown number of patients in the longer term. Prevalence rates in the literature vary from 1% to 11%, depending on the definition.^{263,264} Hypoglycemia is characterized by documentation of Whipple’s triad (including both autonomic and neuroglycopenic symptoms or signs), at the time of a plasma glucose concentration <55 mg/dL with resolution of symptoms and signs after glucose administration. During these episodes, plasma insulin levels are inappropriately high, indicating dysregulation of β -cell function. When it was initially described in patients who had undergone partial pancreatectomy, nesidioblastosis was found in the specimens that are characterized by hyperplasia and/or dysplasia of the pancreatic islets.²⁶⁵ It was initially thought to be endogenous hyperinsulinemia from increased β -cell mass hyperfunctioning islet cells; however, the current thinking is that the recalcitrant symptoms of hyperinsulinemic hypoglycemia after RYGB are related to the anatomic and physiologic changes and not from an inherent change in β -cell mass. One candidate mediator of increased insulin secretion in PGBH is GLP-1, a peptide released from intestinal neuroendocrine L-cells in response to meals. Consistent with this hypothesis, postprandial GLP-1 levels are increased by over tenfold in post-RYGB patients, are higher in those with hyperinsulinemic hypoglycemia and neuroglycopenia, and correlate inversely with postprandial glucose levels.²⁶⁶ PGBH needs to be distinguished from other forms of hypoglycemia such as other functional β -cell disorders such as noninsulinoma pancreatogenous hypoglycemia, insulinoma, reactive hypoglycemia, or early or late dumping syndrome. It is possible that PGBH is a spectrum of hypoglycemia with late dumping being on the end of the spectrum that is more responsive to dietary changes alone while more severe PGBH can be associated with severe symptoms.²⁶³ First-line therapeutic approaches to PGBH include medical nutrition therapy aimed at reducing intake of high glycemic index carbohydrates and premeal treatment with acarbose. Additional therapies that may be considered include octreotide, diazoxide, calcium channel blockers, GLP-1 receptor antagonists, and providing nutrition solely through a gastrostomy tube placed into the bypassed duodenum. Reversal of gastric bypass is not uniformly successful, suggesting the importance of underlying genetics and/or compensatory mechanisms that may persist after surgical reversal.²⁶⁶ Finally, although pancreatic resection was initially employed for patients with life-threatening hypoglycemia, this procedure

is not uniformly successful in remitting hypoglycemia and should not be considered for the majority of patients, who can experience improvement in their symptoms with a combination of medical approaches. A 2017 American Society of Metabolic and Bariatric Surgery (ASMBS) position statement provides a comprehensive summary of this topic and also recommends this multimodal medical approach.²⁶⁷

There is data to suggest that babies born to women following bariatric surgery are at risk for certain complications. In a Swedish study, bariatric surgery was originally associated with reduced risks of gestational diabetes and excessive fetal growth, shorter gestation, and an increased risk of small-for-gestational-age infants. In a later follow-up report, this same group reported a significant association between a history of bariatric surgery and an increased risk of preterm birth and spontaneous preterm birth, in particular.^{119,268}

There is also emerging data from observational studies that some bariatric procedures may be associated with a greater long-term risk of substance and alcohol use disorders, suicide, and nutritional deficiencies. Pharmacokinetic studies indicate that after LRYGB and SG, the anatomic changes lead to very rapid absorption of alcohol and marked increases in blood alcohol concentrations for a single small.^{269,270} In the SOS study, RYGB was associated with increased alcohol consumption and an increase in alcohol abuse events (HR: 4.9) over 20 years.¹⁹⁶ Similarly in the LABS study, alcohol use disorders were found to be more common in the second postoperative year (9.6%) in those undergoing RYGB compared to before surgery (7.6%). Risk factors for alcohol use disorders included male gender, younger age, and preoperative smoking or alcohol use.²⁷¹ At 7-year follow-up in LABS, there was a progressive and significant increase over time in the prevalence of regular alcohol consumption for both RYGB and LAGB. In addition, alcohol use disorders, illicit drug use, and treatment for substance use disorders, increased over the 7-year period for RYGB only.²⁷² Overall, these rates were high, with 20% of RYGB participants reporting incident alcohol use disorder symptoms within 5 years of surgery.

In addition, there may be an increased risk for suicide²⁷³⁻²⁷⁵ following bariatric surgery, although the etiology is unclear and the data is varied and complex to interpret.²⁷⁶ The Utah mortality study showed a 58% increase in all non-disease-related causes of death in the RYGB group compared to the matched control population, including a small but significant increase in suicides, accidents, and intentional poisonings.²⁰² Similar findings were observed in the second Utah Obesity Study.²⁰³ An observational study using Pennsylvania state data found that suicide rates were 13.7 per 10,000 among men and 5.2 per 10,000 among women among postbariatric surgery patients in Pennsylvania over 10 years, which were both significantly higher than age and sex-matched rates in the United States. In addition, the majority (70%) of these deaths occurred in the first 3 years following surgery when clinical follow-up is incomplete.²⁷⁷

Finally, there is evidence that vitamin and micronutrient deficiencies are common following bariatric surgery including calcium, vitamin D, iron, zinc, and copper, and others. Guidelines suggest that all patients should be screened for deficiencies preoperatively as some deficiencies predate the surgical procedure (see “Follow-Up Postoperative Care”). After surgery, patients must be provided daily nutritional supplementation and undergo routine long-term monitoring for deficiencies (see Table 27-4). Data continue to suggest that the prevalence of

micronutrient deficiencies is increasing, while monitoring is decreasing. Aside from these recommendations, there is insufficient evidence currently regarding optimal dietary and nutritional management following bariatric procedures, including how to treat some of the specific complications of bariatric operations such as chronic nausea and vomiting, hypoglycemic episodes, failed weight loss, and anastomotic ulcers and strictures.^{1,278-280}

REOPERATIVE (REVISION AND CONVERSION) BARIATRIC SURGERY

Introduction

Surgical treatments for chronic diseases such as obesity often require additional or revisional surgical procedures when the primary procedure did not sufficiently treat the underlying disease. This is true in joint replacements when treating osteoarthritis, coronary-artery bypass graft surgeries when treating coronary artery disease, and bariatric surgery in the treatment of obesity.²⁸¹ Additionally, we suspect that obesity is a heterogeneous disorder²⁸² and is therefore being treated with a variety of procedures with different mechanisms of action.⁶³ Given this, it is not surprising that some patients are “treatment failures” with respect to improvements in weight, comorbidities, and quality of life. Also, older bariatric surgical procedures such as the jejunal-ileal bypass, the VBG, and early gastric bypass procedures (which utilized a horizontal and/or partitioned stomach) require revision because of a higher complication rate.^{283,284} Initial bariatric surgery cases have averaged greater than 150,000 cases per year for the last 15 years.²⁸⁵ For these reasons, reoperative bariatric surgery has become increasingly prevalent over the last decade. Despite its increasing prevalence, there are challenges in assessing the frequency and effectiveness of these procedures. Reoperative bariatric surgery has been difficult to categorize meaningfully and to quantify due to the multiple procedure codes, many with little specificity. Reports in the literature range from 5% to 50% depending on the primary procedure.²⁸³

Multiple retrospective, as well as case-matched and case-controlled studies of revisional bariatric surgery, demonstrate they are effective with benefits to weight loss and overall health,^{281,283} although this is not without some controversy. The literature supports reoperative bariatric surgery in two situations: treatments of insufficient weight loss or weight regain and the treatment of acute and chronic complications.^{281,285} There are many revisional procedures and approaches that are effective. There is no data-driven evidence to guide in the selection of which patient will benefit most from revisional bariatric surgery. Additionally, there is no evidence-based consensus as to which revisional surgical approach is most optimal in any given situation.²⁸³ Currently, there is also little evidence as to which bariatric surgical procedure will be efficacious for any specific given patient.^{286,287}

Principles and Preoperative Evaluation

As with any other decisions for surgery, revisional or additional bariatric surgery requires evaluating the risks and the benefits of the procedure for specific patient situations. It has been observed that the weight loss following revisional procedures is less than with a primary procedure.²⁸⁸ Reoperations in general are associated with morbidity and mortality that is higher than with primary bariatric procedures^{281,288,289} but are acceptably low if careful selection of patients is coupled with

adequate surgeon experience.^{281,290} Reoperative bariatric surgery should be undertaken by experienced bariatric surgeons in centers with the wide range of medical resources to manage these complex patients.²⁸¹ In some situations, it is reasonable to consider a two-stage or an open vs. laparoscopic approach.²⁸⁵ When evaluating a patient for revisional bariatric surgery, it is most important to establish clearly the reason for revision.^{283,291} Is the issue a surgical complication, insufficient weight loss, or weight regain? Is there a discernable anatomic cause for the patient's symptoms (e.g., abdominal pain, nausea, vomiting, heartburn or reflux, nutritional deficiency)? In situations of noninitial weight loss or weight regain, what is the best justification that can be made? Are there behavioral, or other nonsurgical modifications that might significantly help to attain further weight loss? Will the patient be able to set into place the behavioral modification required of the revisional surgical approach? With consideration for revision, it is reasonable to place less emphasis on absolute weight loss and focus on the comorbidity and quality of life states. A comprehensive preoperative evaluation is required to fully answer these and other questions.

The preoperative evaluation for bariatric surgical revision should include

- Review of the initial surgical operative note to understand the exact initial procedure
- Anatomic evaluation of the GI track utilizing upper gastrointestinal endoscopy and radiology to identify known bariatric surgical complications
- An extensive nutritional evaluation
- A behavioral health evaluation with a focus on the adaptation to the initial bariatric procedure and potential adaptation to a revisional procedure
- A full medical evaluation to determine the patient's suitability to undergo anesthesia and a surgical procedure.^{288,291}

The results from these evaluations are used to formulate a hypothesis to explain the patient's symptoms and outcome from the initial procedure and to assess their suitability for and the potential benefits from the potential revisional surgical options. It will come down to a risk-benefit discussion between the surgeon, other members of the multidisciplinary support team, and the patient.²⁸¹

Treatment for Insufficient Weight Loss or Weight Regain

Vertical Banded Gastroplasty. Reversal of VBG is associated with significant weight gain. Revision of the VBG to a re-VBG was associated with poor outcomes.²⁹² VBGs have been safely converted with open and laparoscopic approaches to RYGB and SG.²⁹³⁻²⁹⁵ Conversion of VBG to BPD/DS procedures has limited data with higher leak rate and mortality.²⁹⁶

Adjustable Gastric Band. There are increasing reports of LAGB failure and disappointing weight loss over the last decade.^{289,297,298} Removal of the band without an additional bariatric procedure has been associated with significant weight regain.²⁸⁹ Repositioning or replacement of the band is technically possible; however, the long-term weight loss outcomes are mixed.²⁹⁹⁻³⁰¹ When converting an LAGB to another bariatric procedure, there is some evidence to suggest possibly fewer complications with a two-step approach when significant adhesions or a thick gastric capsule are present. This two-step approach would include removal of the band, allowing 3 to 6 months

for gastric tissue healing, and then completing the conversion.^{302,303} However, one-stage conversions have been reported with acceptable outcomes.²⁹⁷ Good outcomes have been demonstrated with conversion of LAGBs to SG, RYGB, and BPD/DS.^{285,297} Several investigators advocate that a failed restrictive bariatric surgery due to poor weight loss should include a revision option with a malabsorptive component.²⁸⁵

Sleeve Gastrectomy. Approximately 5% to 10% of primary SG procedures have been reported to require revision for poor weight loss outcomes.^{304,305} The literature supports conversion to RYGB and BPD/DS.³⁰⁶ There is controversy regarding resleeve gastrectomy.^{307,308}

Roux-en-Y Gastric Bypass. Approximately, 10% to 20% of patients after a primary RYGB will have inadequate weight loss or weight regain at 2 years, and a subset of these will require a revisional surgical procedure.³⁰⁹ Options for revision include banding over the Roux-en-Y bypass, gastric pouch and gastrojejunal revisions, RYGB limb lengthening, and conversion to a duodenal switch.^{281,285} Each of these options has strengths and weaknesses in specific situations. Endoscopic revisions to reduce the gastric pouch and/or gastrojejunal stomal size have been shown to arrest weight gain with short-term weight loss, but the studies have been small and are noncontrolled.

Treatment of Surgical Complications

Vertical Banded Gastroplasty. Several complications have been indications for revision/conversion of VBGs: wide outlet, pouch dilation, staple line erosion, stoma stenosis, band erosion, band dehiscence, and GERD. Most often conversion is undertaken, and VBGs have been safely converted to RYGB.^{281,285}

Adjustable Gastric Band. The following LAGB complications may require additional or revisional surgery: early band obstruction, severe or chronic gastric prolapse or symmetrical gastroesophageal dilatation, band erosion, port and tubing problems, severe or persistent esophageal dysmotility, or psychological intolerance to restriction of band. The literature supports repair of tubing and port problems and revision of LAGB to SG, RYGB, BPD/DS in one- or two-stage revisional operations.^{285,297}

Sleeve Gastrectomy. Complications that may require a revisional procedure after sleeve gastrectomy are staple line leaks, sleeve stricture and sleeve dilatation, and gastroesophageal reflux. Obstruction due to stricture usually at the angularis incisura will require first-line treatment of endoscopic dilation and may require a revision to a RYGB. Staple line leaks are initially controlled with endoscopic stenting or drainage. Acute and chronic leaks may develop into fistulous disease and require conversion to RYGB. Persistent gastroesophageal reflux may also require conversion to RYGB.^{281,285}

Roux-en-Y Gastric Bypass. Several complications after primary RYGB have been demonstrated as indications for revisional surgery: gastric pouch dilatation, gastrojejunostomy dilation/stricture, marginal ulcers, bowel loss due to internal hernia or volvulus, roux stasis syndrome, gastrogastic fistulas, anastomotic structures or ulcers, and metabolic/endocrine derangements. These require a revision focused on the mechanism of the complication. Reversal of an RYGB is reserved for severe instances of intractable nausea/vomiting, extreme weight loss and malnutrition, metabolic abnormalities, nonhealing ulceration or leaks, and patient choice. It has been performed rarely, and case reports indicate successful resolution of endocrine, metabolic, and nutritional abnormalities with improved

metabolic parameters. However, 50% to 88% of patients have been reported to regain significant weight.^{281,285}

Biliopancreatic Diversion With Duodenal Switch. Acute complications are similar to RYGB and treated the same. The most severe chronic complication is protein-calorie malnutrition, and incidence ranges from 1% to 6%. Management is meticulous nutritional evaluation and nutritional and pancreatic enzyme support, with surgery as a fall back if weight and protein stores are not stabilized. Surgery would entail lengthening the common channel and is rarely necessary.²⁸¹

SPECIAL ISSUES IN BARIATRIC SURGERY

Bariatric Procedures in Adolescents

The major controversy with regard to adolescents undergoing bariatric surgery includes the general aversion to subjecting an adolescent to surgery as well as the concern for the secondary side effects of bariatric surgery on remaining growth and development. Clearly the younger the patient, the more relevant the latter concern becomes. Bariatric surgery in adolescents has been performed more frequently, with only 800 cases a year in 2003 increasing to 1600 cases in 2009, but overall rates are much lower than in adults.^{310,311} Much of the clinical outcomes data have been extrapolated from the adult literature, and more evidence is needed to demonstrate whether weight loss is durable over time, the impact on obesity-related conditions such as T2DM, hypertension, and others, and how often patients experience short- and longer-term complications.

A meta-analysis involving 131 adolescents undergoing bariatric surgery demonstrated a 17.8 to 22.3 kg/m² decrease in BMI after RYGB.³¹² They also observed improvement of hypertension in more than half the patients and sleep apnea resolution in all 131 patients. There were four mortalities in this cohort, but only one of them was potentially associated with the procedure (*Clostridium difficile* colitis 9 months after operation). Morbidity in the adolescent literature ranges from 0% to 38%. The most common complication in the meta-analysis was nutrient deficiencies. The ASMBS pediatric guidelines suggest using BMI criteria similar to the adult population but with some modifications to comorbidity thresholds.³¹³ They recommend considering surgery in patients with a BMI of 35 kg/m² or greater with major comorbidities (e.g., T2DM, severe nonalcoholic fatty liver disease, OSA) or a BMI of ≥ 40 kg/m² or greater with minor comorbidities (e.g., hypertension, dyslipidemia, insulin resistance). One more recent multicenter, prospective study of bariatric surgery in adolescents, the Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS) study, is following 242 adolescent patients for at least 10 years, who underwent bariatric surgery at 5 academic centers.³¹⁴ Fifty-one percent of adolescents had four or more major comorbid conditions before surgery. LRYGB, SG, and LAGB were performed in 66%, 28%, and 6% of patients, respectively. There were no deaths during the initial hospitalization or within 30 days of operation; major complications such as reoperation were reported in 19 patients (8%). Minor complications such as dehydration were reported in 15%. All reoperations and 85% of readmissions in the 30-day period were related to the bariatric surgery.³¹⁵ Three-year follow-up data on the Teen-LABS cohort reported a mean weight loss of 28% for LRYGB and 26% for SG. Remission of T2DM occurred in 95% of participants who had had the condition before surgery, remission of abnormal kidney function occurred in 86%, remission of prediabetes in 76%, remission of

elevated blood pressure in 74%, and remission of dyslipidemia in 66%. Rates of improvements in comorbid conditions, including T2DM, occurred at higher rates than in adults. Hypoferritinemia was found in 57% of the participants, and 13% of the participants had undergone one or more additional intraabdominal procedures at 3 years.⁵² So despite the clinically significant improvements in weight, diabetes, cardiometabolic health, and weight-related quality of life that were observed at 3 years following surgery, the reoperation and micronutrient risks warrant longer observation and further study.

Cost Effectiveness

In a Canadian study, including five systematic reviews, two economic evaluations, two reviews of guidelines, and six primary evidence-based guidelines, the cost effectiveness for the use of bariatric surgery in adolescents was reviewed.³¹⁶ The limited available evidence suggested superior weight loss, resolution of comorbidities compared to nonsurgical interventions, and potential superior weight loss with RYGB compared to other procedures. Cost-effectiveness data was lacking, but limited evidence suggested that bariatric surgery was cost effective several years after intervention, but not immediately.³¹⁶ A U.S. cost-effectiveness analysis of bariatric surgery in adolescents has been published. In addition to the cost of the surgery, perioperative mortality, complications, and quality of life improvement were included in the modelled analysis. By the fifth year of follow-up, bariatric surgery was found to be cost effective in adolescent patients when compared to a cohort of patients with obesity who had not undergone surgery.³¹⁷

For adults, the overall impact of bariatric surgery to reduce expenditures sufficiently to achieve cost savings continues to be debated. In a Canadian matched cohort study prior to the laparoscopic era, it was shown that bariatric surgery decreases long-term direct healthcare costs and the initial costs of surgery can be amortized over 3.5 years.³¹⁸ In two observational studies, bariatric surgery was shown to be cost saving over a relatively short period of time.^{319,320} In more recent observational studies, including the large SOS study and another an analysis of 30,000 single payor enrollees in the United States, show no evidence of overall cost savings.^{206,321,322}

In general, review of the evidence to date suggests that outpatient costs, including pharmacy costs, are significantly reduced after bariatric surgery. However, long-term inpatient hospital costs are increased or unchanged in those who have undergone bariatric surgery compared with matched nonsurgical patients, so no long-term net cost benefit is achieved. Other modeled cost effectiveness studies are consistent with these results as well.^{323,324} So it is likely that bariatric procedures are cost effective, but do not produce cost savings, compared with nonsurgical treatments.

Quality Assurance

Between 1998 and 2003, with emergence of the laparoscopic technique for bariatric surgery, there was rapid increase in the number bariatric surgical procedures performed. With bariatric surgeons becoming accustomed to laparoscopic techniques and laparoscopic surgeons learning bariatric procedures and patient care, there were realistic concerns regarding the safety of bariatric surgery.³²⁵ In 2004, ASMBS utilized the volume-outcome concept of centers of excellence and developed the first bariatric surgical accreditation program, ASMBS-Center of Excellence (COE). In 2005, the American College of Surgeons (ACS) initiated the ACS Bariatric Surgery Center Network (BSCN).

These accreditation programs verified that bariatric surgery centers had the infrastructure and equipment to care for the morbidly obese, experienced and qualified surgeons and staff, appropriate pre- and postoperative processes in place, and reported outcome data on all surgical cases.³²⁵

In 2012, these two bariatric surgical accreditations merged into a single unified program, the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP). The MBSAQIP has continued to grant accreditation only after a rigorous review process during which a center proves that it can maintain certain physical resources, human resources, and standards of practice.³²⁶ Additionally, prospective outcome data is collected at the clinical center and validated based on standardized definitions and submitted to the quality improvement program. Centers receive back risk-stratified analysis of their data as a means to compare with the national statistics/standards and are then required to utilize the data in quality improvement projects at their center. This newer focus on quality improvement over centers of excellence will likely continue to improve the quality of bariatric surgery in the United States. Recently, in a systematic review, bariatric facility accreditation by this program has been associated with improved outcomes (length of stay, mortality, morbidity).³²⁷

Plastic Surgery After Weight Loss

Patients who have undergone bariatric surgery are often left with skin and subcutaneous tissue deformities. Additional problems include skin rashes and maceration under folds in the pannus, thighs, and breasts; body odor; and poorly fitting clothes. Excess skin can also be a limiting factor in exercise and sexual activity. Plastic and reconstructive surgery is now a part of the continuum of care for bariatric surgery patients. Reconstructive

surgery requires careful preoperative planning and is based on the patient's deformities and priorities. Timing of plastic and reconstructive surgery is typically deferred until weight stability at approximately 1 to 2 years postoperatively to ensure improved healing. Excess tissue of the lower torso is the most common area for which patients undergo surgical intervention and a standard abdominoplasty is typically performed. More radical body contouring can include a circumferential abdominoplasty and lower body lift.^{328,329} This procedure involves excision of tissue from the buttocks and lateral thighs, with skin undermining down the thighs. Circumferential abdominoplasty removes redundant skin of the lower abdomen, flattens the abdomen, and incorporates the lower body lift. It requires central undermining to the xiphoid and minimal lateral undermining of the superior flap. The central abdominal fascia often requires imbrication. If simultaneous abdominal hernia repair is performed, this performs the function of fascial imbrication by creating a repair with some degree of fascial tension. The closure of the superior flap to the inferior skin edge incorporates lateral tension to narrow the waist and advance the anterolateral thighs. Medial thighplasty also may be needed for patients with significant excess medial thigh skin.

Mid-back and epigastric deformity, along with sagging breasts, are corrected with an upper body lift. The upper body lift is a reverse abdominoplasty, removal of mid-torso excessive skin, and reshaping of the breasts. For highly selected individuals, and with a well-organized team, a single-stage total body lift, which includes a circumferential abdominoplasty, lower body lift, medial thighplasty, an upper body lift, and breast reshaping, can be performed safely in under 8 hours (Figs. 27-30 and 27-31).³³⁰ Increasing numbers of patients are seeking these corrective procedures, and data about the results is evolving. There

Figure 27-30. Preoperative frontal, right lateral, and left anterior oblique views of a 36-year-old, 150-lb (68-kg) 5'6" woman who lost 120 lb (54 kg) 2 years after laparoscopic Roux-en-Y bypass procedure. She desired a one-stage total body lift and bilateral brachioplasties, which were performed in the manner described in the text. (Used with permission from Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)

Figure 27-31. Frontal, right lateral, and left anterior oblique views 6 weeks after surgery for the woman in Fig. 27-24. The scars indicate the circumferential abdominoplasty, lower body lift, upper body lift, breast reshaping, and autoaugmentation through a keyhole pattern and bilateral brachioplasties. All redundant skin has been removed, leaving well-positioned scars and feminine features. (Used with permission from Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)

is a hypothesis that if body image is improved with corrective surgery, that weight maintenance in the longer-term may also be positively affected. Several matched controlled studies suggest that plastic surgery after bariatric surgery may improve long-term weight loss results.^{328,331}

FUTURE IMPORTANT QUESTIONS

The volume and quality of literature in the field of bariatric surgery has grown tremendously in the last 10 years. High-quality evidence now shows that bariatric surgical procedures result in greater weight loss than nonsurgical treatments, improved survival, and are more effective at inducing remission of T2DM in people with obesity. More information is still needed about the long-term durability of comorbid health improvements and long-term complications after each of the different bariatric surgical procedures. In addition, the underlying specific mechanism(s) of action for both bariatric and metabolic surgery is still incompletely understood. Future knowledge will come from translational human studies, the ongoing longer-term studies and data registries, randomized studies comparing surgical to nonsurgical treatments, integrated health care systems data, and national “big data” networks. The following are some of the high-priority questions that future research will address.

- What are the specific mechanisms of action responsible for weight loss and the T2DM response to bariatric surgical procedures?
- What patient level factors can predict success with weight loss, health improvements, and cost savings after bariatric surgical procedures? Understanding pre- and postsurgery predictors will help to tailor an individual’s treatment.

- Is bariatric surgery more effective than nonsurgical care for the **longer-term** treatment of T2DM in people with less severe obesity (class I obesity, BMI <35)?
- With more standardized reporting of complications across bariatric studies, what are the long-term complication rates after different bariatric procedures?
- What is the effect of bariatric surgery on long-term microvascular and macrovascular event rates?
- What are the reproductive and mental health outcomes including risk for self-harm and suicide, alcohol use disorders, substance abuse, and other risk-taking behaviors?

Based on the evidence, bariatric/metabolic surgery was recommended to treat Type 2 diabetes in patients with Class III obesity (BMI≥40 kg/m²) and in those with Class II obesity (BMI 35.0-39.9 kg/m²) when hyperglycemia is inadequately controlled by lifestyle and optimal medical therapy. Surgery should also be considered for patients with T2D and BMI 30.0-34.9 kg/m² (Class I obesity) if hyperglycemia is inadequately controlled despite optimal medical treatment.

INTRODUCTORY COMMENTS

The small intestine is a remarkable and complex organ that is not only the principle site of nutrient digestion and absorption but also contains the body's largest reservoir of immunologically active and hormone-producing cells. Hence, it can be conceptualized as the largest organ of the immune and endocrine systems.¹ It achieves this diversity of action through unique

1▶ anatomical features, which provide it with a massive surface area, a diversity of cell types, and a complex neural network to coordinate these functions.

Despite the size and importance of the small intestine, diseases of this organ are relatively infrequent and can present diagnostic and therapeutic challenges. Despite introduction of novel imaging techniques such as capsule endoscopy and double balloon endoscopy, diagnostic tests lack sufficient ability to reliably assess the small bowel. Furthermore, few high-quality, controlled data on the efficacy of surgical therapies for small bowel diseases are available.

Therefore, sound clinical judgment and a thorough understanding of anatomy, physiology, and pathophysiology remain essential to the care of patients with suspected small bowel disorders.

GROSS ANATOMY

The small intestine is a tubular structure that extends from the pylorus to the cecum. The estimated length varies depending on whether radiologic, surgical, or autopsy measurements are made. In the living, it is thought to measure 4 to 6 meters.² The small intestine consists of three segments lying in series: the duodenum, the jejunum, and the ileum. The duodenum, the most proximal segment, lies in the retroperitoneum immediately adjacent to the head and inferior border of the body of the pancreas. The duodenum is demarcated from the stomach by the pylorus and from the jejunum by the ligament of Treitz. The jejunum and ileum lie within the peritoneal cavity and are tethered to the

Key Points

- 1▶ The small intestine performs a diverse set of functions.
- 2▶ Small bowel obstruction is one of the most common surgical diagnoses.
- 3▶ Most cases of small bowel obstruction are due to adhesions from previous surgery and resolve with conservative management.
- 4▶ Tumors and malignancies of the small bowel are rare and difficult to diagnose.
- 5▶ If following surgical resection less than 200 cm of small bowel remains, patients are at risk of developing short bowel syndrome.

retroperitoneum by a broad-based mesentery. No distinct anatomical landmark demarcates the jejunum from the ileum; the proximal 40% of the jejunoileal segment is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve.

The small intestine contains internal mucosal folds known as *plicae circulares* or *valvulae conniventes* that are visible upon gross inspection. These folds are also visible radiographically and help in the distinction between small intestine and colon, which does not contain them, on abdominal radiographs. These folds are more prominent in the proximal intestine than in the distal small intestine. Other features evident on gross inspection that are more characteristic of the proximal than distal small intestine include larger circumference, thicker wall, less fatty mesentery, and longer vasa recta (Fig. 28-1). Gross examination of the small-intestinal mucosa also reveals aggregates of lymphoid follicles. Those follicles, located in the ileum, are the most prominent and are designated *Peyer's patches*.

Most of the duodenum derives its arterial blood from branches of both the celiac and the superior mesenteric arteries. The distal duodenum, the jejunum, and the ileum derive their arterial blood from the superior mesenteric artery. Their venous drainage occurs via the superior mesenteric vein. Lymph drainage occurs through lymphatic vessels coursing parallel to corresponding arteries. This lymph drains through mesenteric lymph nodes to the cisterna chyli, then through the thoracic duct, and ultimately into the left subclavian vein. The parasympathetic and sympathetic innervation of the small intestine is derived from the vagus and splanchnic nerves, respectively.

HISTOLOGY

The wall of the small intestine consists of four distinct layers: mucosa, submucosa, muscularis propria, and serosa (Fig. 28-2).

The mucosa is the innermost layer and it consists of three layers: epithelium, lamina propria, and muscularis mucosae. The epithelium is exposed to the intestinal lumen and is the surface through which absorption from and secretion into the lumen occurs. The lamina propria is located immediately external to the epithelium and consists of connective tissue and a heterogeneous population of cells. It is demarcated from the more external submucosa by the muscularis mucosae, a thin sheet of smooth muscle cells.

The mucosa is organized into villi and crypts (crypts of Lieberkuhn). *Villi* are finger-like projections of epithelium and underlying lamina propria that contain blood and lymphatic (lacteals) vessels that extend into the intestinal lumen. Intestinal, epithelial cellular proliferation is confined to the *crypts*, each of which carries 250 to 300 cells. All epithelial cells in each crypt are derived from an unknown number of multipotent stem cells located at or near the crypt's base. Our understanding of these crypt cells is rapidly expanding. It appears that there are two subgroups of intestinal stem cells, with specific cell markers. Bmi1-positive cells are usually quiescent, radiation-resistant cells that are induced by injury, while LGR5-positive cells facilitate homeostatic vs. injury-induced regeneration and are radiation sensitive.³

The stem cells can differentiate along one of four pathways that ultimately yield *enterocytes* and *goblet*, *enteroendocrine*, and *Paneth* cells. Except for Paneth cells, these lineages complete their terminal differentiation during an upward migration from each crypt to adjacent villi. The journey from the crypt to the villus tip is completed in 2 to 5 days and terminates with cells being removed by apoptosis and/or exfoliation. Thus, the small-intestinal epithelium undergoes continuous renewal, making it one of the body's most dynamic tissues. The high cellular turnover rate contributes to mucosal resiliency but also makes the intestine uniquely susceptible to certain forms of injury such as that induced by radiation and chemotherapy.

Figure 28-1. Gross features of jejunum contrasted with those of ileum. Relative to the ileum, the jejunum has a larger diameter, a thicker wall, more prominent plicae circulares, a less fatty mesentery, and longer vasa recta.

Figure 28-2. Layers of wall of the small intestine. The individual layers and their prominent features are represented schematically.

Enterocytes are the predominant absorptive cell of the intestinal epithelium. Their apical (lumen-facing) cell membrane contains specialized digestive enzymes, transporter mechanisms, and microvilli that are estimated to increase the absorptive surface area of the small intestine by up to 40-fold. *Goblet cells* produce mucin believed to play a role in mucosal defense against pathogens. *Enteroendocrine cells* are characterized by secretory granules containing regulatory agents and are discussed in greater detail in the “Endocrine Function” section. *Paneth cells* are located at the base of the crypt and contain secretory granules containing growth factors, digestive enzymes, and antimicrobial peptides, through which they control the host-microbe interaction and influence the intestinal microbiome. In addition, the intestinal epithelium contains M cells and intraepithelial lymphocytes. These two components of the immune system are discussed in this chapter.

The submucosa consists of dense connective tissue and a heterogeneous population of cells, including leukocytes and fibroblasts. The submucosa also contains an extensive network of vascular and lymphatic vessels, nerve fibers, and ganglion cells of the submucosal (Meissner’s) plexus.

The muscularis propria consists of an outer, longitudinally-oriented layer and an inner, circularly-oriented layer of smooth muscle fibers. Located at the interface between these two layers are ganglion cells of the myenteric (Auerbach’s) plexus.

The serosa consists of a single layer of mesothelial cells and is a component of the visceral peritoneum.

DEVELOPMENT

The first recognizable precursor of the small intestine is the embryonic gut tube, formed from the endoderm during the fourth week of gestation. The gut tube is divided into foregut, midgut, and hindgut. Other than the duodenum, which is a foregut structure, the rest of the small intestine is derived from the midgut. The gut tube initially communicates with the yolk sac; however, the communication between these two structures narrows by the sixth week to form the vitelline duct. The yolk sac and vitelline duct usually undergo obliteration by the end of gestation. Incomplete obliteration of the vitelline duct results in the spectrum of defects associated with Meckel’s diverticuli.

Also during the fourth week of gestation, the mesoderm of the embryo splits. The portion of mesoderm that adheres to the endoderm forms the visceral peritoneum, while the portion that adheres to the ectoderm forms the parietal peritoneum. This mesodermal division results in the formation of a coelomic cavity that is the precursor of the peritoneal cavity.

At approximately the fifth week of gestation, the bowel begins to lengthen to an extent greater than that which can be accommodated by the developing abdominal cavity, resulting in the extracoelomic herniation of the developing bowel. The bowel continues to lengthen during the subsequent weeks and is retracted back into the abdominal cavity during the tenth week of gestation. Subsequently, the duodenum becomes a retroperitoneal structure. Coincident with extrusion and retraction, the bowel undergoes a 270° counterclockwise rotation relative to the posterior abdominal wall. This rotation accounts for the usual locations of the cecum in the right lower quadrant and the duodenojejunal junction to the left of midline (Fig. 28-3).

The celiac and superior mesenteric arteries and veins are derived from the vitelline vascular system, which in turn is derived from blood vessels formed within the splanchnopleuric mesoderm during the third week of gestation. Neurons found in the small intestine are derived from neural crest cells that begin to migrate away from the neural tube during the third week of gestation. These neural crest cells enter the mesenchyme of the primitive foregut and subsequently migrate to the remainder of the bowel.

During the sixth week of gestation, the lumen of the developing bowel becomes obliterated as bowel epithelial proliferation accelerates. Vacuoles form within the bowel substance during the subsequent weeks and coalesce to form the intestinal lumen by the ninth week of gestation. Errors in this recanalization may account for defects such as intestinal webs and stenoses. Most intestinal atresias, however, are believed to be related to ischemic episodes occurring after organogenesis has been completed rather than to errors in recanalization.

During the ninth week of gestation, the intestinal epithelium develops intestine-specific features such as crypt-villus architecture. Organogenesis is complete by approximately the twelfth week of gestation.

Figure 28-3. Developmental rotation of the intestine. **A.** During the fifth week of gestation, the developing intestine herniates out of the coelomic cavity and begins to undergo a counterclockwise rotation about the axis of the superior mesenteric artery. **B** and **C.** Intestinal rotation continues, as the developing transverse colon passes anterior to the developing duodenum. **D.** Final positions of the small intestine and colon resulting from a 270° counterclockwise rotation of the developing intestine and its return into the abdominal cavity.

PHYSIOLOGY

Digestion and Absorption

The intestinal epithelium is the interface through which absorption and secretion occur. It has features characteristic of absorptive epithelia in general, including epithelial cells with cellular membranes possessing distinct apical (luminal) and basolateral (serosal) domains demarcated by intercellular tight junctions and an asymmetric distribution of transmembrane transporter mechanisms that promotes vectorial transport of solutes across the epithelium.

Solutes can traverse the epithelium by active or passive transport. Passive transport of solutes occurs through diffusion or convection and is driven by existing electrochemical gradients. *Active transport* is the energy-dependent net transfer of solutes in the absence of or against an electrochemical gradient.

Active transport occurs through transcellular pathways (through the cell), whereas passive transport can occur through either transcellular or paracellular pathways (between cells through the tight junctions). Transcellular transport requires solutes to traverse the cell membranes through specialized membrane proteins, such as channels, carriers, and pumps. The molecular characterization of transporter proteins is evolving rapidly, with different transporter families, each containing many individual genes encoding specific transporters, now identified. Similarly, understanding of the paracellular pathway is evolving. In contrast to what was once believed, it is becoming apparent that paracellular permeability is substrate-specific, dynamic, and subject to regulation by specific tight junction proteins.

Water and Electrolyte Absorption and Secretion. Eight to 9 L of fluid enter the small intestine daily. Most of this volume consists of salivary, gastric, biliary, pancreatic, and intestinal secretions. Under normal conditions, the small intestine absorbs over 80 percent of this fluid, leaving approximately 1.5 L that enters the colon (Fig. 28-4). Small-intestinal absorption

and secretion are tightly regulated; derangements in water and electrolyte homeostasis characteristic of many of the disorders discussed in this chapter play an important role in contributing to their associated clinical features.

Gut epithelia have two pathways for water transport: (a) the paracellular route, which involves transport through the spaces between cells, (b) the transcellular route, through apical and the basolateral cell membranes, with most occurring through

Figure 28-4. Small intestinal fluid fluxes. Typical quantities (in volume per day) of fluid entering and leaving the small intestinal lumen in a healthy adult are shown.

Figure 28-5. Model of transepithelial Na⁺ absorption. Na⁺ traverses the apical membrane of enterocytes through a variety of mechanisms, including nutrient-coupled Na⁺ transport, Na⁺/H⁺ exchange, and Na⁺ channels. Activity of the Na⁺/K⁺ATPase located on the basolateral membrane generates the electrochemical gradient that provides the driving force for Na⁺ absorption.

the transcellular pathway.⁴ The specific transport mechanisms mediating this transcellular transport are not completely characterized, and they may involve passive diffusion through the phospholipid bilayer, cotransport with other ions and nutrients, or diffusion through water channels called aquaporins. Many different types of aquaporins have been identified; however, their contribution to overall intestinal water absorption appears to be relatively minor.⁵

The prevailing model for intestinal epithelial Na⁺ absorption is shown in Fig. 28-5. Activity of the Na⁺/K⁺ ATPase enzyme, which is located in the basolateral membrane and exchanges three intracellular Na⁺ for every two extracellular K⁺ in an energy-dependent process, generates the electrochemical gradient that drives the transport of Na⁺ from the intestinal lumen into the cytoplasm of enterocytes. Na⁺ ions traverse the apical membrane through several distinct transporter mechanisms, including nutrient-coupled sodium transport (e.g., sodium glucose cotransporter-1, SGLT1), sodium channels, and sodium-hydrogen exchangers (NHEs). Absorbed Na⁺ ions are then extruded from enterocytes through the Na⁺/K⁺ ATPase located in the basolateral membrane. Similar mechanistic models that account for the transport of other common ions such as K⁺ and HCO₃⁻ also exist.

Substantial heterogeneity, with respect to both crypt-villus and craniocaudal axes, exists for intestinal epithelial transport mechanisms. This spatial distribution pattern is consistent with a model in which absorptive function resides primarily in the villus and secretory function in the crypt.

Intestinal absorption and secretion are subject to modulation under physiologic and pathophysiologic conditions by a wide array of hormonal, neural, and immune regulatory mediators (Table 28-1).

Carbohydrate Digestion and Absorption. Approximately 45% of energy consumption in the average Western diet consists of carbohydrates, approximately one-half of which is in the form of starch (linear or branched polymers of glucose) derived from cereals and plants. Other major sources of dietary carbohydrates include sugars derived from milk (lactose), fruits and

vegetables (fructose, glucose, and sucrose), or purified from sugar cane or beets (sucrose). Processed foods contain a variety of sugars including fructose, oligosaccharides, and polysaccharides. Glycogen derived from meat contributes only a small fraction of dietary carbohydrate.

Pancreatic amylase is the major enzyme of starch digestion, although salivary amylase initiates the process. The terminal products of amylase-mediated starch digestion are oligosaccharides, maltotriose, maltose, and alpha-limit dextrins (Fig. 28-6). These products, as well as the major disaccharides in the diet (sucrose and lactose), are unable to undergo absorption in this form. They must first undergo hydrolytic cleavage into their constituent monosaccharides; these hydrolytic reactions are catalyzed by specific brush border membrane hydrolases that are expressed most abundantly in the villi of the duodenum and jejunum. The three major monosaccharides that represent the terminal products of carbohydrate digestion are glucose, galactose, and fructose.

Under physiologic conditions, most of these sugars are absorbed through the epithelium via the transcellular route. Glucose and galactose are transported through the enterocyte brush border membrane via intestinal Na⁺-glucose cotransporter, SGLT1 (Fig. 28-7). Fructose is transported through the brush border membrane by facilitated diffusion via GLUT5 (a member of the facilitative glucose transporter family). All three monosaccharides are extruded through the basolateral membrane by facilitated diffusion using GLUT2 and five transporters. Extruded monosaccharides diffuse into venules and ultimately enter the portal venous system.

There is evidence of overexpression of hexose transporters, specifically SGLT1, in disease states such as diabetes.⁶ Several approaches aimed at downregulation of small intestinal

Figure 28-6. Carbohydrate digestion. These hydrolytic reactions are catalyzed by salivary and pancreatic amylase and by enterocyte brush border hydrolases.

glucose transporter are being investigated as a novel therapy for disease states such as diabetes and obesity. In fact, recent consensus statements have recognized the small bowel as a therapeutic target for treatment of diabetes.⁷

Protein Digestion and Absorption. Ten percent to 15% of energy consumption in the average Western diet consists of proteins. In addition to dietary proteins, approximately one-half of

Figure 28-7. Hexose transporters. Glucose and galactose enter the enterocyte through secondary active transport via the sodium-glucose cotransporter (SGLT1) located on the apical (brush border) membrane. Fructose enters through facilitated diffusion via glucose transporter 5 (GLUT5). Glucose and galactose are extruded basolaterally through facilitated diffusion via glucose transporter 2 (GLUT2). Fructose is extruded basolaterally via GLUT5.

the protein load that enters the small intestine is derived from endogenous sources, including salivary and gastrointestinal secretions and desquamated intestinal epithelial cells. Protein digestion begins in the stomach with action of pepsins. This is not, however, an essential step because surgical patients who are achlorhydric, or have lost part or all their stomach, are still able to successfully digest proteins. Digestion continues in the duodenum with the actions of a variety of pancreatic peptidases. These enzymes are secreted as inactive proenzymes. This contrasts with pancreatic amylase and lipase, which are secreted in their active forms. In response to the presence of bile acids, enterokinase is liberated from the intestinal brush border membrane to catalyze the conversion of trypsinogen to active trypsin; trypsin in turn activates itself and other proteases. The final products of intraluminal protein digestion consist of neutral and basic amino acids and peptides two to six amino acids in length (Fig. 28-8). Additional digestion occurs through the actions of peptidases that exist in the enterocyte brush border and cytoplasm. Epithelial absorption occurs for both single amino acids and di- or tripeptides via specific membrane-bound transporters. Absorbed amino acids and peptides then enter the portal venous circulation.

Of all amino acids, glutamine appears to be a unique, major source of energy for enterocytes. Active glutamine uptake into enterocytes occurs through both apical and basolateral transport mechanisms.

Fat Digestion and Absorption. Approximately 40% of the average Western diet consists of fat. Over 95% of dietary fat is in the form of long-chain triglycerides; the remainder includes phospholipids such as lecithin, fatty acids, cholesterol, and

Figure 28-8. Protein digestion. Dietary proteins must undergo hydrolysis into constituent single amino acids and di- and tripeptides before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by pancreatic peptidases (e.g., trypsin) and by enterocyte brush border peptidases.

fat-soluble vitamins. Over 94% of the ingested fats are absorbed in the proximal jejunum.

Since fats are normally water insoluble, key to successful digestion of ingested fats is solubilization of them into an emulsion by the mechanical actions of mastication and antral peristalsis. Although lipolysis of triglycerides to form fatty acids and monoglycerides is initiated in the stomach by gastric lipase, its principal site is the proximal intestine, where pancreatic lipase is the catalyst (Fig. 28-9).

Bile acids act as detergents that help in solubilization of the lipolysis by forming mixed micelles. These micelles are polymolecular aggregates with a hydrophobic core of fat and a hydrophilic surface that act as shuttles, delivering the products of lipolysis to the enterocyte brush border membrane, where they are absorbed. The bile salts, however, remain in the bowel lumen and travel to the terminal ileum, where they are actively resorbed. They enter the portal circulation and are resecreted into bile, thus completing the enterohepatic circulation.

Dissociation of lipids from the micelles occurs in a thin layer of water (50 to 500 μm thick) with an acidic microenvironment immediately adjacent to the brush border called the *unstirred water layer*. Most lipids are absorbed in the proximal jejunum, whereas bile salts are absorbed in the distal ileum through an active process. Fatty acid binding proteins (FABP) are a family of proteins located on the brush border membrane, facilitating diffusion of long-chain fatty acids across the brush border membrane. Cholesterol crosses the brush border membrane through an active process that is yet to be completely characterized. Within the enterocytes, triglycerides are resynthesized and incorporated into chylomicrons that are secreted

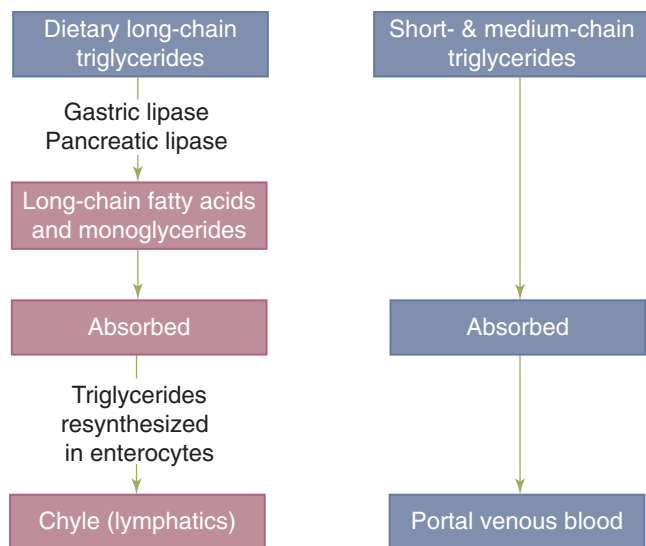

Figure 28-9. Fat digestion. Long-chain triglycerides, which constitute the majority of dietary fats, must undergo lipolysis into constituent long-chain fatty acids and monoglycerides before being absorbed by the intestinal epithelium. These reactions are catalyzed by gastric and pancreatic lipases. The products of lipolysis are transported in the form of mixed micelles to enterocytes, where they are resynthesized into triglycerides, which are then packaged in the form of chylomicrons that are secreted into the intestinal lymph (chyle). Triglycerides composed of short- and medium-chain fatty acids are absorbed by the intestinal epithelium directly, without undergoing lipolysis, and are secreted into the portal venous circulation.

into the intestinal lymphatics and ultimately enter the thoracic duct. In these chylomicrons, lipoproteins serve a detergent-like role similar to that served by bile salts in the mixed micelles.

The aforementioned steps are required for the digestion and absorption of triglycerides containing long-chain fatty acids. However, triglycerides containing short- and medium-chain fatty acids are more hydrophilic and are absorbed without undergoing intraluminal hydrolysis, micellar solubilization, mucosal reesterification, and chylomicron formation. Instead, they are directly absorbed and enter the portal venous circulation rather than the lymphatics. This information provides the rationale for administering nutritional supplements containing medium-chain triglycerides to patients with gastrointestinal diseases associated with impaired digestion and/or malabsorption of long-chain triglycerides.

Vitamin and Mineral Absorption. Vitamin B₁₂ (cobalamin) malabsorption can result from a variety of surgical manipulations. The vitamin is initially bound by saliva-derived R protein. In the duodenum, R protein is hydrolyzed by pancreatic enzymes, allowing free cobalamin to bind to gastric parietal cell-derived intrinsic factor. The cobalamin-intrinsic factor complex can escape hydrolysis by pancreatic enzymes, allowing it to reach the terminal ileum, which expresses specific receptors for intrinsic factor. Subsequent events in cobalamin absorption are poorly characterized, but the intact complex probably enters enterocytes through translocation. Because each of these steps is necessary for cobalamin assimilation, gastric resection, gastric bypass, and ileal resection can each result in vitamin B₁₂ insufficiency.

Other water-soluble vitamins for which specific carrier-mediated transport processes have been characterized include ascorbic acid, folic acid, thiamine, riboflavin, pantothenic acid, and biotin. Fat-soluble vitamins A, D, and E appear to be absorbed through passive diffusion. Vitamin K appears to be absorbed through both passive diffusion and carrier-mediated uptake.

Calcium is absorbed through both transcellular transport and paracellular diffusion. The duodenum is the major site for transcellular transport; paracellular transport occurs throughout the small intestine. A key step in transcellular calcium transport is mediated by calbindin, a calcium-binding protein located in the cytoplasm of enterocytes. Regulation of calbindin synthesis is the principle mechanism by which vitamin D regulates intestinal calcium absorption. Abnormal calcium levels are increasingly seen in surgical patients who have undergone a gastric bypass. Although usual calcium supplementation is often in the form of calcium carbonate, which is cheap, in such patients with low acid exposure, calcium citrate is a better formulation for supplemental therapy.

Iron and magnesium are each absorbed through both transcellular and paracellular routes. A divalent metal transporter capable of transporting Fe²⁺, Zn²⁺, Mn²⁺, Co²⁺, Cd²⁺, Cu²⁺, Ni²⁺, and Pb²⁺ that has been localized to the intestinal brush border may account for at least a portion of the transcellular absorption of these ions.⁸

Barrier and Immune Function

Although the intestinal epithelium allows for the efficient absorption of dietary nutrients, it must discriminate between pathogens and harmless antigens such as food proteins and commensal bacteria, and it must resist invasion by pathogens. Factors contributing to epithelial defense include immunoglobulin A (IgA), mucins, and the relative impermeability of the brush border membrane and tight junctions to macromolecules and

Figure 28-10. Gut-associated lymphoid tissue. Select components of the gut-associated lymphoid tissue (GALT) are schematically represented. Peyer's patches consist of a specialized follicle-associated epithelium (FAE) containing M cells, a subepithelial dome (SED) rich in dendritic cells (DC), and B-cell follicle containing germinal centers (GC). Plasma cells in the lamina propria produce IgA, which is transported to the intestinal lumen where serves as the first line of defense against pathogens. Other components of the GALT include isolated lymphoid follicles, mesenteric lymph nodes, and regulatory and effector lymphocytes.

bacteria. Other factors likely to play important roles in intestinal mucosal defense include antimicrobial peptides such as the defensins.⁹ The intestinal component of the immune system, known as the gut-associated lymphoid tissue (GALT), contains over 70% of the body's immune cells.

The GALT is conceptually divided into inductive and effector sites.¹⁰ Inductive sites include Peyer's patches, mesenteric lymph nodes, and smaller isolated lymphoid follicles scattered throughout the small intestine (Fig. 28-10). Peyer's patches are macroscopic aggregates of B-cell follicles and intervening T-cell areas found in the lamina propria of the small intestine, primarily the distal ileum. Overlying Peyer's patches is a specialized epithelium containing microfold (M) cells. These cells possess an apical membrane with microfolds rather than microvilli, which is characteristic of most intestinal epithelial cells. Using transepithelial vesicular transport, M cells transfer microbes to underlying professional antigen presenting cells (APCs), such as dendritic cells. Dendritic cells, in addition, may sample luminal antigens directly through their dendrite-like processes that extend through epithelial tight junctions. APCs interact with and prime naive lymphocytes, which then exit through the draining lymphatics to enter the mesenteric lymph nodes, where they undergo differentiation. These lymphocytes then migrate into the systemic circulation via the thoracic duct and ultimately accumulate in the intestinal mucosa at effector sites. Alternative induction mechanisms, such as antigen presentation within mesenteric lymph nodes, are also likely to exist.

Effector lymphocytes are distributed into distinct compartments. IgA-producing plasma cells are derived from B cells and are located in the lamina propria. CD4⁺ T cells are also located in the lamina propria. CD8⁺ T cells migrate preferentially to the epithelium, but they are also found in the lamina propria. These T cells are central to immune regulation; in addition, the CD8⁺ T cells have potent cytotoxic (CTL) activity. IgA is transported through the intestinal epithelial cells into the lumen, where it exists in the form of a dimer complexed with a secretory component. This configuration renders IgA resistant to proteolysis by digestive enzymes. IgA is believed to both help prevent the entry of microbes through the epithelium and to promote excretion of antigens or microbes that have already penetrated the laminal propria.

It has been increasingly recognized that the gastrointestinal tract is colonized with many bacteria that are essential for health. Communication between the microbiota and the host defense allows for protective immune responses against pathogens while preventing adverse inflammatory responses to harmless commensal microbes, which could lead to chronic inflammatory disorders such as celiac disease and Crohn's disease.¹¹

Motility

Myocytes of the intestinal muscle layers are electrically and mechanically coordinated in the form of syncytia. Contractions of the muscularis propria are responsible for small-intestinal peristalsis. Contraction of the outer longitudinal muscle layer results in bowel shortening; contraction of the inner circular layer results in luminal narrowing. Contractions of the muscularis mucosa contribute to mucosal or villus motility, but not to peristalsis.

Several distinctive patterns of muscularis propria activity have been observed to occur in the small intestine. These patterns include *ascending excitation and descending inhibition* in which muscular contraction occurs proximal to a stimulus, such as the presence of a bolus of ingested food, and muscular relaxation occurs distal to the stimulus (Fig. 28-11). These two reflexes are present even in the absence of any extrinsic innervation to the small intestine and contribute to peristalsis when they are propagated in a coordinated fashion along the length of the intestine. The *fed or postprandial pattern* begins within 10 to 20 minutes of meal ingestion and abates 4 to 6 hours afterwards. *Rhythmic segmentations* or pressure waves traveling only short distances also are observed. This segmenting pattern is hypothesized to assist in mixing intraluminal contents and in facilitating their contact with the absorptive mucosal surface. The *fasting pattern or interdigestive motor cycle (IDMC)* consists of three phases. Phase 1 is characterized by motor quiescence, phase 2 by seemingly disorganized pressure waves occurring at submaximal rates, and phase 3 by sustained pressure waves occurring at maximal rates. This pattern is hypothesized to expel residual debris and bacteria from the small intestine. The median duration of the IDMC ranges from 90 to 120 minutes. At any given time, different portions of the small intestine can be in different phases of the IDMC.

Figure 28-11. Ascending excitation and descending inhibition. The presence of a food bolus within the intestinal lumen is sensed by a sensory neuron (SN) that relays signals to (a) excitatory motor neurons (EMN) that have projections to intestinal muscle cells located proximal to the food bolus and (b) inhibitory motor neurons (IMN) that have projections to intestinal muscle cells located distal to the food bolus. This stereotypical motor reflex is controlled by the enteric nervous system and occurs in the absence of extra-intestinal innervations. It contributes to peristalsis.

The regulatory mechanisms driving small-intestinal motility consist of both pacemakers intrinsic to the small intestine and external neurohumoral modulatory signals. The interstitial cells of Cajal are pleomorphic mesenchymal cells located within the muscularis propria of the intestine that generate the electrical slow wave (basic electrical rhythm or pacesetter potential) that plays a pacemaker role in setting the fundamental rhythmicity of small-intestinal contractions. The frequency of the slow wave varies along the longitudinal axis of the intestine: it ranges from 12 waves per minute in the duodenum to 7 waves per minute in the distal ileum. Smooth muscle contraction occurs only when an electrical action potential (spike burst) is superimposed on the slow wave. Thus, the slow wave determines the maximum frequency of contractions; however, not every slow wave is associated with a contraction.

This intrinsic contractile mechanism is subject to neural and hormonal regulation. The enteric motor system (ENS) provides both inhibitory and excitatory stimuli. The predominant excitatory transmitters are acetylcholine and substance P, and the inhibitory transmitters include nitric oxide, vasoactive intestinal peptide, and adenosine triphosphate. In general, the sympathetic motor supply is inhibitory to the ENS; therefore, increased sympathetic input into the intestine leads to decreased intestinal smooth muscle activity. The parasympathetic motor supply is more complex, with projections to both inhibitory and excitatory ENS motor neurons. Correspondingly, the effects of parasympathetic inputs into intestinal motility are more difficult to predict.

Endocrine Function

Endocrinology as a discipline was born with the discovery of secretin, an intestinal regulatory peptide that was the first hormone to be identified. Our improving understanding of the physiology of the small intestine has led to identification of many additional intestinal-derived hormones, which make this the largest hormone-producing organ in the body. Over 30 peptide hormone genes have been identified as being expressed in the gastrointestinal tract. Because of differential posttranscriptional and posttranslational processing, over 100 distinct regulatory peptides are produced. In addition, monoamines, such as histamine and dopamine, and eicosanoids with hormone-like activities are produced in the intestine.

“Gut hormones” were previously conceptualized as peptides produced by the enteroendocrine cells of the intestinal mucosa that are released into the systemic circulation to reach receptors in target sites in the gastrointestinal tract. Now it is clear that “gut hormone” genes are widely expressed throughout the body, not only in endocrine cells but also in central and peripheral neurons. The products of these genes are general intercellular messengers that can act as endocrine, paracrine, autocrine, or neurocrine mediators. Thus, they may act as true blood-borne hormones as well as through local effects.

There are notable homology patterns among individual regulatory peptides found in the gastrointestinal tract. Based on these homologies, approximately one-half of the known regulatory peptides can be classified into families.¹² For example, the secretin family includes secretin, glucagon, and glucagon-like peptides, glucose-dependent insulinotropic peptide, vasoactive intestinal polypeptide, peptide histidine isoleucine, growth hormone releasing hormone, and pituitary adenylyl cyclase-activating peptide. Other peptide families include those named for insulin, epidermal growth factor, gastrin, pancreatic polypeptide, tachykinin, and somatostatin.

Receptor subtype multiplicity and cell-specific expression patterns for these receptor subtypes that are characteristic of these regulatory mediators makes definition of their actions complex. Detailed description of these actions is beyond the scope of this chapter; however, examples of regulatory peptides produced by enteroendocrine cells of the small-intestinal epithelium and their most commonly ascribed functions are summarized in Table 28-2. Some of these peptides, or their analogues, are used in routine clinical practice. For example,

Table 28-2

Representative regulatory peptides produced in the small intestine

HORMONE	SOURCE ^a	ACTIONS
Somatostatin	D cell	Inhibits gastrointestinal secretion, motility, and splanchnic perfusion
Secretin	S cell	Stimulates exocrine pancreatic secretion, stimulates intestinal secretion
Cholecystokinin	I cell	Simulates pancreatic exocrine secretion, stimulates gallbladder emptying, inhibits sphincter of Oddi contraction
Motilin	M cell	Simulates intestinal motility
Peptide YY	L cell	Inhibits intestinal motility and secretion
Glucagon-like Peptide 2	L cell	Stimulates intestinal epithelial proliferation
Neurotensin	N cell	Stimulates pancreatic and biliary secretion, inhibits small bowel motility, stimulates intestinal mucosal growth

^aThis table indicates which enteroendocrine cell types located in the intestinal epithelium produce these peptides. These peptides are also widely expressed in nonintestinal tissues.

therapeutic applications of octreotide, a long-acting analogue of somatostatin, include the amelioration of symptoms associated with neuroendocrine tumors (e.g., carcinoid syndrome), postgastrectomy dumping syndrome, enterocutaneous fistulas, and the initial treatment of acute hemorrhage due to esophageal varices. The gastrin secretory response to secretin administration forms the basis for the standard test used to establish the diagnosis of Zollinger-Ellison syndrome. Cholecystokinin is used in evaluations of gallbladder ejection fraction, a parameter that may have utility in patients who have symptoms of biliary colic but are not found to have gallstones. Of the peptides listed in Table 28-2, glucagon-like peptide 2 (GLP-2) has been identified as a specific and potent intestinotrophic hormone and is currently under clinical evaluation as an intestinotrophic agent in patients suffering from the short bowel syndrome, as discussed in the “Short Bowel Syndrome” section.

Intestinal Adaptation

The small intestine has the capacity to adapt in response to varying demands imposed by physiologic and pathologic conditions. Of relevance to many of the diseases discussed in this chapter is the adaptation that occurs in the remnant intestine following surgical resection of a large portion of the small intestine (massive small bowel resection). Postresection intestinal adaptation has been studied extensively using animal models. Within a few hours after bowel resection, the remnant small intestine displays evidence of epithelial cellular hyperplasia. With additional time, villi lengthen, intestinal absorptive surface area increases, and digestive and absorptive functions improve. Postresection intestinal adaptation in human patients is less well studied, but it seems to follow similar steps as that seen in experimental models, and it takes 1 to 2 years to complete.¹³

The mechanisms responsible for inducing postresection intestinal adaptation are under active investigation. Several classes of effectors that stimulate intestinal growth include specific nutrients, peptide hormones and growth factors, pancreatic secretions, and some cytokines. Nutritional components with intestinal growth-stimulating effects include fiber, fatty acids, triglycerides, glutamine, polyamines, and lectins.

Postresection adaptation serves to compensate for the function of intestine that has been resected. Jejunal resection is generally better tolerated, as ileum shows better capacity to compensate. However, the magnitude of this response is limited. If enough small intestine is resected, a devastating condition known as the short bowel syndrome results. This condition is discussed in the “Short Bowel Syndrome” section at the end of this chapter.

SMALL BOWEL OBSTRUCTION

Epidemiology

Mechanical small bowel obstruction is the most frequently encountered surgical disorder of the small intestine. **2▶** Although a wide range of etiologies for this condition exist, the obstructing lesion can be conceptualized according to its anatomical relationship to the intestinal wall as:

1. *intraluminal* (e.g., foreign bodies, gallstones, or meconium)
2. *intramural* (e.g., tumors, Crohn’s disease–associated inflammatory strictures)
3. *extrinsic* (e.g., adhesions, hernias, or carcinomatosis)

Intra-abdominal adhesions related to prior abdominal surgery account for up to 75% of cases of small bowel obstruction. Over 300,000 patients are estimated to undergo surgery to treat **3▶** adhesion-induced small bowel obstruction in the United States annually. A 20-year trend analysis between 1988 and 2007 has documented no decrease in this rate during this period, highlighting the ongoing problem of this “old” disease.¹⁴ In fact, small bowel resection and lysis of adhesions account for two of the seven procedures that were responsible for 80% of the emergency surgeries in the United States between 2008 and 2011.¹⁵

Less prevalent etiologies for small bowel obstruction include hernias, malignant bowel obstruction, and Crohn’s disease. The frequency with which obstruction related to these conditions is encountered varies according to the patient population and practice setting. Cancer-related small bowel obstructions are commonly due to extrinsic compression or invasion by advanced malignancies arising in organs other than the small bowel; few are due to primary small bowel tumors. The most commonly encountered etiologies of small bowel obstruction are summarized in Table 28-3. Although congenital abnormalities capable of causing small bowel obstruction usually **4▶** become evident during childhood, they sometimes elude detection and are diagnosed for the first time in adult patients presenting with abdominal symptoms. For example, intestinal malrotation and midgut volvulus should not be forgotten when considering the differential diagnosis of adult patients with acute or chronic symptoms of small bowel obstruction, especially those without a history of prior abdominal surgery. A rare etiology of obstruction is the superior mesenteric artery syndrome, characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it crosses over this portion of the duodenum. This condition should be

Table 28-3

Hematoma
Congenital abnormalities (e.g., webs, duplications, and malrotation)

considered in young asthenic individuals who have chronic symptoms suggestive of proximal small bowel obstruction.

Pathophysiology

With onset of obstruction, gas and fluid accumulate within the intestinal lumen proximal to the site of obstruction. The intestinal activity increases to overcome the obstruction, accounting for the colicky pain and the diarrhea that some experience even in the presence of complete bowel obstruction. Most of the gas that accumulates originates from swallowed air, although some is produced within the intestine. The fluid consists of swallowed liquids and gastrointestinal secretions (obstruction stimulates intestinal epithelial water secretion). With ongoing gas and fluid accumulation, the bowel distends and intraluminal and intramural pressures rise. The intestinal motility is eventually reduced with fewer contractions. With obstruction, the luminal flora of the small bowel, which is usually sterile, changes and a variety of organisms have been cultured from the contents. Translocation of these bacteria to regional lymph nodes has been demonstrated, although the significance of this process is not well understood. If the intramural pressure becomes high enough, intestinal microvascular perfusion is impaired leading to intestinal ischemia, and, ultimately, necrosis. This condition is termed *strangulated bowel obstruction*.

With *partial small bowel obstruction*, only a portion of the intestinal lumen is occluded, allowing passage of some gas and fluid. The progression of pathophysiologic events described previously tends to occur more slowly than with *complete small bowel obstruction*, and development of strangulation is less likely.

A particularly dangerous form of bowel obstruction is *closed loop obstruction* in which a segment of intestine is obstructed both proximally and distally (e.g., with volvulus). In such cases, the accumulating gas and fluid cannot escape either proximally or distally from the obstructed segment, leading to a rapid rise in luminal pressure and a rapid progression to strangulation.

Clinical Presentation

The symptoms of small bowel obstruction are colicky abdominal pain, nausea, vomiting, and obstipation. Vomiting is a more prominent symptom with proximal obstructions than distal. Character of vomitus is important as with bacterial overgrowth, the vomitus is more feculent, suggesting a more established obstruction. Continued passage of flatus and/or stool beyond 6 to 12 hours after onset of symptoms is characteristic of partial rather than complete obstruction. The signs of small bowel obstruction include abdominal distention, which is most pronounced if the site of obstruction is in the distal ileum and may be absent if the site of obstruction is in the proximal small intestine. Bowel sounds may be hyperactive initially, but in late stages of bowel obstruction, minimal bowel sounds may be heard. Laboratory findings reflect intravascular volume depletion and consist of hemoconcentration and electrolyte abnormalities. Mild leukocytosis is common.

Features of strangulated obstruction include abdominal pain often disproportionate to the degree of abdominal findings, suggestive of intestinal ischemia. Patients often have tachycardia, localized abdominal tenderness, fever, marked leukocytosis, and acidosis. Any of these findings should alert the clinician to the possibility of strangulation and the need for early surgical intervention.

Diagnosis

The diagnostic evaluation should focus on the following goals: (a) distinguish mechanical obstruction from ileus, (b) determine the etiology of the obstruction, (c) discriminate partial from complete obstruction, and (d) discriminate simple from strangulating obstruction.

Important elements to obtain on history include prior abdominal operations (suggesting the presence of adhesions) and the presence of abdominal disorders (e.g., intra-abdominal cancer or inflammatory bowel disease) that may provide insights into the etiology of obstruction. Upon examination, a meticulous search for hernias (particularly in the inguinal and femoral regions) should be conducted.

The diagnosis of small bowel obstruction is usually confirmed with radiographic examination. The *abdominal series* consists of (a) a radiograph of the abdomen with the patient in a supine position, (b) a radiograph of the abdomen with the patient in an upright position, and (c) a radiograph of the chest with the patient in an upright position. The finding most specific for small bowel obstruction is the triad of dilated small bowel loops (>3 cm in diameter), air-fluid levels seen on upright films, and a paucity of air in the colon. The sensitivity of abdominal radiographs in the detection of small bowel obstruction ranges from 70% to 80%. Specificity is low because ileus and colonic obstruction can be associated with findings that mimic those observed with small bowel obstruction. False-negative findings on radiographs can result when the site of obstruction is in the proximal small bowel and when the bowel lumen is filled with fluid but no gas, thereby preventing visualization of air-fluid levels or bowel distention. The latter situation is associated with closed-loop obstruction. Despite these limitations, abdominal radiographs remain an important study in patients with suspected small bowel obstruction because of their widespread availability and low cost (Fig. 28-12).

Computed tomographic (CT) scanning is becoming increasingly the imaging test of choice for patients with small bowel obstruction, and it is ideally done with oral contrast. CT is 80% to 90% sensitive and 70% to 90% specific in the detection of small bowel obstruction. The findings of small bowel obstruction include a discrete transition zone with dilation of bowel proximally, decompression of bowel distally, intraluminal contrast that does not pass beyond the transition zone, and a colon containing little gas or fluid (Figs. 28-13 and 28-14). CT scanning may also provide evidence for the presence of closed-loop obstruction and strangulation. Closed-loop obstruction is suggested by the presence of a U-shaped or C-shaped dilated bowel loop associated with a radial distribution of mesenteric vessels converging toward a torsion point. Strangulation is suggested by thickening of the bowel wall, pneumatosis intestinalis (air in the bowel wall), portal venous gas, mesenteric haziness, and poor uptake of intravenous contrast into the wall of the affected bowel (Fig. 28-15). CT scanning also offers a global evaluation of the abdomen and may therefore reveal the etiology of obstruction. This feature is important in the acute setting when intestinal obstruction represents only one of many diagnoses in patients presenting with acute abdominal conditions.

The CT scan is usually performed after administration of oral water-soluble contrast or diluted barium. The water-soluble contrast has been shown to have prognostic and therapeutic values too. Several studies and several subsequent meta-analysis have shown that water-soluble contrast could in fact have therapeutic and prognostic value. The appearance of the contrast

Figure 28-12. Small bowel obstruction. Plain radiographs (A) supine, which show dilated loops of small bowel in the right upper quadrant; (B) erect, which confirm the presence of airfluid level in the loops of small bowel as well as the stomach, consistent with small bowel obstruction.

in the colon within 24 hours of administration is predictive of nonsurgical resolution of bowel obstruction with a sensitivity of 92% and a specificity of 93%.¹⁶

A limitation of CT scanning is its low sensitivity (<50%) in the detection of low-grade or partial small bowel obstruction. A subtle transition zone may be difficult to identify in the axial images obtained during CT scanning. In such cases, contrast examinations of the small bowel, either *small bowel series* (small bowel follow-through) or *enteroclysis*, can be helpful. For standard small bowel series, contrast is swallowed or instilled into the stomach through a nasogastric tube. Abdominal radiographs are then taken serially as the contrast travels distally in the intestine. Although barium can be used, water-soluble

contrast agents, such as gastrograffin, should be used if the possibility of intestinal perforation exists. These examinations are more labor-intensive and less rapidly performed than CT scanning but may offer greater sensitivity in the detection of luminal and mural etiologies of obstruction, such as primary intestinal tumors. For enteroclysis, 200 to 250 mL of barium followed by 1 to 2 L of a solution of methylcellulose in water is instilled into the proximal jejunum via a long nasoenteric catheter. The double-contrast technique used in enterocolysis

Figure 28-13. Small bowel obstruction. A CT scan of a patient presenting with signs and symptoms of bowel obstruction. Image shows grossly dilated loops of small bowel, with decompressed terminal ileum (I) and ascending colon (C), suggesting a complete distal small bowel obstruction. At laparotomy, adhesive bands from a previous surgery were identified and divided.

Figure 28-14. Chronic partial small bowel obstruction. This patient presented with a several months history of chronic abdominal pain and intermittent vomiting. The coronal CT image shows grossly dilated loops of proximal small bowel on the left side (*wide arrow*), with decompressed loops of small bowel on the right side (*narrow arrow*). The dilated segment shows evidence of fecalization of bowel contents, consistent with the chronic nature of the obstruction. Patient's vomitus had characteristic feculent smell and quality. At exploratory laparotomy, adhesive bands were identified and divided.

Figure 28-15. Intestinal pneumatosis. This CT scan shows intestinal pneumatosis (*arrow*). The cause of this radiological finding was intestinal ischemia. Patient was taken emergently to the operating room and underwent resection of an infarcted segment of small bowel.

permits a better assessment of mucosal surface and detection of relatively small lesions, even through overlapping small bowel loops. Enterocolysis is rarely performed in the acute setting but offers greater sensitivity than small bowel series in the detection of lesions that may be causing partial small bowel obstruction. Recently, CT enterocolysis has been used, and it was reported to be superior to plain X-ray small bowel contrast studies.

Therapy

Small bowel obstruction is usually associated with a marked depletion of intravascular volume due to decreased oral intake, vomiting, and sequestration of fluid in bowel lumen and wall. Therefore, fluid resuscitation is integral to treatment. Isotonic fluid should be given intravenously, and an indwelling bladder catheter may be placed to monitor urine output. Central-venous or pulmonary-artery catheter monitoring are not generally indicated unless the patient has underlying cardiac disease and severe dehydration. Broad-spectrum antibiotics are not indicated unless there is concern for bowel ischemia and surgery is planned.

The stomach should be continuously evacuated of air and fluid using a nasogastric (NG) tube. Effective gastric decompression decreases nausea, distention, and the risk of vomiting and aspiration. Longer nasoenteric tubes, with tips placed into the jejunum or ileum, were favored in the past but are rarely used today, as they are associated with higher complication rates than NG tubes, with no proven greater efficacy in several studies.

While a period of close observation and nonoperative management has been the mainstay of treatment for partial bowel obstruction, the standard therapy for *complete* small bowel obstruction has generally been expeditious surgery, with the dictum that “the sun should never rise and set on a complete bowel obstruction.” The rationale for favoring early surgical intervention is to minimize the risk for bowel strangulation, which is associated with an increased risk for morbidity and mortality. Clinical signs and currently available laboratory tests and imaging studies do not reliably permit the distinction

between patients with simple obstruction and those with strangulated obstruction prior to the onset of irreversible ischemia. Therefore, the goal is to operate before the onset of irreversible ischemia. This treatment approach has, however, undergone significant reassessment in recent years, with many advocating for nonoperative approaches in management of these patients, providing closed-loop obstruction is ruled out and there is no evidence of intestinal ischemia. In a study of 145 patients with CT-diagnosed high-grade complete small bowel obstruction, 46% of the overall cohort were managed nonoperatively. More specifically, of the 104 patients who did not meet criteria for immediate surgery, 66 patients were successfully managed nonoperatively.¹⁷

Thus, conservative therapy in the form of NG decompression and fluid resuscitation is now commonly recommended in the initial management of nonischemic bowel obstruction. Nonoperative management has been documented to be successful in 65% to 81% of patients with partial small bowel obstruction. Of those successfully treated nonoperatively, only 5% to 15% have been reported to have symptoms that were not substantially improved within 48 hours after initiation of therapy. Therefore, most patients with partial small obstruction whose symptoms do not improve within 48 hours after initiation of nonoperative therapy should be considered for surgery. In a study using the National Inpatient Sample, this principle was further highlighted. The authors concluded that a 2-day limit of watchful waiting before surgery is not associated with an increase in mortality or postoperative morbidity, although inpatient costs were higher.¹⁸

The observation that administration of water-soluble oral contrast has not only diagnostic but also therapeutic and prognostic value has led to the creation of several protocols and pathways for management of patients presenting with small bowel obstruction. An example of such a pathway that is utilized at our institution is outlined in Fig. 28-16. Several studies and subsequent meta-analyses have shown that use of water-soluble contrast not only predicts likelihood of success of nonoperative management but also reduces the need for surgery (odds ratio 0.44), length of stay by about 2 days, and time to resolution by about 28 hours, without an increase in morbidity or mortality.¹⁶

The operative procedure performed for small bowel obstruction varies according to the etiology of the obstruction. For example, adhesions are lysed, tumors are resected, and hernias are reduced and repaired. Regardless of the etiology, the affected intestine should be examined, and nonviable bowel should be resected. Criteria suggesting viability are normal color, peristalsis, and marginal arterial pulsations. Usually, visual inspection alone is adequate in judging viability. In borderline cases, a Doppler probe may be used to check for pulsatile flow to the bowel, and arterial perfusion can be verified by visualizing intravenously administered fluorescein dye in the bowel wall under ultraviolet illumination. Neither technique has, however, been found to be superior to clinical judgment. In general, if the patient is hemodynamically stable, short lengths of bowel of questionable viability should be resected, and primary anastomosis of the remaining intestine should be performed. However, if the viability of a large proportion of the intestine is in question, a concerted effort to preserve intestinal tissue should be made. In such situations, the bowel of uncertain viability should be left intact and the patient reexplored in 24 to 48 hours in a “second-look” operation. At that time, definitive resection of nonviable bowel is completed.

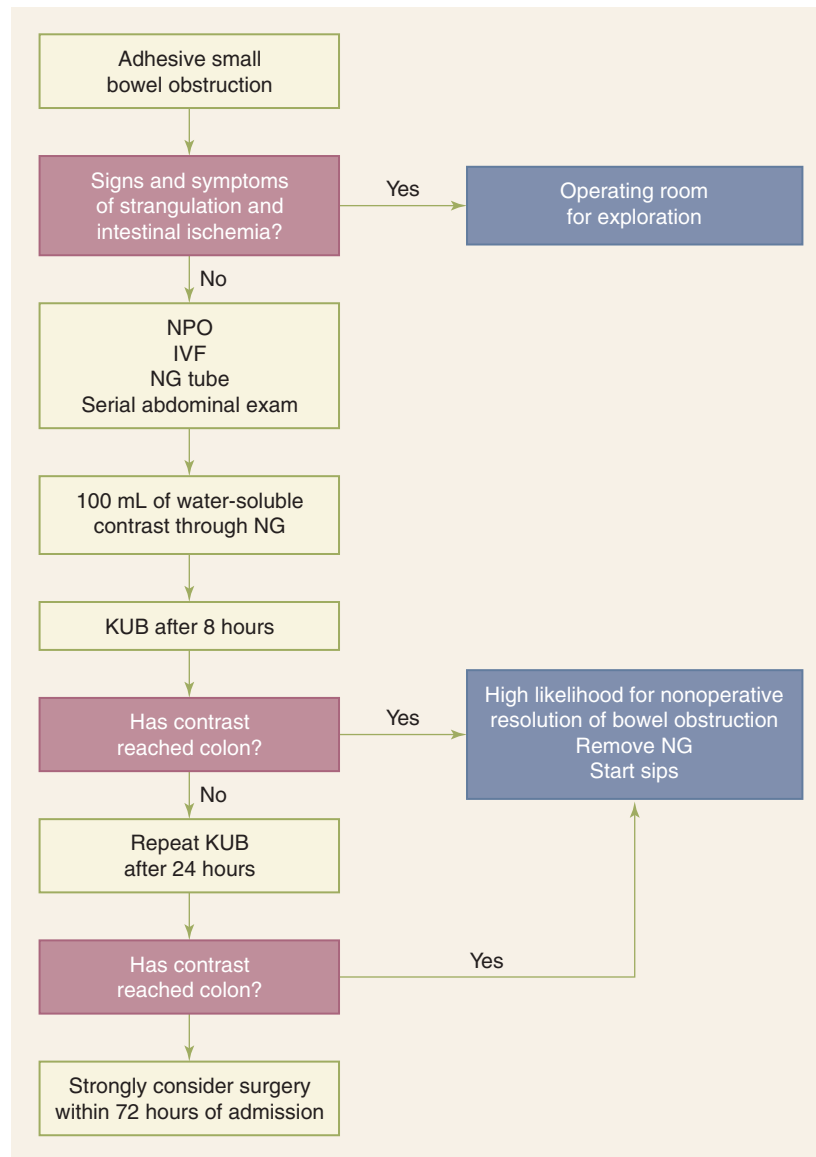

Figure 28-16. Management of small bowel obstruction.

Successful laparoscopic surgery for bowel obstruction is being reported with greater frequency. In a propensity score-matched study of patients who underwent adhesiolysis for small bowel obstruction, the laparoscopic approach was associated with significantly lower rates of overall complications, surgical site infections, and a shorter length of hospital stay (4 vs. 10 days).¹⁹ Since distended loops of bowel can interfere with adequate visualization, early cases of proximal small bowel obstruction that are likely due to a single adhesive band are best suited for this approach. Presence of bowel distention and multiple adhesions can cause these procedures to be difficult, with a reported conversion rate of 17% to 33%. One of the major concerns with the laparoscopic approach has been the risk of iatrogenic bowel injury. A pooled analysis of 11 nonrandomized comparative studies has, however, shown that the risk of bowel injury and reoperation were not different between the two procedures, although the laparoscopic approach was associated with greater surgical time.²⁰

Outcomes

The perioperative mortality rate associated with surgery for nonstrangulating small bowel obstruction is less than 5%,

with most deaths occurring in elderly patients with significant comorbidities. Mortality rates associated with surgery for strangulated obstruction is higher, highlighting the need for prompt intervention in this group. Long-term prognosis is related to the etiology of obstruction. Many patients who are treated conservatively for adhesive small bowel obstruction do not require future readmissions; less than 20% of such patients will have a readmission over the subsequent 5 years with another episode of bowel obstruction.

In a study of 286 patients who had undergone surgical intervention for adhesive small bowel obstruction, the risk of recurrent obstruction was 5.5% at 1 year, 11.3% at 3 years, and 13.5% at 5 years. The risk of reoperation for recurrent obstruction was 3.7% at 1 year, 4.8% at 3 years, and 5.8% at 5 years.²¹ Considering the frequency of small bowel obstruction and the varied degree of clinical severity and presentation, there is often variation in the care of patients admitted with bowel obstruction. Studies have shown that a standard hospital-wide policy can help improve care of patients with bowel obstruction, reducing their time to surgery and shortening their length of hospital stay.²²

Prevention

With adhesive small bowel obstruction representing a large therapeutic burden, prevention of postoperative adhesions has become an area of great interest. Good surgical technique, careful handling of tissue, and minimal use and exposure of peritoneum to foreign bodies, forms the cornerstone of adhesion prevention. These measures alone are often inadequate. In patients undergoing colorectal or pelvic surgery, hospital readmission rates of greater than 30% over the subsequent 10 years have been reported for adhesive small bowel obstruction.²³

Use of laparoscopic surgery, when possible, has been strongly promoted. A recent study using the Swedish National Inpatient Register has shown that, compared to laparoscopy, open surgery is associated with a fourfold increase in risk of small bowel obstruction within 5 years of the index procedure, even after accounting for other risk factors such as age, comorbidity, and previous abdominal surgery.²⁴

In those undergoing open surgery, several strategies for adhesion prevention have been tried; however, the only therapy that has shown some success has been the use of hyaluronan-based agents, such as SperaFilm. The use of this barrier has been clearly shown to reduce the incidence of postoperative bowel adhesions; however, their effect in actually reducing the incidence of small bowel obstruction remains less well defined.²⁵ The use of these products is often left to the discretion of the surgeon and the clinical context. Wrapping of an intestinal anastomosis with the material may be associated with increased leak rates and is generally discouraged.²⁶

Other Causes of Small Bowel Obstruction

Early postoperative bowel obstruction, as defined by signs, symptoms, and radiographic signs of SBO occurring within 30 days following surgery, been reported to occur in 0.7% to 9% of patients, with a higher rate in patients undergoing pelvic surgery, especially colorectal procedures.²⁷ CT scanning or small bowel series is often required to make the diagnosis. Obstruction that occurs in the early postoperative period is usually partial and only rarely is associated with strangulation. Therefore, a period of extended nonoperative therapy (2–3 weeks) consisting of bowel rest, hydration, and TPN administration is usually warranted. However, if complete obstruction is demonstrated or if signs suggestive of peritonitis are detected, expeditious reoperation should be undertaken without delay. In a series of 180 patients undergoing anterior resection for rectal cancer, 12.8% developed early postoperative bowel obstruction on the median postoperative day 5, with 4 requiring surgical exploration at a median interval of 2 weeks from the index case.²⁷

Crohn's disease as a cause of small bowel obstruction is discussed in more detail later in this chapter in the “Crohn's Disease” section.

Malignant small bowel obstruction can be a challenging problem. Although it often indicates advanced disease with poor prognosis, 25% to 33% of patients with a history of cancer who present with small bowel obstruction have adhesions as the etiology of their obstruction and therefore should not be denied appropriate therapy. Even in cases in which the obstruction is related to recurrent malignancy, palliative resection or bypass can be performed, and in select cases these procedures lead to improved quality of life. In a series of 81 patients with small bowel obstruction, palliation was achieved in over 80% of patients, with over 70% able to reestablish oral intake. In this series, the surgical morbidity was high, with 7% developing an enterocutaneous fistula/

anastomotic leak and a 30-day mortality rate of 6%.²⁸ Patients with obvious carcinomatosis and multifocal obstruction pose a difficult challenge, given their limited prognosis. Thus, management must be tailored to an individual patient's prognosis and desires. At the time of surgery, relief of the obstruction may be best achieved by a bypass procedure, avoiding a potentially difficult bowel resection, and even if that is not feasible, a palliative gastrostomy tube can be considered to help resolve nausea and vomiting.

ILEUS AND OTHER DISORDERS OF INTESTINAL MOTILITY

Ileus and intestinal pseudo-obstruction are clinical syndromes caused by impaired intestinal motility and are characterized by symptoms and signs of intestinal obstruction in the absence of a lesion-causing mechanical obstruction. Ileus is a temporary motility disorder that is reversed with time as the inciting factor is corrected. In contrast, chronic intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility.

Ileus is a major cause of morbidity in hospitalized patients. A degree of intestinal ileus is a normal physiological response to abdominal surgery, which often resolves quickly without any long-term sequela. However, when postoperative ileus is prolonged, it can cause significant morbidity and cost. Prolonged postoperative ileus is the most frequently implicated cause of delayed discharge following abdominal operations, and its economic impact has been estimated to be between \$750 million and \$1 billion annually in the United States.²⁹

Pathophysiology

Numerous factors capable of impairing intestinal motility, and thus inciting ileus, have been described (Table 28-4). The most

Table 28-4

Ileus: common etiologies

Abdominal surgery
Infection
Sepsis
Intra-abdominal abscess
Peritonitis
Pneumonia
Electrolyte abnormalities
Hypokalemia
Hypomagnesemia
Hypermagnesemia
Hyponatremia
Medications
Anticholinergics
Opiates
Phenothiazines
Calcium channel blockers
Tricyclic antidepressants
Hypothyroidism
Ureteral colic
Retroperitoneal hemorrhage
Spinal cord injury
Myocardial infarction
Mesenteric ischemia

frequently encountered factors are abdominal operations, infection and inflammation, electrolyte abnormalities, and drugs.

Following most abdominal operations or injuries, the motility of the gastrointestinal tract is transiently impaired. Among the proposed mechanisms responsible for this dysmotility are surgical stress-induced sympathetic reflexes, inflammatory response mediator release, and anesthetic/analgesic side effects; each of which can inhibit intestinal motility. The return of normal motility generally follows a characteristic temporal sequence, with small-intestinal motility returning to normal within the first 24 hours after laparotomy and gastric and colonic motility returning to normal by 48 hours and 2 to 5 days, respectively. Since small bowel motility is returned before colonic and gastric motility, listening for bowel sounds is not a reliable indicator that ileus has fully resolved. Functional evidence of coordinated gastrointestinal motility in the form of passing flatus or bowel movement is a more useful indicator. Resolution of ileus may be delayed in the presence of other factors capable of inciting ileus such as the presence of intra-abdominal abscesses or electrolyte abnormalities.

Chronic intestinal pseudo-obstruction can be caused by a large number of specific abnormalities affecting intestinal smooth muscle, the myenteric plexus, or the extraintestinal nervous system (Table 28-5). Visceral myopathies constitute a group of diseases characterized by degeneration and fibrosis of the intestinal muscularis propria. Visceral neuropathies encompass a variety of degenerative disorders of the myenteric and submucosal plexuses. Both sporadic and familial forms of visceral myopathies and neuropathies exist. Systemic disorders involving the smooth muscle such as progressive systemic sclerosis and progressive muscular dystrophy, and neurological diseases such as Parkinson's disease, can also be complicated by chronic intestinal pseudo-obstruction. In addition, viral infections, such as those associated with cytomegalovirus and Epstein-Barr virus, can cause intestinal pseudo-obstruction.

Table 28-5

Chronic intestinal pseudo-obstruction: etiologies

Primary Causes

Familial types

- Familial visceral myopathies (types I, II, and III)
- Familial visceral neuropathies (types I and II)
- Childhood visceral myopathies (types I and II)

Sporadic types

- Visceral myopathies
- Visceral neuropathies

Secondary Causes

Smooth muscle disorders

- Collagen vascular diseases (e.g., scleroderma)
- Muscular dystrophies (e.g., myotonic dystrophy)
- Amyloidosis

Neurological disorders

- Chagas disease, Parkinson's disease, spinal cord injury

Endocrine disorders

- Diabetes, hypothyroidism, hypoparathyroidism

Miscellaneous disorders

- Radiation enteritis

Pharmacological causes

- E.g., phenothiazines and tricyclic antidepressants

Viral infections

Clinical Presentation

The clinical presentation of ileus resembles that of small bowel obstruction. Inability to tolerate liquids and solids by mouth, nausea, and lack of flatus or bowel movements are the most common symptoms. Vomiting and abdominal distension may occur. Although bowel sound characteristics are not diagnostic, they are usually diminished or absent, in contrast to the hyperactive bowel sounds that usually accompany mechanical small bowel obstruction. The clinical manifestations of chronic intestinal pseudo-obstruction include variable degrees of nausea and vomiting and abdominal pain and distention.

Diagnosis

Routine postoperative ileus should be expected and requires no diagnostic evaluation. Definition of prolonged postoperative ileus has been varied but generally diagnosed if ileus persists beyond 5 days postoperatively. A recent global survey synthesized the results of the data to define postoperative ileus as "interval from surgery until passage of flatus/stool AND tolerance of an oral diet," with prolonged postoperative ileus being defined as "two or more of nausea/vomiting, inability to tolerate oral diet over 24 h, absence of flatus over 24 h, distension, radiologic confirmation occurring on or after day 4 postoperatively without prior resolution of postoperative ileus."³⁰ Prolonged ileus is reported to occur in 10% to 15% of patients undergoing intestinal surgery.³¹

Once suspected, diagnostic evaluation to detect specific underlying factors capable of inciting ileus and to rule out the presence of mechanical obstruction is warranted.

Patient medication lists should be reviewed for the presence of drugs, especially opiates, known to be associated with impaired intestinal motility. Measurement of serum electrolytes may demonstrate electrolyte abnormalities commonly associated with ileus. Abdominal radiographs are often obtained, but the distinction between ileus and mechanical obstruction may be difficult based on this test alone. In the postoperative setting, CT scanning is the test of choice as it can demonstrate the presence of an intra-abdominal abscess or other evidence of peritoneal sepsis that may be causing ileus and can exclude the presence of complete mechanical obstruction. Distinction of postoperative ileus from early postoperative obstruction can be difficult but is helpful in developing the appropriate management plan.

The diagnosis of chronic pseudo-obstruction is suggested by clinical features and confirmed by radiographic and manometric studies. Diagnostic laparotomy or laparoscopy with full-thickness biopsy of the small intestine may be required to establish the specific underlying cause in cases of suspected neural disorder.

Therapy

The management of ileus consists of limiting oral intake and correcting the underlying inciting factor. If vomiting or abdominal distention are prominent, the stomach should be decompressed using a nasogastric tube. Fluid and electrolytes should be administered intravenously until ileus resolves. If the duration of ileus is prolonged, total parental nutrition (TPN) may be required.

Given the frequency of postoperative ileus and its financial impact, many strategies have been tested to reduce its duration. The administration of nonsteroidal anti-inflammatory drugs such as ketorolac and concomitant reductions in opioid dosing have been shown to reduce the duration of ileus in most studies. Similarly, the use of perioperative thoracic epidural anesthesia/analgesia with

Table 28-6

Measures to reduce postoperative ileus

Intraoperative measures
Minimalize handling of the bowel
Laparoscopic approach, if possible
Restricted intraoperative fluid administration
Postoperative measures
Avoid nasogastric tubes
Early enteral feeding
Epidural anesthesia, if indicated
Restricted IV fluid administration
Correct electrolyte abnormalities
Consider mu-opioid antagonists

regimens containing local anesthetics combined with limitation or elimination of systemically administered opioids has been shown to reduce duration of postoperative ileus, although they have not reduced the overall length of hospital stay.³² Many studies have also suggested that limiting intra- and postoperative fluid administration can also result in reduction of postoperative ileus and shortened hospital stay.³³ Furthermore, studies have shown that early postoperative feeding after GI surgery is generally well tolerated and can lead to reduced postoperative ileus and a shorter hospital stay. Table 28-6 summarizes some of the measures used to minimize postoperative ileus. Such data have generated significant interest in Early Recovery After Surgery (ERAS) pathways, which are a collection of steps taken to expedite postoperative recovery in general. ERAS protocols typically involve 15 to 20 steps that involve the pre-, intra- and postoperative phases of care and form a multimodal pathway. Although the contribution of each element to the overall outcome has not been well studied, the bundle of steps leads to reduced length of stay and surgical complications. In cases of GI surgery, many of these steps are targeted towards reducing postoperative ileus, which is often the barrier to early discharge.

Although prokinetic agents have been tried to promote return of GI motility, they are associated with efficacy-toxicity profiles that are too unfavorable to warrant routine use. Recently, administration of alvimopan, a novel, peripherally active mu-opioid receptor antagonist with limited oral absorption, has been shown to reduce duration of postoperative ileus, hospital stay, and rate of readmissions in several prospective, randomized, placebo-controlled trials and the subsequent meta-analysis.³⁴ Any cost savings associated with the use of this drug outside of a clinical trial has, however, been debated.³⁵

The therapy of patients with *chronic* intestinal pseudo-obstruction focuses on palliation of symptoms as well as fluid, electrolyte, and nutritional management. Surgery should be avoided if possible. No standard therapies are curative or delay the natural history of any of the specific disorders causing intestinal pseudo-obstruction. Prokinetic agents, such as metoclopramide and erythromycin, are associated with poor efficacy. Cisapride has been associated with palliation of symptoms; however, because of cardiac toxicity and reported deaths, this agent is restricted to compassionate use in the United States.

Patients with refractory disease may require strict limitation of oral intake and long-term TPN administration. Despite these measures, some patients will continue to have severe abdominal pain or such copious intestinal secretions that vomiting and fluid and electrolyte losses remain substantial. These patients may require a decompressive gastrostomy or an extended small bowel

resection to remove abnormal intestine. Small-intestinal transplantation has been applied in these patients with increasing frequency; the ultimate role of this modality remains to be defined.

CROHN'S DISEASE

Crohn's disease is a chronic, idiopathic transmural inflammatory disease with skip lesions that may affect any part of the alimentary tract, although there is propensity to affect the distal small bowel. Nearly 80% of patients with Crohn's disease have small bowel involvement, with 30% having terminal ileitis exclusively. Recent studies suggest a prevalence of about 241 cases per 100,000 in the United States.³⁶ The rates of Crohn's and ulcerative colitis have been increasing globally over the past several decades with substantial regional variations in incidence. The highest incidences are reported in western nations and those in northern latitudes, with Canada having the highest reported rates.³⁷ In countries such as China, the prevalence of Crohn's disease is substantially below that seen in the West, but rates have been rapidly increasing recently.³⁸ The incidence of Crohn's disease varies among ethnic groups within the same geographic region. For example, members of Eastern European Ashkenazi Jewish population are at a two- to fourfold higher risk of developing Crohn's disease than members of other populations living in the same location.

Most studies suggest that Crohn's disease is slightly more prevalent in females than in males. The mean age at which patients are diagnosed with Crohn's disease falls in the third decade of life years, with a second smaller peak in the sixth decade of life, giving it a bimodal distribution. The age at diagnosis can, however, range from early childhood through the entire lifespan.

Both genetic and environmental factors appear to influence the risk for developing Crohn's disease. The relative risk among first-degree relatives of patients with Crohn's disease is 14 to 15 times higher than that of the general population, with about 20% of patients reporting a family history. The concordance rate among monozygotic twins is as high as 67%; however, Crohn's disease is not associated with simple Mendelian inheritance patterns. Although there is a tendency within families for either ulcerative colitis or Crohn's disease to be present exclusively, mixed kindreds also occur, suggesting the presence of some shared genetic traits as a basis for both diseases.

Higher socioeconomic status is associated with an increased risk of Crohn's disease. Most studies have found breastfeeding to be protective against the development of Crohn's disease. Crohn's disease is more prevalent among smokers. Furthermore, smoking is associated with the increased risk for both the need for surgery and the risk of relapse after surgery for Crohn's disease.

Pathophysiology

Crohn's disease is characterized by sustained inflammation. Whether this inflammation represents an appropriate response to a yet unrecognized pathogen or an inappropriate response to a normally innocuous stimulus is unknown. Various hypotheses on the roles of environmental and genetic factors in the pathogenesis of Crohn's disease have been proposed. Many infectious agents have been suggested to be the causative organism of Crohn's disease; however, there has been no conclusive evidence to confirm any. Studies using animal models suggest that in a genetically susceptible host, a nonpathogenic gut microbiome is sufficient to induce a chronic inflammatory response resembling

that associated with Crohn's disease. In these models, the sustained intestinal inflammation is the result of either abnormal epithelial barrier function or immune dysregulation. A full discussion of the role of gut immune system and microbiome in the development of Crohn's disease is beyond the scope of this work, but it is an area of great interest and under investigation. In general, poor barrier function is hypothesized to permit inappropriate exposure of lamina propria lymphocytes to antigenic stimuli derived from the intestinal lumen. In addition, a variety of defects in immune regulatory mechanisms, e.g., overresponsiveness of mucosal T cells to enteric flora-derived antigens, can lead to defective immune tolerance and sustained inflammation.

Specific genetic defects associated with Crohn's disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called IBD1 locus) has been linked to Crohn's disease. The IBD1 locus has been identified as the *NOD2* gene. Persons with allelic variants on both chromosomes have a 40-fold relative risk of Crohn's disease compared to those without variant *NOD2* genes. The relevance of this gene to the pathogenesis of Crohn's disease is biologically plausible, as the protein product of the *NOD2* gene mediates the innate immune response to microbial pathogens. Other putative IBD loci have been identified on other chromosomes (IBD2 on chromosome 12q, and IBD3 on chromosome 6), and are under investigation.

Although appendectomy has been shown to lower the risk of subsequent development of ulcerative colitis, it was suspected that the surgery may increase the risk of developing Crohn's disease. A meta-analysis has, however, suggested that the observed increased risk of Crohn's disease in the first few years after an appendectomy may in fact reflect diagnostic difficulty in a group of patients with incipient Crohn's.³⁹

Although the pathological hallmark of Crohn's disease is focal, transmural inflammation of the intestine, a spectrum of pathological lesions can be present. The earliest lesion characteristic of Crohn's disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn's disease and are reported to be present in up to 70% of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestoned appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation can also result in fibrosis with stricture formation, intra-abdominal abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn's disease can affect discontinuous portions of intestine, so-called skip lesions that are separated by intervening normal-appearing intestine.

A feature of Crohn's disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of *fat wrapping*, which represents encroachment of mesenteric fat onto the serosal surface of the bowel (Fig. 28-17). This finding is virtually pathognomonic of Crohn's

Figure 28-17. Crohn's disease. This intraoperative photograph demonstrates encroachment of mesenteric fat onto the serosal surface of the intestine ("fat wrapping") that is characteristic of intestinal segments affected by active Crohn's disease.

disease. The presence of fat wrapping correlates well with the presence of underlying acute and chronic inflammation.

Features that allow for differentiation between Crohn's disease of the colon and ulcerative colitis include the layers of the bowel wall affected (inflammation in ulcerative colitis is limited to the mucosa and submucosa but may involve the full-thickness of the bowel wall in Crohn's disease) and the longitudinal extent of inflammation (inflammation is continuous and characteristically affects the rectum in ulcerative colitis but may be discontinuous and spare the rectum in Crohn's disease). In the absence of full expression of features of advanced disease, Crohn's colitis can sometimes be difficult to distinguish from ulcerative colitis. It is also important to remember that although ulcerative colitis is a disease of the colon, it can be associated with inflammatory changes in the distal ileum (backwash ileitis).

Clinical Presentation

The most common symptoms of Crohn's disease are abdominal pain, diarrhea, and weight loss. However, the clinical features are highly variable among individual patients and depend on which segment(s) of the gastrointestinal tract is (are) predominantly affected, the intensity of inflammation, and the presence or absence of specific complications. In fact, some patients with Crohn's disease may have been initially misdiagnosed as having irritable bowel syndrome or celiac disease.

Patients can be classified by their predominant clinical manifestation as having primarily (a) fibrostenotic disease, (b) fistulizing disease, and (c) aggressive inflammatory disease. There is substantial overlap among these disease patterns in individual patients, however. The onset of symptoms is insidious, and once present, their severity follows a waxing and waning course. Constitutional symptoms, particularly weight loss and fever, or growth retardation in children, may also be prominent and are occasionally the sole presenting features of Crohn's disease.

The disease affects the small bowel in 80% of cases and colon alone in 20%. In those with small bowel disease, the majority have ileocecal disease. Isolated perineal and anorectal disease occurs in 5% to 10% of affected patients. Uncommon sites of involvement include the esophagus, stomach, and duodenum.

An estimated one-fourth of all patients with Crohn's disease will have an extraintestinal manifestation of their disease. One

Table 28-7

Interstitial lung disease
Amyloidosis
Pancreatitis

fourth of those affected will have more than one manifestation. Many of these complications can be seen with both Crohn's disease and ulcerative colitis, although they are more prevalent among patients with Crohn's disease. The most common extraintestinal manifestations are listed in Table 28-7. The clinical severity of some of these manifestations, such as erythema nodosum and peripheral arthritis, are correlated with the severity of intestinal inflammation. The severity of other manifestations, such as pyoderma gangrenosum and ankylosing spondylitis, bear no apparent relationship to the severity of intestinal inflammation.

Diagnosis

The diagnosis is usually established with endoscopic findings in a patient with a compatible clinical history. The diagnosis should be considered in those presenting with acute or chronic abdominal pain, especially when localized to the right lower quadrant, chronic diarrhea, evidence of intestinal inflammation on radiography or endoscopy, the discovery of a bowel stricture or fistula arising from the bowel, and evidence of inflammation or granulomas on intestinal histology. Disorders associated with clinical presentations that resemble those of Crohn's disease include ulcerative colitis, functional bowel disorders such as irritable bowel syndrome, mesenteric ischemia, collagen vascular diseases, carcinoma and lymphoma, diverticular disease, and infectious enteritides. Infectious enteritides are most frequently diagnosed in immunocompromised patients, but they can also occur in patients with normal immune function. Acute ileitis caused by *Campylobacter* and *Yersinia* species can be difficult to distinguish from that caused by an acute presentation of Crohn's disease. Typhoid enteritis caused by *Salmonella*

typhosa can lead to overt intestinal bleeding and perforation, most often affecting the terminal ileum. The distal ileum and cecum are the most common sites of intestinal involvement by infection due to *Mycobacterium tuberculosis*. This condition can result in intestinal inflammation, strictures, and fistula formation, like those seen in Crohn's disease. Cytomegalovirus (CMV) can cause intestinal ulcers, bleeding, and perforation.

No single symptom, sign, or diagnostic test establishes the diagnosis of Crohn's disease. Instead, the diagnosis is based on a complete assessment of the clinical presentation with confirmatory findings derived from radiographic, endoscopic, and in most cases, pathologic tests. Patients presenting with a history of Crohn's disease should have their full blood count, electrolytes and renal function, liver function, iron, B12, ESR, and CRP levels checked. The results may be abnormal, showing anemia, but these results are nondiagnostic. Colonoscopy with intubation of terminal ileum is the main diagnostic tool and can reveal focal ulcerations adjacent to areas of normal appearing mucosa along with polypoid mucosal changes that give a "cobblestone appearance." Skip areas of involvement are typical with segments of normal-appearing bowel interrupted by large areas of obvious disease; this pattern is different from the continuous involvement in ulcerative colitis. Pseudopolyps, as seen in ulcerative colitis, are also often present. Barium small bowel follow-through, CT enterography, or MR enterography may be used as contrast examinations of the small bowel to reveal strictures or networks of ulcers and fissures. CT scanning may reveal intra-abdominal abscesses and is useful in acute presentations to rule out the presence of other intra-abdominal disorders. Esophagogastroduodenoscopy (EGD) is done for disease of the proximal alimentary tract. Because Crohn's disease often affects the small bowel, which is difficult to image, capsule endoscopy has been increasing used to make this diagnosis (Fig. 28-18).⁴⁰

Figure 28-18. Crohn's disease. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. It demonstrates a superficial ulceration in the small bowel consistent with Crohn's disease. (Used with permission from Anne T. Wolf, M.D., Department of Medicine, Brigham and Women's Hospital, Boston, MA.)

Several antibodies have also been identified in patients with inflammatory bowel disease, which may have diagnostic value. The most commonly tested antibodies are antineutrophil cytoplasmic antibody (pANCA) and antisaccharmyces cerevisiae antibody (ASCA). ASCA+/pANCA-, is associated with a diagnosis of Crohn's disease, while ASCA-/pANCA+, correlates with ulcerative colitis. Although these antibody tests have high specificity, their use has been hampered by low test sensitivities. There is ongoing interest in developing other antibody tests to diagnose inflammatory bowel disease and help differentiate Crohn's disease from ulcerative colitis. There have been attempts to develop stool tests to diagnose inflammatory bowel disease, and although fecal calprotectin or lactoferrin can identify patients with intestinal inflammation, they are not routinely done in clinical practice.

Because of the insidious, and often nonspecific, presentation of Crohn's disease, a diagnosis of Crohn's is typically made only after symptoms have been present for several years. However, in acute presentations, the diagnosis is sometimes made intraoperatively or during surgical evaluation. The initial manifestation of Crohn's disease can consist of right lower quadrant abdominal mimicking the presentation of acute appendicitis. In patients with this presentation, Crohn's disease can be discovered for the first time during laparotomy or laparoscopy performed for presumed appendicitis. In some patients, the initial manifestation of Crohn's disease is an acute abdomen related to small bowel obstruction, intra-abdominal abscess, or free intestinal perforation. In other patients, perianal abscesses and fistulas requiring surgical therapy may be the first manifestation of Crohn's disease.

Therapy

Because no curative therapies are available for Crohn's disease, the goal of treatment is to palliate symptoms rather than to achieve cure. Medical therapy is used to induce and maintain disease remission. Surgery is reserved for specific indications described later in this chapter. In addition, nutritional support in the form of aggressive enteral regimens or, if necessary, parenteral nutrition, is used to manage the malnutrition that is common in patients with Crohn's disease.

Medical Therapy. Pharmacologic agents used to treat Crohn's disease include antibiotics, aminosalicylates, corticosteroids, immunomodulators, and biologic therapies. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn's disease. They are also used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Crohn's disease activity is assessed using the Crohn's disease Activity Index or Harvey-Bradshaw Index, and depending on the scores, it can be categorized as asymptomatic, mild, moderate, or severe disease to guide therapy. While patients with mild and moderate disease can be managed on an outpatient basis, those with severe or fulminant disease often require hospitalization for treatment, bowel rest, and possible nutritional support. There are two general approaches to treating Crohn's disease: top-down (which starts with the most potent agents to achieve remission with a subsequent decrease in medication) or step-up (starts with less potent and often safer drugs, and if symptoms fail to improve advances to the next group of medications).

The use of oral 5-aminosalicylic acid (5-ASA) drugs (e.g., mesalamine) is somewhat controversial with mixed results from several randomized studies and meta-analyses. Aminosalicylates

are associated with minimal toxicity and are available in a variety of formulations that allow for their delivery to specific regions of the alimentary tract. Thus, many continue to recommend use of mesalamine as an initial step in management of mild symptoms in patients with small bowel Crohn's disease.

Orally administered glucocorticoids are used to treat patients with mild disease that does not respond to aminosalicylates, or as initial treatment of patients with moderate disease. Patients with severe active disease usually require intravenous administration of glucocorticoids. Although glucocorticoids are effective in inducing remission, they are ineffective in preventing relapse, and their adverse side-effect profile makes long-term use hazardous. Therefore, they should be tapered once remission is achieved. Some patients are unable to undergo glucocorticoid tapering without suffering recurrence of symptoms. Such patients are said to have steroid dependence. These patients, along with those who do not respond to steroids at all (steroid resistant), should be considered for immune modulator therapies. Controlled ileal-released budesonide is an oral steroid with high first-pass hepatic metabolism and few systemic effects that can be tried in those with ileal and colonic Crohn's disease.

For those with severe disease, the thiopurine antimetabolites azathioprine and its active metabolite, 6-mercaptopurine, have demonstrated efficacy in inducing remission, maintaining remission, and allowing for glucocorticoid tapering in glucocorticoid-dependent patients. A response to these medications is usually observed in 3 to 6 months, during which patients may need to continue with steroids. There is also some evidence that they decrease the risk of relapse after intestinal resection for Crohn's disease. These agents are relatively safe but can induce bone marrow suppression and promote infectious complications. For patients who do not respond to the thiopurines, methotrexate is an alternative that is usually initially given intramuscularly before switching to oral form after achieving symptomatic control. There is little role for cyclosporine in Crohn's disease; its efficacy/toxicity profile in this disease is poor.

The successful introduction of infliximab (Remicade), an anti-TNF α antibody, heralded the era of biological therapies for inflammatory bowel disease. Infliximab is a chimeric monoclonal antitumor necrosis-factor alpha (TNF α) antibody that has been shown to have efficacy in inducing remission and in promoting closure of enterocutaneous fistulae. There are two other anti-TNF α antibodies, with no randomized studies comparing efficacy of the drugs head to head. In general, it is thought that there is no significant difference in efficacy between them. While infliximab is a mouse-human chimeric antibody, adalimumab (Humira) is a fully human antibody. Certolizumab pegol (Cimzia) is a PEGylated Fab fragment of a humanized TNF inhibitor monoclonal antibody. These agents are generally used for patients who are resistant to standard therapy, to help taper steroid dosage. They are generally well tolerated, but they should not be used in patients with ongoing septic processes, such as undrained intra-abdominal abscesses. Antibodies against other targets in this inflammatory pathway have also been developed, including vedolizumab (Entyvio), a humanized anti- $\alpha_4\beta_7$ integrin monoclonal antibody, with more specific anti-inflammatory effect in the intestine.

For patients with perianal disease, antibiotic therapy with metronidazole or ciprofloxacin is the primary step. Two to 4 weeks of therapy is needed before improvements are seen, and often long-term therapy is required to prevent relapse. In cases of relapse, azathioprine can be considered. In patients with fistulas, infliximab and azathioprine are drugs of choice.

Table 28-8

Indications for surgical intervention in Crohn's disease

Acute onset of severe disease:
Crohn's colitis +/- toxic megacolon (rare)
Failure of medical therapy:
Persistent symptoms despite long-term steroid use
Recurrence of symptoms when high-dose steroids are tapered
Drug-induced complications (Cushing's disease, hypertension)
Development of disease complications:
Obstruction
Perforation
Complicated fistulas
Hemorrhage
Malignancy risk

Surgical Therapy. With introduction of new treatments, the need for surgery for Crohn's disease has decreased steadily over the past few decades. Recent meta-analysis estimated the risk of surgery to be 16.3%, 33.3%, and 46.6% at 1, 5, and 10 years respectively.⁴¹ Surgery is generally reserved for patients whose disease is unresponsive to aggressive medical therapy or who develop complications of their disease (Table 28-8). Failure of medical management may be the indication for surgery if symptoms persist despite aggressive therapy for several months or if symptoms recur whenever aggressive therapy is tapered. Surgery should be considered if medication-induced complications arise, specifically corticosteroid-related complications, such as cushingoid features, cataracts, glaucoma, systemic hypertension, compression fractures, or aseptic necrosis of the femoral head. Growth retardation constitutes an indication for surgery in 30% of children with Crohn's disease.

One of the most common indications for surgical intervention is intestinal obstruction. Abscesses and fistulas are frequently encountered during operations performed for intestinal obstruction in these patients, but they are rarely the only indication for surgery. Most abscesses are amenable to percutaneous drainage, and fistulas, unless associated with symptoms or metabolic derangements, do not require surgical intervention. Less common complications that require surgical intervention are acute gastrointestinal hemorrhage, perforations, and development of cancer.

Although surgery for Crohn's disease is usually planned, an uncommon, but not rare, scenario is the intraoperative discovery of inflammation limited to the terminal ileum during operations performed for presumed appendicitis. This scenario can result from an acute presentation of Crohn's disease or from acute ileitis caused by bacteria such as *Yersinia* or *Campylobacter*. Both conditions should be treated medically; ileal resection is not generally indicated. However, the appendix, even if normal appearing, should be removed (unless the cecum is inflamed, increasing the potential morbidity of this procedure) to eliminate appendicitis from the differential diagnosis of abdominal pain in these patients, particularly those with Crohn's disease who may be destined to have recurring symptoms.

When the diagnosis of Crohn's disease is known and surgery is planned, a thorough examination of the entire intestine should be performed. The presence of active disease is suggested by thickening of the bowel wall, narrowing of the lumen, serosal inflammation and coverage by creeping fat, and thickening of

the mesentery. Skip lesions are present in approximately 20% of cases and should be sought. The length of uninvolved small intestine should be noted.

Segmental intestinal resection of grossly evident disease followed by primary anastomosis is the usual procedure of choice. Microscopic evidence of Crohn's disease at the resection margins does not compromise a safe anastomosis, and frozen section analysis of resection margins is unnecessary. In a randomized prospective trial, the effects of achieving 2-cm resection margins beyond grossly evident disease were compared with achieving 12-cm resection margins.⁴² There were no evident differences with respect to clinical recurrence rates or anastomotic recurrences. Recurrence rates were similar whether margins were histologically free of or involved with Crohn's disease. An area of controversy in surgical management of Crohn's disease has been the ideal anastomotic technique for the bowel after intestinal resection. This issue was addressed in a randomized study of 139 patients undergoing an ileocolic resection for Crohn's disease, with a mean follow-up of 11.9 months. There were no differences in endoscopic or symptomatic disease recurrence between the groups reconstructed using end-to-end sutured (2-0 PDS) anastomosis versus those with side-to-side staples anastomosis.⁴³

An alternative to segmental resection for obstructing lesions is stricturoplasty (Fig. 28-19). This technique allows for preservation of intestinal surface area and is especially well suited to patients with extensive disease and fibrotic strictures who may have undergone previous resection and are at risk for developing short bowel syndrome. In this technique, the bowel is opened longitudinally to expose the lumen. Any

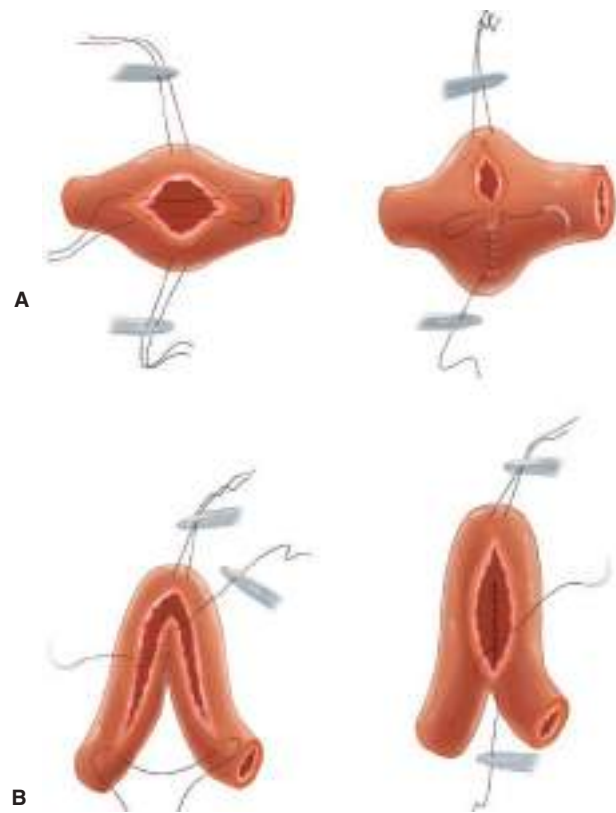

Figure 28-19. Stricturoplasty. The wall of the strictured bowel is incised longitudinally. Reconstruction is performed by closing the defect transversely in a manner similar to the Heinecke-Mickulicz pyloroplasty for short strictures (A), or the Finney pyloroplasty for longer strictures (B).

intraluminal ulcerations should be biopsied to rule out the presence of neoplasia. Depending on the length of the stricture, the reconstruction can be fashioned in a manner similar to the Heinecke-Mickulicz pyloroplasty (for strictures less than 12 cm in length) or the Finney pyloroplasty (for longer strictures as much as 25 cm in length). For longer strictures, variations on the standard stricturoplasty, namely the side-to-side isoperistaltic enteroenterostomy, have been advocated and used for strictures with mean lengths of 50 cm.⁴⁴ Stricturoplasty sites should be marked with metallic clips to facilitate their identification on radiographs and during subsequent operations. Stricturoplasty is associated with recurrence rates that are no different from those associated with segmental resection. Because the affected bowel is left in situ rather than resected, there is the potential for cancer developing at the stricturoplasty site. However, as data on this complication are limited to anecdotes, this risk remains a theoretical one. Stricturoplasty is contraindicated in patients with intra-abdominal abscesses or intestinal fistulas. The presence of a solitary stricture relatively close to a segment for which resection is planned is a relative contraindication. In general, stricturoplasty is performed in cases where single or multiple strictures are identified in diffusely involved segments of bowel, or where previous resections have been performed and maintenance of intestinal length is of great importance.

Intestinal bypass procedures are sometimes required in the presence of intramesenteric abscesses or if the diseased bowel is coalesced in the form of a dense inflammatory mass, making its mobilization unsafe. Bypass procedures (gastrojejunostomy) are also used in the presence of duodenal strictures, for which stricturoplasty and segmental resection can be technically difficult.

Since the 1990s, laparoscopic surgical techniques have been applied to patients with Crohn's disease. The inflammatory changes associated with Crohn's disease such as thickened and for eshortened mesentery, obliterated tissue planes, and friable tissues with engorged vasculature can make laparoscopic approach challenging. Randomized studies and a meta-analysis have confirmed that laparoscopic surgery for Crohn's disease is associated with less postoperative pain, shorter duration of ileus, and a shorter hospital stay. The rates of disease recurrence were similar between the two groups.⁴⁵

Outcomes

Overall complication rates following surgery for Crohn's disease range from 15% to 30%. Wound infections, postoperative intra-abdominal abscesses, and anastomotic leaks account for most of these complications.

Surgery is not a curative intervention in Crohn's disease, and many patients develop recurrence. If recurrence is defined endoscopically, 70% recur within 1 year of a bowel resection and 85% by 3 years.⁴⁶ Clinical recurrence, defined as the return of symptoms confirmed as being due to Crohn's disease, affects 60% of patients by 5 years and 94% by 15 years after intestinal resection. Reoperation becomes necessary in approximately one-third of patients by 5 years after the initial operation, with a median time to reoperation of 7 to 10 years.⁴⁷ Of patient-modifying factors, smoking is a strong risk factor for disease recurrence.

INTESTINAL FISTULAS

A *fistula* is defined as an abnormal communication between two epithelialized surfaces. The communication occurs between two parts of the gastrointestinal tract or adjacent organs in an *internal fistula* (e.g., enterocolonic fistula or colovesicular

fistula). An *external fistula* (e.g., enterocutaneous fistula or rectovaginal fistula) involves the skin or another external surface epithelium. Enterocutaneous fistulas that drain less than 200 mL of fluid per day are known as *low-output fistulas*, whereas those that drain more than 500 mL of fluid per day are known as *high-output fistulas*.

Over 80% of enterocutaneous fistulas represent iatrogenic complications that occur as the result of enterotomies or intestinal anastomotic dehiscences. Fistulas that arise spontaneously without antecedent iatrogenic injury are usually manifestations of progression of underlying Crohn's disease or cancer.

Pathophysiology

The manifestations of fistulas depend on which structures are involved. Low-resistance enteroenteric fistulas, which allow luminal contents to bypass a significant proportion of the small intestine, may result in clinically-significant malabsorption. Enterovesicular fistulas often cause recurrent urinary tract infections. The drainage emanating from enterocutaneous fistulas are irritating to the skin and cause excoriation. The loss of enteric luminal contents, particularly from high-output fistulas originating from the proximal small intestine, results in dehydration, electrolyte abnormalities, and malnutrition.

Fistulas have the potential to close spontaneously. Factors inhibiting spontaneous closure, however, include malnutrition, sepsis, inflammatory bowel disease, cancer, radiation, obstruction of the intestine distal to the origin of the fistula, foreign bodies, high output, short fistulous tract (<2 cm) and epithelialization of the fistula tract (Table 28-9).

Clinical Presentation

Iatrogenic enterocutaneous fistulas usually become clinically evident between the fifth and tenth postoperative days. Fever, leukocytosis, prolonged ileus, abdominal tenderness, and wound infection are the initial signs. The diagnosis becomes obvious when drainage of enteric material through the abdominal wound or through existing drains occurs. These fistulas are often associated with intra-abdominal abscesses.

Diagnosis

CT scanning following the administration of enteral contrast is the most useful initial test. Leakage of contrast material from the intestinal lumen can be observed. Intra-abdominal abscesses

Table 28-9

Factors negatively impacting enteric fistula closure

Patient factors
Poor nutrition
Medications such as steroids
Etiological factors
Malignant fistula
Fistula related to Crohn's disease
Fistula in radiated fields
Fistula site
Gastric
Duodenal
Local Factors
Persistence of local inflammation and sepsis
Presence of a foreign body (e.g., meshes or sutures)
Epithelialization of fistula tract
Fistula tract <2 cm
Distal obstruction to the fistula site

should be sought and drained percutaneously. If the anatomy of the fistula is not clear on CT scanning, a small bowel series or enteroclysis examination can be obtained to demonstrate the fistula's site of origin in the bowel. This study is also useful to rule out the presence of intestinal obstruction distal to the site of origin. Occasionally, contrast administered into the intestine does not demonstrate the fistula tract. A *fistulogram*, in which contrast is injected under pressure through a catheter placed percutaneously into the fistula tract, may offer greater sensitivity in localizing the fistula origin.

Therapy

The treatment of enterocutaneous fistulas should proceed through an orderly sequence of steps⁴⁸:

1. **Stabilization.** Fluid and electrolyte resuscitation is begun. Nutrition is provided, usually through the parenteral route initially. Sepsis is controlled with antibiotics and drainage of abscesses. The skin is protected from the fistula effluent with ostomy appliances or fistula drains.
2. **Investigation.** The anatomy of the fistula is defined using the aforementioned studies.
3. **Decision.** The available treatment options are considered, and a time line for conservative measures is determined.
4. **Definitive Management.** This entails the surgical procedure and requires appropriate preoperative planning and surgical experience.
5. **Rehabilitation.**

The overall objectives are to increase the probability of spontaneous closure. Nutrition and time are the key components of this approach. Most patients will require TPN; however, a trial of oral or enteral nutrition should be attempted in patients with low-output fistulas originating from the distal intestine. The somatostatin analogue octreotide is a useful adjunct, particularly in patients with high-output fistulas. A meta-analysis of several randomized studies confirmed that somatostatin treatment reduced length of hospital stay and time to closure of fistulas; however, its administration did not lead to a significant difference in fistula closure rates.⁴⁹ Use of negative pressure wound therapy has increased in management of enterocutaneous fistulas. The system can allow better management of the fistula output. In a study of 91 patients with enterocutaneous fistulas, 40% of fistulae reached minimal output within a week, and with an average follow-up of 90 days, spontaneous closure rate was 46%.⁵⁰

Timing of Surgical Intervention. Most surgeons would pursue 2 to 3 months of conservative therapy before considering surgical intervention. This approach is based on evidence that 90% of fistulas that are going to close do so within 5 weeks and that surgical intervention after this period is associated with better outcomes and lower morbidity.⁵¹

If the fistula fails to resolve during this period, surgery may be required, during which the fistula tract, together with the segment of intestine from which it originates, should be resected. Simple closure of the opening in the intestine from which the fistula originates is associated with high recurrence rates. Patients with intestinal fistulas typically have extensive and dense intra-abdominal adhesions. Thus, operations performed for nonhealing fistulas can present formidable challenges. Successful applications of alternative therapies to close intestinal fistulas such as the use of biologic sealants have been reported. The indications for their use remain to be defined.

Outcomes

Over 50% of intestinal fistulas close spontaneously. A useful mnemonic designates factors that inhibit spontaneous closure of intestinal fistulas: "FRIEND" (Foreign body within the fistula tract, Radiation enteritis, Infection/Inflammation at the fistula origin, Epithelialization of the fistula tract, Neoplasm at the fistula origin, Distal obstruction of the intestine).

In a 23-year old retrospective review of 153 cases of enterocutaneous fistulas that were treated surgically, most fistulas were found to originate from the small bowel and be iatrogenic in nature, with patients having undergone five or more previous abdominal surgeries. Operative repair was associated with a 30-day mortality of approximately 4% and a 1-year mortality of 15%. Morbidity was over 80%. First attempt at surgical repair was successful in 70% of cases, with an overall closure rate of 84% and some patients requiring up to 3 attempts at surgical repair. The authors identified closure of the abdominal fascia as an important factor in reducing rates of refistulization and postoperative mortality.⁵² In another similar study, fistula recurrence rates of 30% were documented and were independently associated with high output fistulas and the type of surgical treatment: operations not involving resection of the fistula had a much higher rate of recurrence.⁵³

SMALL BOWEL NEOPLASMS

Adenomas are the most common benign neoplasm of the small intestine. Other benign tumors include fibromas, lipomas, hemangiomas, lymphangiomas, and neurofibromas. The prevalence of small bowel tumors identified at autopsy is 0.2% to 0.3%, which is significantly higher than the rate of operation for small bowel tumors. This suggests that majority of small bowel tumors are asymptomatic. These lesions are most frequently encountered in the duodenum as incidental findings during esophagogastroduodenoscopic (EGD) examinations (Fig. 28-20). The reported prevalence of

Figure 28-20. Duodenal polyp. This polyp was incidentally encountered during EGD. It was biopsied and found to be an adenoma.

duodenal polyps, as detected during EGD performed for other reasons, range from 0.3% to 4.6%.

Benign neoplasms account for 30% to 50% of small bowel tumors and include adenomas, lipomas, hematomas, and hemangiomas. Primary small bowel cancers are rare but have been increasing in incidence, with an estimated incidence of 10,190 cases in 2017 in the United States. Among small bowel cancers, adenocarcinomas comprise 35% to 50% of all cases, carcinoid tumors comprise 20% to 40%, and lymphomas comprise approximately 10% to 15%. In a retrospective review of a large U.S. database (SEER) between 1992 and 2006, of a total number of 10,945 small intestine cancers, 4315 were neuroendocrine in origin, 3412 were carcinomas, 2023 were lymphomas, and 1084 were sarcomas.⁵⁴ Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors arising in the small intestine and comprise the vast majority of tumors that were formerly classified as leiomyomas, leiomyosarcomas, and smooth muscle tumors of the intestine. The small intestine is frequently affected by metastases from or local invasion by cancers originating at other sites. Melanoma, in particular, is associated with a propensity for metastasis to the small intestine.

Most patients with small-intestinal cancers are in their fifth or sixth decade of life. Reported risk factors for developing small-intestinal cancers include consumption of red meat, ingestion of smoked or cured foods, Crohn's disease, celiac sprue, hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome.

Pathophysiology

The small intestine contains over 90% of the mucosal surface area of the gastrointestinal tract but only 1.1% to 2.4% of all gastrointestinal malignancies. Proposed explanations for the low frequency of small-intestinal neoplasms include (a) dilution of environmental carcinogens in the liquid chyme present in the small-intestinal lumen; (b) rapid transit of chyme, limiting the contact time between carcinogens and the intestinal mucosa; (c) a relatively low concentration of bacteria in small-intestinal chyme and, therefore, a relatively low concentration of carcinogenic products of bacterial metabolism; (d) mucosal protection by secretory IgA and hydrolases such as benzpyrene hydroxylase that may render carcinogens less active; and (e) efficient epithelial cellular apoptotic mechanisms that serve to eliminate clones harboring genetic mutations.

Recent advances have begun to clarify the molecular pathogenesis of small-intestinal adenocarcinomas and GISTs; there has been less progress with respect to the pathogenesis of the other small-intestinal malignancies (Table 28-10). Small-intestinal adenocarcinomas are believed to arise from

Figure 28-21. Small bowel polyp in Peutz-Jeghers syndrome. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. (Used with permission from Anne T. Wolf, M.D., Department of Medicine, Brigham and Women's Hospital, Boston, MA.)

preexisting adenomas through a sequential accumulation of genetic abnormalities in a model like that described for the pathogenesis of colorectal cancer. Adenomas are histologically classified as tubular, villous, and tubulovillous. Tubular adenomas have the least aggressive features. Villous adenomas have the most aggressive features and tend to be large, sessile, and located in the second portion of the duodenum. Malignant degeneration has been reported to be present in up to 45% of villous adenomas by the time of diagnosis. Patients with FAP have a nearly 100% cumulative lifetime risk of developing duodenal adenomas that have the potential to undergo malignant transformation. The risk of duodenal cancer in these patients is over 100-fold greater than in the general population. Indeed, duodenal cancer is the leading cause of cancer-related death among patients with FAP who have undergone colectomy. Patients with Peutz-Jeghers syndrome develop hamartomatous polyps; however, these polyps can contain adenomatous foci that can undergo malignant transformation (Fig. 28-21).

A defining feature of GISTs is their gain of function mutation of proto-oncogene KIT, a receptor tyrosine kinase.

Table 28-10

Features of small intestinal malignancies

TUMOR TYPE	CELL OF ORIGIN	FREQUENCY ^a	PREDOMINANT SITE
Adenocarcinoma	Epithelial cell	35–50%	Duodenum
Carcinoid	Enterochromaffin cell	20–40%	Ileum
Lymphoma	Lymphocyte	10–15%	Ileum
GIST	Interstitial cell of Cajal	10–15%	—

^aFrequencies given as percentages of small intestinal malignancies comprised by each of the tumor types. Gastrointestinal stromal tumors (GISTs) display no regional variation in prevalence within the small intestine.

Pathological KIT signal transduction is believed to be a central event in GIST pathogenesis. The majority of GISTs have activating mutations in the *c-kit* proto-oncogene, which cause KIT to become constitutively activated, presumably leading to persistence of cellular growth or survival signals. Because the interstitial cells of Cajal normally express KIT, these cells have been implicated as the cell of origin for GISTs. KIT expression is assessed by staining the tissues for CD117 antigen, which is part of the KIT receptor and is present in 95% of GISTs.

Clinical Presentation

Most small-intestinal neoplasms are asymptomatic until they become large. Partial small bowel obstruction, with associated symptoms of crampy abdominal pain and distention, nausea, and vomiting, is the most common mode of presentation. Obstruction can be the result of either luminal narrowing by the tumor itself or intussusception, with the tumor serving as the lead point. Hemorrhage, usually indolent, is the second most common mode of presentation.

Physical examination may be unrevealing, but it also may reveal a palpable abdominal mass in those with large tumors. Findings of intestinal obstruction may be present in some patients. A fecal occult blood test may be positive. Jaundice secondary to biliary obstruction or hepatic metastasis may be present. Cachexia, hepatomegaly, and ascites may be present with advanced disease.

Although the clinical presentation is usually not specific for tumor type, some general comments are appropriate. Adenocarcinomas, as well as adenomas (from which most are believed to arise), are most commonly found in the duodenum, except in patients with Crohn's disease, in whom most are found in the ileum. Lesions in the periampullary location can cause obstructive jaundice or pancreatitis. Adenocarcinomas located in the duodenum tend to be diagnosed earlier in their progression than those located in the jejunum or ileum, which are rarely diagnosed prior to the onset of locally advanced or metastatic disease.

Carcinoid tumors of the small intestine are also usually diagnosed after the development of metastatic disease. These tumors are associated with a more aggressive behavior than the more common appendiceal carcinoid tumors. Approximately 25% to 50% of patients with carcinoid tumor-derived liver metastases will develop manifestations of the carcinoid syndrome. These manifestations include diarrhea, flushing, hypotension, tachycardia, and fibrosis of the endocardium and valves the right heart. Candidate tumor-derived mediators of the carcinoid syndrome such as serotonin, bradykinin, and substance

P undergo nearly complete metabolism during the first passage through the liver. As a result, symptoms of carcinoid syndrome are rare in the absence of liver metastases.

Lymphoma may involve the small intestine primarily or as a manifestation of disseminated systemic disease. Primary small-intestinal lymphomas are most commonly located in the ileum, which contains the highest concentration of lymphoid tissue in the intestine. Although partial small bowel obstruction is the most common mode of presentation, 10% of patients with small-intestinal lymphoma present with bowel perforation.

The small intestine is the second most common site of GIST tumors after the stomach, containing 25% to 35% of GISTs. There appears to be no regional variation in the prevalence of GISTs within the small intestine. GISTs have a greater propensity to be associated with overt hemorrhage than the other small-intestinal malignancies (Fig. 28-22).

Metastatic tumors involving the small intestine can induce intestinal obstruction and bleeding.

Diagnosis

Because of the absent or nonspecific symptoms associated with most small-intestinal neoplasms, these lesions are rarely diagnosed preoperatively. Laboratory tests are nonspecific, except for elevated urinary 5-hydroxyindole acetic acid (5-HIAA) and serum chromogranin A (CgA) levels in patients with carcinoid syndrome, both of which have low sensitivity. Elevated carcinoembryonic antigen (CEA) levels are associated with small-intestinal adenocarcinomas, but only in the presence of liver metastases.

Contrast radiography of the small intestine may demonstrate benign and malignant lesions. Enterocolysis is reported to have a sensitivity of over 90% in the detection of small bowel tumors and is the test of choice, particularly for tumors located in the distal small bowel. Upper GI with small bowel follow-through examinations have reported sensitivities ranging from only 30% to 44% (Fig. 28-23). CT scanning can detect abnormalities in 70% to 80% of cases with small bowel tumor and assess for metastatic spread. Tumors associated with significant bleeding can be localized with angiography or radioisotope-tagged red blood cell (RBC) scans.

Tumors located in the duodenum can be visualized and biopsied on EGD. In addition, endoscopic ultrasonography (EUS) can offer additional information such as the layers of the intestinal wall involved by the lesion. Occasionally, the distal ileum can successfully be visualized during colonoscopy. Intraoperative enteroscopy can be used to directly visualize small-intestinal tumors beyond the reach of standard endoscopic techniques. For more distal small bowel lesions, capsule endoscopy and double-balloon

Figure 28-22. Jejunal gastrointestinal stromal tumor (GIST). This patient presented with overt obscure GI bleeding and was found to have a 7-cm jejunal GIST. The picture represents the laparoscopic view of the mass (*black arrow*), arising from the antimesenteric side of the small bowel (***). He underwent a successful laparoscopic resection.

Figure 28-23. Small bowel lesion identified during a small bowel follow-through (*arrow*). This patient had previously had a metastatic renal lesion to his duodenum requiring a Whipple procedure. During follow-up imaging 3 years later, he was found to have this new lesion in his jejunum. He underwent a laparoscopic small bowel resection. Pathology revealed a benign jejunal sessile polyp.

endoscopy have been used to evaluate small bowel. CT and MR enterography are also increasing utilized as noninvasive tests to look for small bowel masses. PET scans can also help assess metabolic activity of lesions and risk of malignancy.

Therapy

Benign neoplasms of the small intestine that are symptomatic should be surgically resected or removed endoscopically, if feasible. Tumors located in the duodenum, including asymptomatic lesions incidentally found during EGD, can pose the greatest therapeutic challenges. These lesions should be biopsied; symptomatic tumors and adenomas, because of their malignant potential, should be removed. In general, duodenal tumors less than 1 cm in diameter are amenable to endoscopic polypectomy. Lesions greater than 2 cm in diameter are technically difficult to remove endoscopically and may need to be removed surgically. Surgical options include transduodenal polypectomy and segmental duodenal resection. Tumors located in the second portion of the duodenum near the ampulla of Vater may require pancreaticoduodenectomy. EUS may offer utility for duodenal tumors ranging in size between 1 and 2 cm in diameter, with those limited to the mucosa being amenable to endoscopic polypectomy. Endoscopic resection of biopsy-proven benign duodenal periampullary adenomas leads to equivalent efficacy to surgery but with lower morbidity. Adenomas can recur; therefore, surveillance endoscopy is required after these procedures.⁵⁵

Duodenal adenomas occurring in the setting of FAP require an especially aggressive approach to management. Patients with FAP should undergo screening EGD starting sometime during their second or third decade of life. Adenomas detected should

be removed endoscopically, if possible, followed by surveillance endoscopy in 6 months and yearly thereafter, in the absence of recurrence. If surgery is required, pancreaticoduodenectomy is generally necessary because adenomas in patients with FAP tend to be multiple and sessile, with a predilection for the periampullary region. Further, localized resections are complicated by high recurrence rates. Given the potential for recurrences in the duodenal remnant following pylorus-preserving pancreaticoduodenectomy, there is rationale for recommending the application of standard pancreaticoduodenectomy in these patients. However, recurrences have been reported even following this procedure; therefore, continuing surveillance is necessary. For most adenocarcinomas of the duodenum, except those in the third or fourth portion of the duodenum where a local resection could be considered, pancreaticoduodenectomy is required.

The surgical therapy of jejunal and ileal malignancies usually consists of wide-local resection of the intestine harboring the lesion. For adenocarcinomas, a wide excision of corresponding mesentery is done to achieve regional lymphadenectomy, as is done for adenocarcinomas of the colon. In the presence of locally-advanced or metastatic disease, palliative intestinal resection or bypass is performed. Chemotherapy has no proven efficacy in the adjuvant or palliative treatment of small-intestinal adenocarcinomas.

The goal of surgical therapy for carcinoids is resection of all visible disease. Localized small-intestinal carcinoid tumors should be treated with segmental intestinal resection and regional lymphadenectomy. Nodal metastases are unusual with tumors less than 1 cm in diameter, but they are present with 75% to 90% of tumors larger than 3 cm in diameter. In approximately 30% of cases, multiple small-intestinal carcinoid tumors are present (Fig. 28-24). Therefore, the entire small intestine should

Figure 28-24. Small bowel carcinoid tumor. This patient presented with history of abdominal pain and on CT was found to have a circumferentially thickened loop of distal small bowel with associated mesenteric stranding and lymphadenopathy. An octreotide scan demonstrated abnormal activity in the area, concerning for a carcinoid tumor. He underwent an open small bowel resection. Pathology revealed a multifocal carcinoid tumor with 50 distinct nodules and metastasis to mesenteric lymph nodes.

be examined before planning extent of resection. In the presence of metastatic disease, tumor debulking should be conducted as it can be associated with long-term survival and amelioration of symptoms of the carcinoid syndrome. Response rates of 30% to 50% have been reported to chemotherapy regimens based on agents such as doxorubicin, 5-fluorouracil, and streptozocin. However, none of these regimens is associated with a clearly demonstrable impact on the natural history of disease. Octreotide is the most effective pharmacologic agent for management of symptoms of carcinoid syndrome.

Localized small-intestinal lymphoma should be treated with segmental resection of the involved intestine and adjacent mesentery. If the small intestine is diffusely affected by lymphoma, chemotherapy rather than surgical resection should be the primary therapy. The value to adjuvant chemotherapy after resection of localized lymphoma is controversial.

Small-intestinal GISTs should be treated with segmental intestinal resection. If the diagnosis is known prior to resection, wide lymphadenectomy can be avoided as GISTs are rarely associated with lymph node metastases. GISTs are resistant to conventional chemotherapy agents. Imatinib (Gleevec) is a tyrosine kinase inhibitor with potent activity against tyrosine kinase KIT, and it is used in those with metastatic disease. Clinical trials have shown that 80% of patients with unresectable or metastatic GISTs derive clinical benefit from the administration of Imatinib, with 50% to 60% having objective evidence of reduction in tumor volume.⁵⁶ Imatinib has shown great promise as a neoadjuvant and adjuvant therapy for GISTs. Studies have emphasized the potential for development of tumor resistance to this agent. In this setting, an alternative tyrosine kinase inhibitor, sunitinib, has been used with good results.

Metastatic cancers affecting the small intestine that are symptomatic should be treated with palliative resection or bypass except in the most advanced cases. Systemic therapy may be offered if effective chemotherapy exists for the primary cancer.

Outcomes

Complete resection of duodenal adenocarcinomas is associated with postoperative 5-year survival rates ranging from 50% to 60%. Complete resection of adenocarcinomas located in the jejunum or ileum is associated with 5-year survival rates of 20% to 30%.⁵⁷ Five-year survival rates of 75% to 95% following resection of localized small-intestinal carcinoid tumors have been reported. In the presence of carcinoid tumor-derived liver metastases, 5-year survival rates of 19% to 54% have been reported. The overall 5-year survival rate for patients diagnosed with intestinal lymphoma ranges from 20% to 40%. For patients with localized lymphoma amenable to surgical resection, the 5-year survival rate is 60%.

The recurrence rate following resection of GISTs averages 35%. The 5-year survival rate following surgical resection has been reported to range from 35% to 60%. Both tumor size and mitotic index are independently correlated with prognosis. Low-grade tumors (mitotic index <10 per high-power field) measuring less than 5 cm in diameter are associated with excellent prognosis.

RADIATION ENTERITIS

Radiation therapy is a component of multi-modality therapy for many intra-abdominal and pelvic cancers such as those of the cervix, endometrium, ovary, bladder, prostate, and rectum. An

undesired side effect of radiation therapy is radiation-induced injury to the small intestine, which can present clinically as two distinct syndromes: acute and chronic radiation enteritis. Acute radiation enteritis is a transient condition that occurs in approximately 75% of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation enteritis is inexorable and develops in approximately 5% to 15% of these patients.

Pathophysiology

Radiation induces cellular injury directly and through the generation of free radicals. The principal mechanism of radiation-induced cell death is believed to be apoptosis resulting from free-radical-induced breaks in double-stranded DNA. Because radiation has its greatest impact on rapidly proliferating cells, the small-intestinal epithelium is acutely susceptible to radiation-induced injury. Pathological correlates of this acute injury include villus blunting and a dense infiltrate of leukocytes and plasma cells within the crypts. With severe cases, mucosal sloughing, ulceration, and hemorrhage are observed. The intensity of injury is related to the dose of radiation administered, with most cases occurring in patients who have received *at least* 4500 cGy. Risk factors for acute radiation enteritis include conditions that may limit splanchnic perfusion such as hypertension, diabetes mellitus, coronary artery disease, and restricted mobility of the small intestine due to adhesions. Injury is potentiated by concomitant administration of chemotherapeutic agents, such as doxorubicin, 5-fluorouracil, actinomycin D, and methotrexate, that act as radiation-sensitizers. Because of the intestinal epithelium's capacity for regeneration, the mucosal injury that is characteristic of acute radiation enteritis resolves after the cessation of radiation therapy.

In contrast, chronic radiation enteritis is characterized by a progressive occlusive vasculitis that leads to chronic ischemia and fibrosis that affects all layers of the intestinal wall, rather than the mucosa alone. These changes can lead to strictures, abscesses, and fistulas, which are responsible for the clinical manifestations of chronic radiation enteritis.

Clinical Presentation

The most common manifestations of acute radiation enteritis are nausea, vomiting, diarrhea, and crampy abdominal pain. Symptoms are generally transient and subside after the discontinuation of radiation therapy. Because the diagnosis is usually obvious, given the clinical context, no specific diagnostic tests are required. However, if patients develop signs suggestive of peritonitis, CT scanning should be performed to rule out the presence of other conditions capable of causing acute abdominal syndromes.

The clinical manifestations of chronic radiation enteritis usually become evident within 2 years of radiation administration, although they can begin as early as several months or as late as decades afterwards. The most common clinical presentations are diarrhea or one of partial small bowel obstruction with nausea, vomiting, intermittent abdominal distention, crampy abdominal pain, and weight loss. The terminal ileum is the most frequently affected segment. Other manifestations of chronic radiation enteritis include complete bowel obstruction, acute or chronic intestinal hemorrhage, and abscess or fistula formation.

Diagnosis

Evaluation of patients suspected of having chronic radiation enteritis should include review of the records of their

Figure 28-25. Radiation enteritis. This contrast radiograph reveals widely separated loops of small bowel with luminal narrowing, loss of mucosal folds, and ulceration. This patient had received radiation therapy for a pelvic malignancy 8 years before this examination.

radiation treatments for information on total radiation dose administered, fractionation, and volume of treatment. Areas that received high doses should be noted, as lesions subsequently found in imaging studies usually localize to areas that had received high radiation doses. Enterocolysis is the most accurate imaging test for diagnosing chronic radiation enteritis, with reported sensitivities and specificities of over 90% (Fig. 28-25). CT scan findings are neither very sensitive nor specific for chronic radiation enteritis. However, CT scanning should be obtained to rule out the presence of recurrent cancer since its clinical manifestations may overlap with those of chronic radiation enteritis.

Therapy

Most cases of acute radiation enteritis are self-limited. Supportive therapy, including the administration of antiemetics, is usually sufficient. Patients with diarrhea-induced dehydration may require hospital admission and parenteral fluid administration. Rarely are symptoms severe enough to necessitate reduction in or cessation of radiation therapy.

In contrast, the treatment of chronic radiation enteritis represents a formidable challenge. Antidiarrheal agents may have a role in the management of diarrhea while, in those with obstructive symptoms, a low residue diet may be tried. Surgery for this condition is difficult, is associated with high morbidity rates, and should be avoided in the absence of specific indications such as high-grade obstruction, perforation, hemorrhage, intra-abdominal abscesses, and fistulas. The goal of surgery is limited resection of diseased intestine with primary anastomosis

between healthy bowel segments. However, the characteristically diffuse nature of fibrosis and dense adhesions among bowel segments can make limited resection difficult to achieve. Further, it is difficult to distinguish between normal and irradiated intestine intraoperatively by either gross inspection or even frozen section analysis. This distinction is important as anastomoses between irradiated segments of intestine have been associated with leak rates as high as 50%.⁵⁸ If limited resection is not achievable, an intestinal bypass procedure may be an option, except in cases for which hemorrhage is the surgical indication. There remain cases in which resections extensive enough to cause short bowel syndrome are unavoidable. This condition is discussed in detail below in the “Short Bowel Syndrome” section.

Outcomes

Acute radiation injury to the intestine is self-limited; its severity is not correlated with the probability of chronic radiation enteritis developing. Surgery for chronic radiation enteritis is associated with high morbidity rates and reported mortality rates averaging 10%.

Prevention

In view of significant morbidity associated with radiation enteritis, groups have studied possible measures to reduce or prevent such side effects. Keeping radiation exposure to below 5000 cGy is associated with minimal long-term side effects and is recommended where clinically possible.

Uses of multibeam radiation techniques to minimize the area of maximal radiation exposure, as well as tilt tables to move the bowel out of the pelvic during radiation, are increasingly utilized. Few small studies have suggested that oral sulphasalazine may help reduce the incidence of acute radiation-induced enteritis.⁵⁹

In patients undergoing pelvic surgery that are likely to require postoperative radiation therapy, surgical techniques that keep the small bowel out of the pelvic have been recommended. These measures include use of absorbable mesh sling to separate the pelvic from the true abdominal cavity and prevent the small bowel from being exposed to pelvic radiation.⁶⁰

MECKEL'S DIVERTICULA

Meckel's diverticulum is the most prevalent congenital anomaly of the gastrointestinal tract, affecting approximately 2% of the general population. Meckel's diverticuli are designated *true diverticuli* because their walls contain all the layers found in normal small intestine. Their location varies among individual patients, but they are usually found in the ileum within 100 cm of the ileocecal valve (Fig. 28-26). Approximately 60% of Meckel's diverticuli contain heterotopic mucosa, of which over 60% consist of gastric mucosa. Pancreatic acini are the next most common; others include Brunner's glands, pancreatic islets, colonic mucosa, endometriosis, and hepatobiliary tissues. A useful, although crude, mnemonic describing Meckel's diverticuli is the “rule of twos”: 2% prevalence, 2:1 male predominance, location 2 feet proximal to the ileocecal valve in adults, and half of those who are symptomatic are under 2 years of age.

Pathophysiology

During the eighth week of gestation, the omphalomesenteric (vitelline) duct normally undergoes obliteration. Failure or

Figure 28-26. Meckel's diverticulum. This intraoperative photograph shows Meckel's diverticulum in ileum that has been eviscerated.

incomplete vitelline duct obliteration results in a spectrum of abnormalities, the most common of which is Meckel's diverticulum. Other abnormalities include omphalomesenteric fistula, enterocyst, and a fibrous band connecting the intestine to the umbilicus. A remnant of the left vitelline artery can persist to form a mesodiverticular band tethering a Meckel's diverticulum to the ileal mesentery.

Bleeding associated with Meckel's diverticulum is usually the result of ileal mucosal ulceration that occurs adjacent to acid-producing, heterotopic gastric mucosa located within the diverticulum. Intestinal obstruction associated with Meckel's diverticulum can result from several mechanisms:

1. Volvulus of the intestine around the fibrous band attaching the diverticulum to the umbilicus
2. Entrapment of intestine by a mesodiverticular band (Fig. 28-27)
3. Intussusception with the diverticulum acting as a lead point
4. Stricture secondary to chronic diverticulitis

Meckel's diverticuli can be found in inguinal or femoral hernia sacs (known as Littre's hernia). These hernias, when incarcerated, can cause intestinal obstruction.

Figure 28-27. Meckel's diverticulum with mesodiverticular band (A). One mechanism by which Meckel's diverticuli can cause small bowel obstruction is entrapment of the intestine by a mesodiverticular band (B).

Clinical Presentation

Meckel's diverticuli are asymptomatic unless associated complications arise. The lifetime incidence rate of complications arising in patients with Meckel's diverticuli has been estimated to be approximately 4% to 6%.^{61,62} Although initial data had suggested that the risk of developing a complication related to Meckel's diverticulum decreases with age, this has been questioned. In a population-based reviews at Olmsted County, Cullen and colleagues suggested that the risk of developing Meckel's diverticulum-related complications does not change with age.⁶²

The most common presentations associated with symptomatic Meckel's diverticuli are bleeding, intestinal obstruction, and diverticulitis. Bleeding is the most common presentation in children with Meckel's diverticuli, representing over 50% of Meckel's diverticulum-related complications among patients less than 18 years of age. Bleeding associated with Meckel's diverticuli is rare among patients older than 30 years of age.

Intestinal obstruction is the most common presentation in adults with Meckel's diverticuli. Diverticulitis, present in 20% of patients with symptomatic Meckel's diverticuli, is associated with a clinical syndrome that is indistinguishable from acute appendicitis. Neoplasms, most commonly carcinoid tumors, are present in 0.5% to 3.2% of symptomatic Meckel's diverticuli that are resected.

Diagnosis

Most Meckel's diverticuli are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. In the absence of bleeding, Meckel's diverticuli rarely are diagnosed prior to the time of surgical intervention. For those presenting with symptoms suggestive of a Meckel's diverticulum, confirmatory imaging can be challenging. The sensitivity of CT scanning for the detection of Meckel's diverticuli is too low to be clinically useful. Enterocolysis is associated with an accuracy of 75% but is usually not applicable during acute presentations of complications related to Meckel's diverticuli. Radionuclide scans (^{99m}Tc–pertechnetate) can be helpful in the diagnosis of Meckel's diverticulum; this test is, however, positive only when the diverticulum contains associated ectopic gastric mucosa that is capable of uptake of the tracer (Fig. 28-28). The accuracy of radionuclide scanning is reported to be 90% in pediatric patients but less than 50% in adults. Angiography can localize the site of bleeding during acute hemorrhage related to Meckel's diverticuli.

Figure 28-28. Meckel's diverticulum with ectopic gastric tissue. The diagnosis was made in this patient using ^{99m}Tc -pertechnetate scintigraphy. The study revealed an abnormal focus of radiotracer accumulation in the right lower quadrant (*arrow*).

Therapy

The surgical treatment of symptomatic Meckel's diverticuli should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor or if the base of the diverticulum is inflamed or perforated.

The management of incidentally found (asymptomatic) Meckel's diverticuli is controversial. Until recently, most authors recommended against prophylactic removal of asymptomatic Meckel's diverticuli, given the low lifetime incidence of complications. Supporting this approach, a meta-analysis has shown that 758 prophylactic diverticulectomies needed to be performed to prevent one Meckel's-related death.⁶³ Others have had greater enthusiasm for prophylactic diverticulectomy has appeared in the literature.⁶⁴ Proponents of this approach cite the minimal morbidity associated with removing Meckel's diverticuli and the possibility that previous estimates of the lifetime incidence of complications related to Meckel's diverticuli may be erroneously low. Many have advocated a selective approach, with a recommendation to remove diverticuli in patients younger than 50 years of age, or those with band attachments, those with ectopic tissue,

or those >2 cm in length on the assumption that these diverticuli are more likely to develop complications. No controlled data supporting or refuting these recommendations exist.

ACQUIRED DIVERTICULA

Acquired diverticuli are designated *false diverticuli* because their walls consist of mucosa and submucosa but lack a complete muscularis. Acquired diverticuli are more common in the duodenum, and tend to be located near the ampulla; such diverticuli are known as *periampullary*, *juxtapapillary*, and *perivaterian diverticuli*. Approximately 75% of juxtapapillary diverticuli arise on the medial wall of the duodenum. Acquired diverticuli in the jejunum or ileum are known as *jejunoileal diverticuli*. Eighty percent of jejunoileal diverticuli are localized to the jejunum, 15% to the ileum, and 5% to both jejunum and ileum. Diverticuli in the jejunum tend to be large and accompanied by multiple other diverticuli, whereas those in the ileum tend to be small and solitary.

The prevalence of duodenal diverticuli, as detected on upper GI examinations (Fig. 28-29), has been reported to range from 0.16% to 6%.⁶⁵ Their prevalence, as detected during ERCP examinations, has been reported to range from 5% to 27%. A 23% prevalence rate has been reported in an autopsy series. The prevalence of duodenal diverticuli increases with age; they are

Figure 28-29. Duodenal diverticulum. This contrast radiograph demonstrates a duodenal diverticulum (*arrows*) that extends medially into the substance of the head of the pancreas.

rare in patients under the age of 40 years. The mean age of diagnosis ranges from 56 to 76 years.

The prevalence of jejunoileal diverticuli (Fig. 28-30) has been estimated to range from 1% to 5%.⁶⁶ Their prevalence increases with age; most patients diagnosed with these diverticuli are in the sixth and seventh decades of life.

Pathophysiology

The pathogenesis of acquired diverticuli is hypothesized to be related to acquired abnormalities of intestinal smooth muscle

or dysregulated motility, leading to herniation of mucosa and submucosa through weakened areas of muscularis.

Acquired diverticuli can be associated with bacterial overgrowth, leading to vitamin B₁₂ deficiency, megaloblastic anemia, malabsorption, and steatorrhea. Periapillary duodenal diverticuli have been described to become distended with intraluminal debris and to compress the common bile duct or pancreatic duct, thus causing obstructive jaundice or pancreatitis, respectively. Jejunoileal diverticuli can also cause intestinal obstruction through intussusception or compression of adjacent bowel.

Figure 28-30. Jejunoileal diverticuli. This picture demonstrates incidental jejunal diverticuli identified during a laparoscopic cholecystectomy. The diverticuli are typically located on the mesenteric aspect of the jejunum. Resection was not indicated as the diverticuli were asymptomatic.

Clinical Presentation

Acquired diverticuli are asymptomatic unless associated complications arise. Such complications are estimated to occur in 6% to 10% of patients with acquired diverticuli and include intestinal obstruction, diverticulitis, hemorrhage, perforation, and malabsorption. Periapillary duodenal diverticuli may be associated with choledocholithiasis, cholangitis, recurrent pancreatitis, and sphincter of Oddi dysfunction. However, a clear link between the presence of the diverticuli and the development of these conditions has not been demonstrated. Symptoms such as intermittent abdominal pain, flatulence, diarrhea, and constipation are reported to be present in 10% to 30% of patients with jejunoileal diverticuli. The relationship between these symptoms and the presence of the diverticuli is similarly unclear.

Diagnosis

Most acquired diverticuli are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. On ultrasound and CT scanning, duodenal diverticuli may be mistaken for pancreatic pseudocysts and fluid collections, biliary cysts, and periapillary neoplasms. These lesions can be missed on endoscopy, particularly with forward-viewing endoscopes, and are best diagnosed on upper gastrointestinal radiographs. Enterocolysis is the most sensitive test for detecting jejunoileal diverticuli.

Therapy

Asymptomatic-acquired diverticuli should be left alone. Bacterial overgrowth associated with acquired diverticuli is treated with antibiotics. Other complications, such as bleeding and diverticulitis, are treated with segmental intestinal resection for diverticuli located in the jejunum or ileum.

Bleeding and obstruction related to lateral duodenal diverticuli are generally treated with diverticulectomy alone. Treatment of such complications in medial duodenal diverticuli that penetrate the substance of the pancreas can be very challenging. Complications related to these medial duodenal diverticuli should be managed nonoperatively if possible, using endoscopy. In emergent situations, bleeding related to medial duodenal diverticuli can be controlled using a lateral duodenotomy and oversewing of the bleeding vessel. Similarly, perforation can be managed with wide drainage rather than complex surgery. Whether diverticulectomy should be done in patients with biliary or pancreatic symptoms is controversial and is not routinely recommended.

MESENTERIC ISCHEMIA

Mesenteric ischemia can present as one of two distinct clinical syndromes: acute mesenteric ischemia and chronic mesenteric ischemia.

Four distinct pathophysiologic mechanisms can lead to *acute mesenteric ischemia*:

1. Arterial embolus
2. Arterial thrombosis
3. Vasospasm (also known as nonocclusive mesenteric ischemia or NOMI)
4. Venous thrombosis

Embolus is the most common cause of acute mesenteric ischemia and is responsible for over 50% of cases. The embolic source is usually in the heart, most often the left atrial or ventricular thrombi or valvular lesions. Indeed, up to 95% of patients with acute mesenteric ischemia due to emboli will

have a documented history of cardiac disease. Embolism to the superior mesenteric artery accounts for 50% of cases; most of these emboli become wedged and cause occlusion at branch points in the mid- to distal superior mesenteric artery, usually distal to the origin of the middle colic artery. In contrast, acute occlusions due to thrombosis tend to occur in the proximal mesenteric arteries, near their origins. Acute thrombosis is usually superimposed on preexisting atherosclerotic lesions at these sites. NOMI is the result of vasospasm and is usually diagnosed in critically ill patients receiving vasopressor agents.

Mesenteric venous thrombosis accounts for 5% to 15% of cases of acute mesenteric ischemia and involves the superior mesenteric vein in 95% of cases.⁶⁷ The inferior mesenteric vein is only rarely involved. Mesenteric venous thrombosis is classified as primary if no etiologic factor is identifiable, or as secondary if an etiologic factor, such as heritable or acquired coagulation disorders, is identified.

Regardless of the pathophysiologic mechanism, acute mesenteric ischemia can lead to intestinal mucosal sloughing within 3 hours of onset and full-thickness intestinal infarction by 6 hours.

In contrast, *chronic mesenteric ischemia* develops insidiously, allowing for development of collateral circulation, and, therefore, rarely leads to intestinal infarction. Chronic mesenteric arterial ischemia results from atherosclerotic lesions in the main splanchnic arteries (celiac, superior mesenteric, and inferior mesenteric arteries). In most patients with symptoms attributable to chronic mesenteric ischemia, at least two of these arteries are either occluded or severely stenosed. A chronic form of mesenteric venous thrombosis can involve the portal or splenic veins and may lead to portal hypertension, with resulting esophagogastric varices, splenomegaly, and hypersplenism.

Severe abdominal pain, out of proportion to the degree of tenderness on examination is the hallmark of acute mesenteric ischemia, regardless of the pathophysiologic mechanism. The pain is typically perceived to be colicky and most severe in the mid-abdomen. Associated symptoms can include nausea, vomiting, and diarrhea. Physical findings are characteristically absent early in the course of ischemia. With the onset of bowel infarction, abdominal distension, peritonitis, and passage of bloody stools occur.

Chronic mesenteric ischemia presents insidiously. Postprandial abdominal pain is the most prevalent symptom, producing a characteristic aversion to food (“food fear”) and weight loss. These patients are often thought to have a malignancy and suffer a prolonged period of symptoms before the correct diagnosis is made.

Most patients with chronic mesenteric venous thrombosis are asymptomatic because of the presence of extensive collateral venous drainage routes; this condition is usually discovered as an incidental finding on imaging studies. However, some patients with chronic mesenteric venous thrombosis present with bleeding from esophagogastric varices.

The diagnosis and management of these disorders, which are of primary vascular origin, are discussed in the section on “Mesenteric Artery Occlusive Disease” in Chapter 23 “Arterial Disease.”

MISCELLANEOUS CONDITIONS

Obscure GI Bleeding

Up to 90% of lesions responsible for GI bleeding are within the reach of EGD and colonoscopy. *Obscure GI bleeding* refers to gastrointestinal bleeding for which no source has been identified by routine endoscopic studies (EGD and colonoscopy). *Overt*

GI bleeding refers to the presence of hematemesis, melena, or hematochezia. In contrast, *occult GI bleeding* occurs in the absence of overt bleeding and is identified on laboratory tests (e.g., iron-deficiency anemia) or examination of the stool (e.g., positive guaiac test). Obscure GI bleeding is occult in 20% of cases.⁶⁸

Obscure bleeding can be frustrating for both the patient and the clinician, and this is particularly true for obscure-overt bleeding, which cannot be localized despite aggressive diagnostic measures. Most of the small bowel is beyond the reach of these examinations and, hence, contains most lesions responsible for obscure GI bleeding. Small intestinal angiodysplasias account for approximately 75% of cases in adults, and neoplasms account for approximately 10%. Meckel's diverticulum is the most common etiology of obscure GI bleeding in children. Other etiologies of obscure GI bleeding include Crohn's disease, infectious enteritides, nonsteroidal anti-inflammatory drug (NSAID)-induced ulcers and erosions, vasculitis, ischemia, varices, diverticuli, and intussusception.

The diagnostic evaluation of patients with obscure GI bleeding should be tailored to the severity of bleeding and to the availability of technology and expertise. Enteroscopy is playing an increasingly important role. Several endoscopic techniques for visualizing the small intestine are available: push enteroscopy, sonde enteroscopy, intraoperative enteroscopy, double balloon enteroscopy, and wireless capsule enteroscopy.

Push enteroscopy entails advancing a long endoscope (such as a pediatric or adult colonoscope or a specialized instrument) beyond the ligament of Treitz into the proximal jejunum. This procedure can allow for visualization of approximately 60 cm of the proximal jejunum. Diagnostic yield in patients with obscure GI bleeding ranges from 3% to 65%. In addition to diagnosis, push enteroscopy allows for cauterization of bleeding sites.

In Sonde enteroscopy, a long, thin fiberoptic instrument is propelled through the intestine by peristalsis following inflation of a balloon at the instrument's tip. Visualization is done during instrument withdrawal; approximately 50% to 75% of the small intestinal mucosa can be examined. However, this instrument lacks biopsy or therapeutic capability. Further, it lacks tip deflection capability, limiting complete mucosal visualization, and has therefore been abandoned in favor of capsule endoscopy.

Wireless capsule endoscopy is an excellent tool in the patient who is hemodynamically stable but continues to bleed. This technique has reported success rates as high as 90% in identifying a small bowel pathology. In a randomized study of patients with obscure GI bleeding, evaluation with capsule endoscopy vs. small bowel contrast study had a much higher diagnostic yield (30% vs. 7%, respectively); however, this did not translate into an improvement in outcomes. The rates of rebleeding, hospitalization, need for blood transfusion, and therapeutic interventions were similar between the two arms.

The inability to perform biopsies or carry out any therapeutic interventions of capsule endoscope likely prevents the improved diagnostic yield of the test from translating into improved patient outcomes and highlights the continuing challenge with evaluation of the small bowel.⁶⁹

For patients in whom bleeding from an obscure GI source has apparently stopped, push enteroscopy or capsule endoscopy is a reasonable initial study. If these examinations do not reveal a potential source of bleeding, then enterocolysis should be performed. Standard small bowel follow-through

examinations are associated with a low diagnostic yield in this setting and should be avoided. ^{99m}Tc–pertechnetate scintigraphy to diagnose Meckel's diverticulum should be considered, although its yield in patients older than 40 years of age is extremely low. If still no diagnosis has been made, a “watch-and-wait” approach is reasonable, although angiography should be considered if the episode of bleeding was overt. Angiography can reveal angiodysplasia and vascular tumors in the small intestine even in the absence of ongoing bleeding. In many instances, however, angiography is done in patients with persistent bleeding from an obscure GI source, and it is also often performed after a ^{99m}Tc-labeled RBC scan, which, if positive, is followed by angiography to localize the source of bleeding. Patients who remain undiagnosed but continue to bleed and those with recurrent episodic bleeding significant enough to require blood transfusions should then undergo exploratory laparoscopy or laparotomy with intraoperative enteroscopy. An endoscope (usually a colonoscope) is inserted into the small bowel through peroral intubation or through an enterotomy made in the small bowel or cecum. The endoscope is advanced by successively telescoping short segments of intestine onto the end to the instrument. In addition to the endoscopic image, the transilluminated bowel should be examined externally with the operating room lights dimmed, as this maneuver may facilitate the identification of angiodysplasias. Identified lesions should be marked with a suture placed on the serosal surface of the bowel; these lesions can be resected after completion of endoscopy. Examination should be performed during instrument insertion rather than withdrawal because instrument-induced mucosal trauma can be confused with angiodysplasias.

Figure 28-31 provides a diagnostic and management algorithm for patients with obscure GI bleeding.

Small Bowel Perforation

Prior to the 1980s, duodenal perforation due to peptic ulcer disease was the most common form of small bowel perforation. Today, iatrogenic injury incurred during gastrointestinal endoscopy is the most common cause of small bowel perforation. Other etiologies of small bowel perforation include infections (especially tuberculosis, typhoid, and CMV), Crohn's disease, ischemia, drugs (e.g., potassium- and NSAID-induced ulcers), radiation-induced injury, Meckel's and acquired diverticuli, neoplasms (especially lymphoma, adenocarcinoma, and melanoma), and foreign bodies.

Among iatrogenic injuries, duodenal perforation during endoscopic retrograde cholangiography (ERCP) with endoscopic sphincterotomy (ES) is the most common. With improved technique and technology, the incidence of this is decreasing but remains at around 0.5%.⁷⁰ The Stapfer classification is commonly used to categorize different types of ERCP-related perforations. These are:

- Type I: Free bowel wall perforation
- Type II: Retroperitoneal duodenal perforation secondary to periampullary injury
- Type III: Perforation of the pancreatic or bile duct
- Type IV: Retroperitoneal air alone

Type II (retroperitoneal duodenal injuries) are the most common and can often be managed nonsurgically. Manifestations of such contained duodenal perforation following ERCP can resemble those of ERCP-induced pancreatitis, including hyperamylasemia.

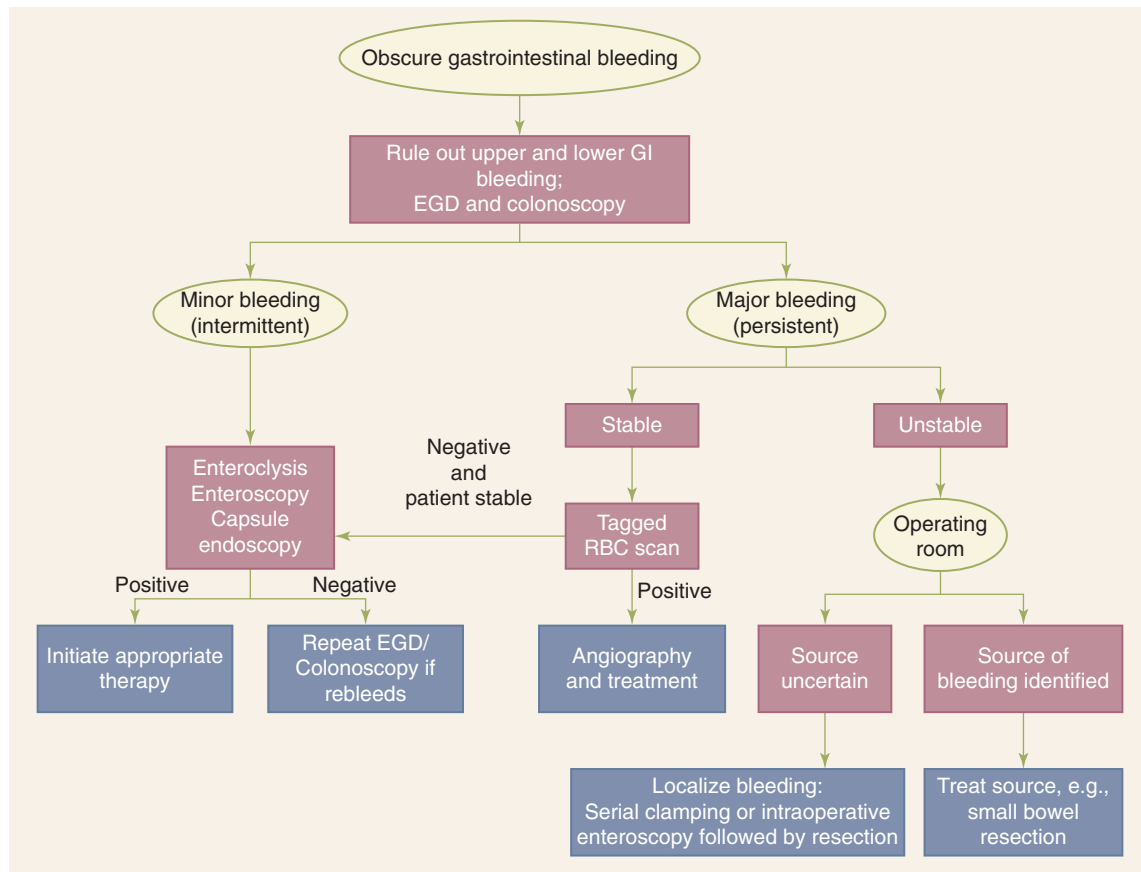

Figure 28-31. Diagnostic and management algorithm for obscure gastrointestinal bleeding.

CT scanning is the most sensitive test for diagnosing duodenal perforations; positive findings include pneumoperitoneum for free perforations, but more commonly retroperitoneal air, contrast extravasation, and paraduodenal fluid collections. If all patients undergoing a therapeutic ERCP are imaged with a CT scan following the procedure, up to 30% will have evidence of air in the retroperitoneum, but the majority are asymptomatic. These patients do not require any specific therapy.⁷¹

True cases of retroperitoneal perforations of the duodenum can be managed nonoperatively in the absence of progression and sepsis. However, intraoperative duodenal perforations require surgical repair with pyloric exclusion and gastrojejunostomy or tube duodenostomy. Iatrogenic small bowel perforation incurred during endoscopy, if immediately recognized, can sometimes be repaired using endoscopic techniques.

Perforation of the jejunum and ileum occurs into the peritoneal cavity and usually causes overt symptoms and signs, such as abdominal pain, tenderness, and distention accompanied by fever and tachycardia. Plain abdominal radiographs may reveal free intraperitoneal air if intraperitoneal perforation has occurred. If perforation is suspected but not clinically obvious, CT scanning should be performed. Jejunal and ileal perforations require surgical repair or segmental resection.

Chylous Ascites

Chylous ascites refers to the accumulation of triglyceride-rich peritoneal fluid with a milky or creamy appearance, caused by the presence of intestinal lymph in the peritoneal cavity. Chylomicrons, produced by the intestine and secreted into lymph

during the absorption of long-chain fatty acids, account for the characteristic appearance and triglyceride content of chyle.

The most common etiologies of chylous ascites in Western countries are abdominal malignancies and cirrhosis. In Eastern and developing countries, infectious etiologies, such as tuberculosis and filariasis, account for most cases. Chylous ascites can also develop as a complication of abdominal and thoracic operations and trauma. Operations particularly associated with this complication include abdominal aortic aneurysm repair, retroperitoneal lymph node dissection, inferior vena cava resection, and liver transplantation. Other etiologies of chylous ascites include congenital lymphatic abnormalities (e.g., primary lymphatic hypoplasia), radiation, pancreatitis, and right-sided heart failure.

Three mechanisms have been postulated to cause chylous ascites: (a) exudation of chyle from dilated lymphatics on the wall of the bowel and in the mesentery caused by obstruction of lymphatic vessels at the base of the mesentery or the cisterna chyli (e.g., by malignancies), (b) direct leakage of chyle through a lymphoperitoneal fistula (e.g., those that develop as a result of trauma or surgery), and (c) exudation of chyle through the wall of dilated retroperitoneal lymphatic vessels (e.g., in congenital lymphangiectasia or thoracic duct obstruction).

Patients with chylous ascites develop abdominal distention over a period of weeks to months. Postoperative chylous ascites can present acutely during the first postoperative week. Delayed presentations following surgery can occur if the mechanism of ascites formation is adhesion-induced lymphatic obstruction rather than lymphatic vessel disruption.

Paracentesis is the most important diagnostic test. Chyle typically has a cloudy and turbid appearance; however, it may be clear in fasting patients (such as those in the immediate postoperative period). Fluid triglyceride concentrations above 110 mg/dL are diagnostic. CT scanning may be useful in identifying pathological intraabdominal lymph nodes and masses and in identifying extent and localization of fluid. Lymphangiography and lymphoscintigraphy may help localize lymph leaks and obstruction; this information is particularly useful for surgical planning.

There is little data on optimal management of patients with chylous ascites. The general approach is to focus on evaluating and treating the underlying causes, especially for patients with infectious, inflammatory, or hemodynamic etiologies for this condition.

Most patients respond to administration of a high-protein and low-fat diet supplemented with medium-chain triglycerides. This regimen is designed to minimize chyle production and flow. Medium-chain triglycerides are absorbed by the intestinal epithelium and are transported to liver through the portal vein; they do not contribute to chylomicron formation.

Patients who do not respond to this approach should be fasted and placed on TPN. Octreotide can further decrease lymph flow. Paracentesis is indicated for respiratory difficulties related to abdominal distention. Overall, two-thirds of patients will respond to conservative therapy. However, one-third of patients will require surgical therapy for chylous ascites. In general, postoperative and trauma-related cases that fail to respond to initial nonoperative therapy are best managed by surgical repair. Lymphatic leaks are localized and repaired with fine nonabsorbable sutures. If extravasation of chyle is localized to the periphery of the small bowel mesentery, then a limited small bowel resection can be performed instead. For patients who are poor surgical candidates and who do not respond to prolonged conservative therapy, peritoneovenous shunting may be an option. However, these shunts are associated with high rates of complications, including sepsis and disseminated intravascular coagulation. Because of the viscosity of chyle, these shunts are associated with a high occlusion rate.

Intussusception

Intussusception refers to a condition where one segment of the intestine becomes drawn in to the lumen of the distal segment of the bowel. It is usually seen in the pediatric population, where

the ileum intussuscepts into the cecum (ileocolic intussusception). In children, it is often an idiopathic condition and treated nonsurgically by radiological reduction.

Intussusceptions are far less common and usually have a distinct pathologic lead point, which can be malignant in up to one-half of cases.⁷² They commonly present with a history of intermittent abdominal pain and signs and symptoms of bowel obstruction. CT scan is the investigation of choice, where a “target sign” may be seen (Fig. 28-32). Treatment is surgical resection of the involved segment and the lead point, which needs to undergo pathological evaluation to rule out an underlying malignancy.

With increasing use of CT imaging, target signs are sometimes seen on CT scans of patients who do not have a clinical presentation indicative of bowel obstruction. In such cases, the finding is of little clinical significance and is probably related to normal peristalsis.

In patients who have undergone a Roux-en-Y gastric bypass surgery, an atypical form of intussusception has been increasingly described. In these cases, the distal bowel is drawn in to the lumen of the proximal bowel (retrograde intussusception). These intussusceptions are usually not associated with a lead point and may represent a motility disorder of the bowel following the Roux-en-Y reconstruction. Surgical reductions without resection have been successfully reported in these patients.⁷³

Pneumatosis Intestinalis

Pneumatosis intestinalis indicates the presence of gas within the bowel wall. It may affect any region of the GI tract, but it is most commonly seen in the jejunum. Pneumatosis intestinalis is not a disease but merely a sign that can be idiopathic or associated with many intestinal or nonintestinal disorders, such as obstructive pulmonary disease and asthma. Most cases of pneumatosis intestinalis are secondary to an identifiable cause, and 15% are idiopathic. The pathogenesis of pneumatosis intestinalis is not fully understood.

The surgical interest in this finding is the association of it with bowel ischemia and infarction, both of which necessitate emergent surgical intervention (Fig. 28-33). Thus, patients with this radiological finding need to be fully evaluated and monitored closely to rule out such intraabdominal catastrophes.

Figure 28-32. Small bowel intussusception. **A.** Target sign seen on CT scans in patients with small bowel intussusception (*arrow*). **B.** The distal bowel is clearly within the lumen of the proximal bowel (*arrow*).

Figure 28-33. STEP procedure. This illustration depicts the serial transverse enteroplasty (STEP) procedure. Lengthening of dilated small intestine is accomplished by serial applications of an intestinal stapling device, with firings oriented perpendicular to the long axis of the intestine. (Used with permission from Patrick Javid, M.D. and Tom Jaksic, M.D., Department of Surgery, Children's Hospital, Boston, MA.)

SHORT BOWEL SYNDROME

Intestinal resection is performed for many of the diseases discussed in this chapter and generally is associated with minimal morbidity. However, when extent of resection is great enough, a devastating condition known as short bowel syndrome may result. Although the best definition of short bowel syndrome is

5▶ likely a functional one, reflecting a state of significant malabsorption of both macronutrients and micronutrients, some have used a more anatomical definition with it being arbitrarily defined as the presence of less than 200 cm of residual small bowel in adult patients.⁷⁴

In adults, the most common etiologies of short bowel syndrome are acute mesenteric ischemia, malignancy, and Crohn's disease. Seventy-five percent of cases result from resection of a large amount of small bowel at a single operation. Twenty-five percent of cases result from the cumulative effects of multiple operations during which small intestine is resected. This latter pattern is typical of patients with Crohn's disease who develop short bowel syndrome; the former is typical of patients with acute mesenteric ischemia who develop intestinal infarction. In pediatric patients, intestinal atresias, volvulus, and necrotizing enterocolitis are the most common etiologies of short bowel syndrome.

The prevalence of short bowel syndrome is hard to estimate due to its multifactorial nature and wide spectrum of presentation and treatment, which may include home total parenteral nutrition (TPN).

Pathophysiology

Resection of less than 50% of the small intestine is generally well tolerated. However, clinically significant malabsorption occurs when greater than 50% to 80% of the small intestine has been resected. Among adult patients who lack a functional colon, lifelong TPN dependence is likely to persist if there is less than 100 cm of residual small intestine. Among adult patients who have an intact and functional colon, lifelong TPN dependence is likely to persist if there is less than 60 cm of residual small intestine. Among infants with short bowel syndrome, weaning from TPN-dependence has been achieved with as little as 10 cm of residual small intestine.

Residual bowel length is not the only factor predictive of achieving independence from TPN (enteral autonomy),

however. Other determinants of the severity of malabsorption include the presence or absence of an intact colon, as indicated previously. The colon has the capacity to absorb large fluid and electrolyte loads. In addition, the colon can play an important, albeit small, role in nutrient assimilation by absorbing short chain fatty acids. Second, an intact ileocecal valve is believed to be associated with decreased malabsorption. The ileocecal valve delays transit of chyme from the small intestine into the colon, thereby prolonging the contact time between nutrients and the small-intestinal absorptive mucosa. Third, healthy, rather than diseased, residual small intestine is associated with decreased severity of malabsorption. Fourth, resection of jejunum is better tolerated than resection of ileum, as the capacity for bile salt and vitamin B₁₂ absorption is specific to the ileum (Table 28-11).

During the first 1 to 2 years following massive small bowel resection, the remaining intestine undergoes compensatory adaptation, as discussed previously. Clinically, the period of adaptation is associated with reductions in volume and frequency of bowel movements, increases in the capacity for enteral nutrient assimilation, and reductions in TPN requirements. As this process completes, some patients are successfully weaned off TPN. Understanding the mechanisms mediating intestinal adaptation may suggest strategies for enhancing adaptation in patients with short bowel syndrome who are unable to achieve independence from TPN. To date, the phenomenon of intestinal adaptation in patients remains poorly understood.¹³

Malabsorption in patients who have undergone massive small bowel resection is exacerbated by a characteristic hypergastrinemia-associated gastric acid hypersecretion that persists for 1 to 2 years postoperatively. The increased acid

Table 28-11

Risk factors for development of short bowel syndrome after massive small bowel resection

Small bowel length <200 cm
Absence of ileocecal valve
Absence of colon
Diseased remaining bowel (e.g., Crohn's disease)
Ileal resection

load delivered to the duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions.

Therapy

Medical Therapy. For patients after massive small bowel resection, the initial treatment priorities include management of the primary condition precipitating the intestinal resection and the repletion of fluid and electrolytes lost in the severe diarrhea that characteristically occurs. Most patients will require TPN, at least initially. Enteral nutrition should be gradually introduced, once ileus has resolved. High-dose histamine-2 receptor antagonists or proton pump inhibitors should be administered to reduce gastric acid secretion. Antimotility agents, such as loperamide hydrochloride or diphenoxylate, may be administered to delay small-intestinal transit. Octreotide can be administered to reduce the volume of gastrointestinal secretions, although, in animal models, its use is associated with an inhibition of intestinal adaptation.

During the period of adaptation, generally lasting 1 to 2 years postoperatively, TPN and enteral nutrition are titrated to allow for independence from TPN. Patients who remain dependent on TPN face substantial TPN-associated morbidities including catheter sepsis, venous thrombosis, liver and kidney failure, and osteoporosis. Liver failure is a significant source of morbidity and often leads to liver transplantation (always in combination with small bowel transplantation). Due to these complications, patients with short bowel syndrome on TPN have a reduced life expectancy, with 5-year survival rates of 50% to 75%.

Nontransplant Surgical Therapy. Among patients with stomas, restoration of intestinal continuity should be performed whenever possible, to capitalize on the absorptive capacity of all residual intestine. Other forms of nontransplant surgery designed to improve intestinal absorption are associated with unclear efficacy and/or substantial morbidities and therefore should not be applied routinely.

The goal of these operations is to increase nutrient and fluid absorption by either slowing intestinal transit or increasing intestinal length. Operations designed to slow intestinal transit include segmental reversal of the small bowel, interposition of a segment of colon between segments of small bowel, construction of small-intestinal valves, and electrical pacing of the small intestine. Reported experience with these procedures is limited to case reports or series of a few cases. Objective evidence of increased absorption is lacking; further, these procedures are frequently associated with intestinal obstruction.

The intestinal lengthening operation for which has the longest history is the longitudinal intestinal lengthening and tailoring (LILT) procedure, first described by Bianchi in 1980.⁷⁵ The procedure entails separation of the dual vasculature of the small intestine, followed by longitudinal division of the bowel with subsequent isoperistaltic end-to-end anastomosis. This procedure has the potential to double the length of small intestine to which it is applied. This procedure has generally been used for pediatric patients with *dilated* residual small bowel.

An alternative surgical approach to lengthening the small bowel is the serial transverse enteroplasty procedure (STEP) has been described. This procedure is designed to accomplish lengthening of dilated small intestine without the need for separating its dual vasculature (Fig. 28-33). A report from an international registry of 111 patients showed that 47% of

patients achieved enteral autonomy at a median follow-up of 21 months.⁷⁶

Intestinal Transplantation. This complex procedure is being increasingly performed to treat patients with short bowel syndrome. The currently accepted indication for intestinal transplantation is the presence of life-threatening complications attributable to intestinal failure and/or long-term TPN therapy. Specific complications for which intestinal transplantation is indicated include (a) impending or overt liver failure, (b) thrombosis of major central veins, (c) frequent episodes of catheter-related sepsis, and (d) frequent episodes of severe dehydration.

Of the transplants involving the intestine, 37% were intestine-alone transplants, 30% included intestine, liver, and pancreas, and 24% were intestine and liver.⁷⁷

Isolated intestinal transplantation is used for patients with intestinal failure who have no significant liver disease or failure of other organs. Combined intestine/liver transplantation is used for patients with both intestinal and liver failure. Multivisceral transplantation has been used for patients with giant desmoid tumors involving the vascular supply of the liver and pancreas as well as that of the intestine, for diffuse gastrointestinal motility disturbances, and for diffuse splanchnic thrombosis.

Nearly 80% of survivors have full intestinal graft function with no need for TPN. However, morbidities associated with intestinal transplantation are substantial and include acute and chronic rejection, CMV infection, and posttransplant lymphoproliferative disease.

Alternative Therapies. Pharmacologic and biologic therapies designed to expand intestinal mucosal surface area or to enhance the efficiency of intestinal absorption are beginning to undergo clinical evaluation. Promising regimens include GLP-2 and the combination of glutamine and growth hormone with a modified, high-carbohydrate diet.

Outcomes

Approximately 50% to 70% of patients with short bowel syndrome who initially require TPN are ultimately able to achieve independence from TPN.⁷³ Prognosis for achieving enteral autonomy is better among pediatric patients than among adults.

Information on survival among patients with short bowel syndrome is limited. In a recently reported study of 124 adults with short bowel syndrome due to nonmalignant etiologies, the survival rates at 2 and 5 years of follow up were 86% and 45%, respectively.⁷⁷ Patients with end-enterostomies and those having less than 50 cm of residual small intestine had significantly worse survivals than those without these features.

No randomized trials comparing intestinal transplantation to chronic TPN administration among patients with short bowel syndrome have been reported. One-, 5-, and 10-year graft survival rates of intestine-alone recipients were 80%, 44%, and 26%; while those for intestine and liver and intestine, liver, and pancreas were 62%, 45%, 36% and 69%, 48%, 33%, respectively.⁷⁸

EMBRYOLOGY AND ANATOMY

Embryology

The embryonic gastrointestinal tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: *foregut*, *midgut*, and *hindgut*. Both *midgut* and *hindgut* contribute to the colon, rectum, and anus.

The *midgut* develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the midgut herniates out of the abdominal cavity and then rotates 270° counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation. The *hindgut* develops into the distal transverse colon, descending colon, rectum, and

Key Points

- 1▶ Resection principles: The mesenteric clearance technique dictates the extent of resection and is determined by the nature of the primary pathology, the intent of resection, the location of the lesion, and the condition of the mesentery.
- 2▶ Function after resection: Bowel function is often compromised after colorectal resection, especially after low anterior resection. For this reason, it is important to obtain a history of prior anorectal trauma and/or incontinence before considering a low anastomosis.
- 3▶ Ostomies/Stomas: Preoperative marking for a planned stoma is critical for a patient's quality of life. Ideally, a stoma should be located within the rectus muscle, in a location where the patient can easily see and manipulate the appliance, and away from previous scars, bony prominences, or abdominal creases.
- 4▶ Inflammatory bowel disease: Both Crohn's disease and ulcerative colitis are associated with an increased risk of colorectal carcinoma. Risk depends on the amount of colon involved and the duration of disease.
- 5▶ Pathogenesis of colorectal cancer: A variety of mutations have been identified in colorectal cancer. Mutations may cause activation of oncogenes (*K-ras*) and/or inactivation of tumor suppressor genes (adenomatous polyposis coli [*APC*], deleted in colorectal carcinoma [*DCC*], *p53*).
- 6▶ Minimally invasive resection: Laparoscopy and HAL have been shown to be both safe and efficacious for colorectal resection. Robotic surgery increasingly has been used, especially for rectal/pelvic dissection.
- 7▶ Anal epidermoid carcinoma: Unlike rectal adenocarcinoma, anal epidermoid carcinoma is treated primarily with chemoradiation. Surgery is reserved for patients with persistent or recurrent disease.
- 8▶ Rectal prolapse: Rectal prolapse occurs most commonly in elderly women. Transabdominal repair (rectopexy with or without resection) offers more durability than perineal proctosigmoidectomy, but it carries greater operative risk.
- 9▶ Hemorrhoids: Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fibers. They are thought to play a role in maintaining continence. Resection is only indicated for refractory symptoms.
- 10▶ Fistula in ano: Treatment of fistula in ano depends on the location of the fistula, amount of anal sphincter involved in the fistula, and the underlying disease process.

proximal anus, all of which receive their blood supply from the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the *cloaca*, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

Anatomy

The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the *colon*, *rectum*, and *anal canal*. The wall of the colon and rectum comprise four distinct layers: mucosa, submucosa, muscularis propria (inner circular muscle, outer longitudinal muscle), and serosa. In the colon, the outer longitudinal muscle is separated into three *teniae coli*, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is circumferential. In the distal rectum, the inner smooth muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one-third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

Colon Landmarks. The colon begins at the junction of the terminal ileum and cecum and extends approximately 150 cm (3 to 5 feet) to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three *teniae coli* coalesce to form the outer longitudinal smooth muscle layer of the rectum. The *cecum* is the widest diameter portion of the colon (normally 7.5–8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum. The hepatic flexure marks the transition to the transverse colon. The transverse colon is

relatively mobile, but it is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon is usually located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

Colon Vascular Supply. The arterial supply to the colon is highly variable (Fig. 29-1). In general, the *superior mesenteric artery* branches into the *ileocolic artery* (absent in up to 20% of people), which supplies blood flow to the terminal ileum and proximal ascending colon; the *right colic artery*, which supplies the ascending colon; and the *middle colic artery*, which supplies the transverse colon. The *inferior mesenteric artery* branches into the *left colic artery*, which supplies the descending colon; several *sigmoidal branches*, which supply the sigmoid colon; and the *superior rectal artery*, which supplies the proximal rectum. The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate via the *marginal artery of Drummond*. This arcade is complete in only 15% to 20% of people.

Figure 29-1. Arterial blood supply to the colon. a. = artery.

Except for the *inferior mesenteric vein*, the veins of the colon parallel their corresponding arteries and bear the same terminology (Fig. 29-2). The inferior mesenteric vein ascends in the retroperitoneal plane over the psoas muscle and continues posterior to the pancreas to join the splenic vein. During a colectomy, this vein is often mobilized independently and ligated at the inferior edge of the pancreas.

Colon Lymphatic Drainage. The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the

Figure 29-2. Venous drainage of the colon. v. = vein. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main).

Colon Nerve Supply. The colon is innervated by both *sympathetic* (inhibitory) and *parasympathetic* (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6–T12 and L1–L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2–S4 to form the *nervi erigentes*.

Anorectal Landmarks. The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the *valves of Houston*, extend into the rectal lumen. Posteriorly, the *preseacral fascia* separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the *rectosacral fascia* (*Waldeyer's fascia*) extends anteriorly and caudally and attaches to the fascia propria at the anorectal junction. Anteriorly, *Denonvilliers' fascia* separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The *lateral ligaments* support the lower rectum.

The *anatomic anal canal* extends from the dentate or pectinate line to the anal verge. The *dentate* or *pectinate line* marks the transition point between columnar rectal mucosa and squamous anoderm. The *anal transition zone* includes mucosa proximal to the dentate line that shares histologic characteristics of columnar, cuboidal, and squamous epithelium. Although the anal transition zone was long thought to extend only 1 to 2 cm proximal to the dentate line, it is known that the proximal extent of this zone is highly variable and can be as far as 15 cm proximal to the dentate line. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses (Fig. 29-3). In contrast to the anatomic anal canal, the surgical anal canal begins at the

Figure 29-3. The lining of the anal canal. (Reproduced with permission from Goldberg SM, Gordon PH, Nivatvongs S: *Essentials of Anorectal Surgery*. Philadelphia, PA: JB Lippincott Company; 1980.)

anorectal junction and terminates at the anal verge. The surgical anal canal measures 2 to 4 cm in length and is generally longer in men than in women. It begins at the anorectal junction and terminates at the anal verge.

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the *subcutaneous*, *superficial*, and *deep external sphincter*. The *deep external anal sphincter* is an extension of the *puborectalis muscle*. The *puborectalis*, *iliococcygeus*, and *pubococcygeus muscles* form the *levator ani muscle* of the pelvic floor (Fig. 29-4).

Anorectal Vascular Supply. The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia (Fig. 29-5).

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

Anorectal Lymphatic Drainage. Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but can also drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Figure 29-4. The distal rectum and anal canal. m. = muscle.

Figure 29-5. Arterial supply to the rectum and anal canal.

Anorectal Nerve Supply. Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1–L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the *hypogastric plexus*, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the *nervi erigentes* and originate from S2–S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers; both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the *inferior rectal branch* of the *internal pudendal nerve*. The levator ani receives innervation from both the *internal pudendal nerve* and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the *inferior rectal branch* of the *pudendal nerve*. While the rectum is relatively insensate, the anal canal below the dentate line receives somatic innervation.

Congenital Anomalies

Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

NORMAL PHYSIOLOGY

Fluid and Electrolyte Exchanges

Water, Sodium, Potassium, Chloride, Bicarbonate, and Ammonia. The colon is a major site for water absorption and electrolyte exchange. Under normal circumstances, approximately 90% of the water contained in ileal fluid is absorbed

in the colon (1000–2000 mL/d), but up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via sodium-potassium (Na^+/K^+) ATPase. The colon can absorb up to 400 mEq of sodium per day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride-bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends in part on intraluminal pH. A decrease in colonic bacteria (e.g., due to broad-spectrum antibiotic use) and/or a decrease in intraluminal pH (e.g., due to lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids

Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and inflammation, the latter termed “diversion colitis.”

Colonic Microflora and Intestinal Gas

Approximately 30% of fecal dry weight is composed of bacteria (10^{11} – 10^{12} bacteria/g of feces). Anaerobes are the predominant class of microorganism, and *Bacteroides* species are the most common (10^{11} – 10^{12} organisms/mL). *Escherichia coli* are the most numerous aerobes (10^8 – 10^{10} organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as *Clostridium difficile*, a phenomenon termed “colonization resistance.” However, the high bacterial load of the large intestine may contribute to sepsis in critically ill patients and may contribute to intra-abdominal sepsis, abscess, and wound infection following colectomy. Burgeoning research on the human gut microbiome offers new concepts of bacterial community structure and its impact on gastrointestinal disease. Use of 16S ribosomal RNA, universally present in bacteria, allows for a more complete understanding of colonic samples, without the use of stool cultures.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The gastrointestinal tract usually contains between 100 and 200 mL of gas, and 400 to 1200 mL/d are released as flatus, depending on the type of food ingested.

Motility, Defecation, and Continence

Motility. Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent

contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude, prolonged duration, propagated contractions (HAPCs) occur in a more coordinated fashion and create “mass movements,” four to ten times per day, mostly after meals and awakening. Bursts of “rectal motor complexes” also have been described. In general, cholinergic activation increases colonic motility.

Defecation. Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This “sampling reflex” allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (*accommodation response*). Defecation proceeds by coordinating increasing intra-abdominal pressure via a Valsalva maneuver with rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

Continence. The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a “sling” around the distal rectum, forming a relatively acute angle that distributes intra-abdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. The hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Finally, liquid stools exacerbate abnormalities with these anatomic and physiologic mechanisms, so a formed stool contributes to maintaining continence. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or neuropathy.

CLINICAL EVALUATION

Clinical Assessment

Obtaining a complete history and performing a physical examination are the starting points for evaluating any patient with suspected disease of the colon, rectum, or anus. Special attention should be paid to the patient’s past medical and surgical history to detect underlying conditions that might contribute to a gastrointestinal problem. If patients have had prior intestinal surgery, it is essential that one understand the resultant gastrointestinal anatomy. A history of anorectal surgery may be critical for patients with either abdominal or anorectal complaints. The obstetrical history in women is essential to detect occult pelvic floor and/or anal sphincter damage. Identifying

a family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. In addition to a family history of colorectal disease, a history of other malignancies may suggest the presence of a genetic syndrome. Medication use must be detailed as many drugs cause gastrointestinal symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

Anoscopy. The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscope should then be withdrawn. It is rotated 90° and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

Proctoscopy. The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. A smaller “pediatric” proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination. An operating platform for transanal surgery known as *transanal endoscopic microsurgery* (TEM) has a much wider diameter and can be used for excisions of large polyps and tumors. *Transanal minimally invasive surgery* (TAMIS) can achieve similar resections to TEM, but it does not utilize a proctoscope and instead depends on insufflation to create a working space in the rectum while utilizing a circular wound protector to open the anus.

Flexible Sigmoidoscopy and Colonoscopy. Video or fiberoptic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas is usually adequate for sigmoidoscopy, and most patients can tolerate this procedure without sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation is usually necessary for colonoscopy, and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery should generally not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

Capsule Endoscopy. Capsule endoscopy uses a small ingestible camera. After swallowing the camera, images of the mucosa of the gastrointestinal tract are captured, transmitted by radiofrequency to a belt-held receiver, and then downloaded to a computer for viewing and analysis. Capsule endoscopy largely has been used to detect small bowel lesions. Recent advances in the development of maneuverable capsules may improve the sensitivity of this procedure.¹ Finally, concern over the possibility of an acute obstruction has led to the development of a dissolvable capsule that can detect obstruction lesions. Although this technology is promising, the ultimate utility of capsule endoscopy remains unknown.

Imaging

Plain X-Rays and Contrast Studies. Despite advanced radiologic techniques, plain X-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain X-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. Although Gastrografin cannot provide the mucosal detail provided by barium, this water-soluble contrast agent is recommended if perforation or leak is suspected. Double-contrast barium enema (use of barium followed by the insufflation of air into the colon) has been reported to be 70% to 90% sensitive for the detection of mass lesions greater than 1 cm in diameter. Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

Computed Tomography. Computed tomography (CT) commonly is employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma because of its sensitivity in detection of hepatic metastases.

Extravasation of oral or rectal contrast may also confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions.

Computed Tomography Colonography. CT colonography (virtual colonoscopy) is a radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation have been used to maximize sensitivity. Experience with this technology has shown a sensitivity and specificity for detecting 1 cm or larger polyps of 85% to 90% in most studies, making it comparable to traditional colonoscopy. Although this technology has yet to be widely adopted, it remains an alternative to traditional colonoscopy for select patients.²

Magnetic Resonance Imaging. The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting

bony involvement or pelvic sidewall extension of rectal tumors. MRI accurately determines the extent of spread of rectal cancer into the adjacent mesorectum and can reliably predict difficulty achieving radial margin clearance of a rectal cancer by surgery alone. When the radial margin is threatened, neoadjuvant chemoradiation is indicated. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

Positron Emission Tomography. Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors. ¹⁸F-fluorodeoxyglucose (FDG) is injected as a tracer; metabolism of this molecule then results in positron emission. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis. By combining PET and CT technology (PET/CT), anatomic correlation between regions of high isotope accumulation (“hot spots”) on PET and abnormalities on CT can be determined. PET/CT increasingly is used to diagnose recurrent and/or metastatic colorectal cancer. However, the efficacy and utility of this technology remains unproven.

Scintigraphy to Assess Gastrointestinal Bleeding. Scintigraphy to assess for gastrointestinal bleeding (technetium-99-tagged red blood cell [RBC] scan; “tagged RBC scan”) is a nuclear medicine test that uses ^{99m}Tc-erythrocytes and dynamic images to localize a bleeding source. Patients must be actively bleeding at the time of imaging, and a normal distribution of ^{99m}Tc-erythrocytes in vasculature, liver, spleen, penile circulation with mild uptake in kidneys and bladder can interfere with localization in bowel segments near those structures. Patients must be stable enough to tolerate imaging intervals of up to 4 hours, but slow bleeding at a rate of 0.05 to 0.2 mL/minute can be detected.³

Single Photon Emission Computed Tomography (SPECT/CT). Radiolabeled erythrocytes are also used for SPECT/CT, but cross-sectional images provide a more specific localization of the bleeding source, which can be very helpful for surgical planning, especially if direct visualization via endoscopy has not been successful.⁴

Angiography. Angiography is occasionally used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic. If surgical resection is required, the angiographic catheter can be left in place to assist with identification of the bleeding site intraoperatively.

CT and magnetic resonance angiography are also useful for assessing patency of visceral vessels. This technique uses three-dimensional reconstruction to detect vascular lesions. If an abnormality is found, more traditional techniques (angiography, surgery) may then be used to further define and/or correct the problem.

Endorectal and Endoanal Ultrasound. Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 29-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based on the integrity of the submucosal layer. Ultrasound can also differentiate superficial T1-T2 from deeper T3-T4 tumors. Overall,

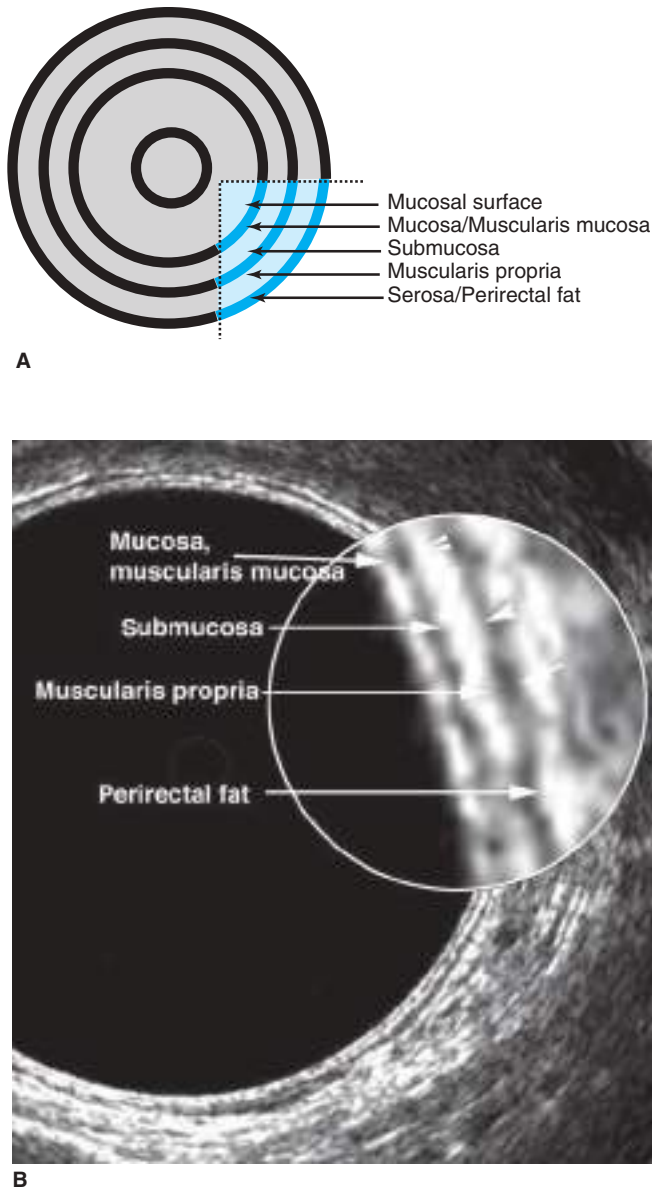

Figure 29-6. A. Schematic of the layers of the rectal wall observed on endorectal ultrasonography. B. Normal endorectal ultrasonography. (A. Used with permission from Charles O. Finne III, MD, Minneapolis, MN.)

the accuracy of ultrasound in detecting depth of mural invasion ranges between 81% and 94%. This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58% to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.⁵

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas. MRI has also proven to be helpful in delineating the anatomy of fistulae, especially in complex cases. This modality increasingly is utilized for the evaluation of anal fistulae.

Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are

useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other functional disorders of the pelvic floor.

Manometry. Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The *resting pressure* in the anal canal reflects the function of the internal anal sphincter (normal 40–80 mmHg), whereas the *squeeze pressure*, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal 40–80 mmHg above resting pressure). The *high-pressure zone* estimates the length of the anal canal (normal 2.0–4.0 cm). The *rectoanal inhibitory reflex* can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung’s disease.

Neurophysiology. Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal 1.8–2.2 ms); prolonged latency suggests the presence of neuropathy. Electromyographic (EMG) recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to “squeeze” and decreases when a patient is instructed to “push.” Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor latency testing to assess pudendal nerve function and endoanal ultrasound to map the sphincters.

Rectal Evacuation Studies. Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient’s ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum, and defecation is then recorded fluoroscopically. Defecography is used to help diagnose obstructed defecation from nonrelaxation of the puborectalis muscle or anal sphincter dyssynergy, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

Fecal Occult Blood Testing and Fecal Immunohistochemical Testing. Fecal occult blood testing (FOBT) has been used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based on serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Increased specificity for cancer detection is possible by using fecal immunohistochemical test (FIT). Reported sensitivity of 79% and specificity

of 94% has led to widespread use of FIT in current population-based screening approaches. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin and are more specific for identifying occult bleeding from the colon or rectum. Any positive FOBT or FIT mandates further investigation, usually by colonoscopy.⁶ More recently, stool DNA testing has been proposed for early detection of colorectal cancer.⁷

Stool Studies. Stool studies are often helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive *E coli* or *Shigella* species. Stool cultures can detect pathogenic bacteria, ova, and/or parasites. *C difficile* colitis is diagnosed by detecting bacterial toxin in the stool. Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

Tumor Markers. Carcinoembryonic antigen (CEA) may be elevated in 60% to 90% of patients with colorectal cancer. Preoperative CEA level has recently been suggested to be a prognostic indicator.⁸ Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery in order to detect early recurrence of colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit associated with its serial measurements has yet been proven. It is also important to note that CEA may be mildly elevated in patients who smoke tobacco. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma.

Genetic Testing. Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer.⁹

Tests for mutations in the adenomatous polyposis coli (*APC*) gene responsible for FAP and in mismatch repair genes responsible for HNPCC are commercially available and extremely accurate in families with known mutations. However, in the absence of an identified mutation, a negative result is uninformative. For individuals from high-risk families without an identified mutation, increased surveillance is recommended.¹⁰ Although many of these mutations are also present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower, and these tests are not recommended for screening. Due to the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.

Evaluation of Common Symptoms

Pain

Abdominal Pain Abdominal pain is a nonspecific symptom with myriad causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain X-rays and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy

performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation or near complete obstruction is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.

Pelvic Pain Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass, or fecal impaction in a constipated patient. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis, although with access to high-quality imaging, indications for diagnostic surgery should be rare.

Anorectal Pain. Anorectal pain is most often secondary to an anal fissure, perirectal abscess and/or fistula, or a thrombosed hemorrhoid. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical exam is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI or other imaging studies may be helpful in select cases where the etiology of pain is elusive.

Lower Gastrointestinal Bleeding. The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy should be performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (^{99m}Tc)-tagged red blood cell (tagged RBC scan) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the ^{99m}Tc-tagged RBC scan is positive, angiography can then be both diagnostic and potentially therapeutic. If the patient is hemodynamically stable, a rapid bowel preparation (over 4–6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection/application of epinephrine into the bleeding site may be used to control hemorrhage. A SPECT/CT may be helpful if other modalities have not achieved localization, particularly in distinguishing between small intestinal and colon sources. Colectomy may be required if bleeding persists despite interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. “Blind” subtotal colectomy

Figure 29-7. Algorithm for treatment of colorectal hemorrhage. NG = nasogastric; ^{99m}Tc = technetium-99; RBC = red blood cell. (Reproduced with permission of Gordon PH, Nivatvongs S: Principles and Practice of Surgery for the Colon, Rectum, and Anus, 2nd ed. New York, NY: Marcel Dekker, Inc; 1999.)

very rarely may be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, just prior to proceeding with a “blind” subtotal colectomy, it is crucial to irrigate the rectosigmoid and reexamine the mucosa of the anal canal and rectum by anoscopy and proctoscopy to ensure the source of ongoing bleeding is not distal to the planned resection margin (Fig. 29-7).

Occult blood loss from the gastrointestinal tract may manifest as iron-deficiency anemia or may be detected with FOBT or FIT. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.

Hematochezia is commonly caused by hemorrhoids or a fissure. Sharp, knife-like pain and bright red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

Constipation and Obstructed Defecation. Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem.

Constipation has many causes. Underlying metabolic, pharmacologic, endocrine, psychological, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy, barium enema, or CT colonography. After these causes have been excluded, evaluation focuses on differentiating *slow-transit constipation* from *outlet obstruction*. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. In this study, patients ingest radiopaque studies and are followed radiographically for 5 days. Retention of 20% or greater of these markers in the colon demonstrated slow transit. If these markers are congregated in the rectosigmoid colon and rectum, obstructed defecation/outlet obstruction is suggested. Anorectal manometry and EMG can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex

suggests Hirschsprung's disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis or anal sphincter dyssynergy often responds to biofeedback. Surgery to correct rectocele and rectal prolapse (with or without sigmoid resection) has a variable effect on symptoms of constipation but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. While this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected and counseled.¹¹

Diarrhea and Irritable Bowel Syndrome. Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive *E coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Entamoeba histolytica*, or *C difficile*), inflammatory bowel disease (ulcerative colitis or Crohn's colitis), or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short gut syndrome can cause chronic diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide-secreting tumor [VIPoma], somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Workup reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

Incontinence. The true incidence of fecal incontinence is unknown, but has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and/or liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial, and diarrhea is often contributory. In general, causes of incontinence can be classified as *neurogenic* or *anatomic*. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia (rectal prolapse), overflow incontinence secondary to impaction or an obstructing neoplasm, and trauma. The most common

traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures. Physical examination and defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects (Fig. 29-8).

Therapy depends on the underlying abnormality. Diarrhea should be treated medically (fiber, antidiarrheal agents). Even in the absence of frank diarrhea, the addition of dietary fiber may improve continence. Some patients may respond to biofeedback and this approach may be considered in patients who fail dietary modification. Many patients with a sphincter defect are candidates for an overlapping sphincteroplasty. Sacral nerve

stimulation been shown to decrease episodes of fecal incontinence and has proven durability in the long term (5 years). The artificial bowel sphincter may be useful in patients who fail other interventions. Other options include radiofrequency energy to the anal canal (SECCA procedure), magnetic anal sphincter, and injectable submucosal bulking agents, but long-term efficacy has not yet been proven.¹²⁻¹⁴ Finally, a stoma can provide relief for severely incontinent patients who have failed or are not candidates for other interventions.

GENERAL SURGICAL CONSIDERATIONS

Colorectal resections are performed for a wide variety of conditions, including neoplasms (benign and malignant), inflammatory bowel diseases, and other benign conditions. Although the indication and urgency for surgery will alter some of the technical details, the operative principles of colorectal resections, anastomoses, and use of ostomies are well established.

Resections

The mesenteric clearance technique dictates the extent of colonic resection and is determined by the nature of the primary pathology (malignant or benign), the intent of the resection (curative or palliative), the precise location(s) of the primary pathology, and the condition of the mesentery (thin and soft or thick and indurated). In general, a proximal mesenteric ligation will eliminate the blood supply to a greater length of colon and require a more extensive “colectomy.” Curative resection of a colorectal cancer is usually best accomplished by performing a proximal mesenteric vessel ligation and radical mesenteric clearance of the lymphatic drainage basin of the tumor site (Fig. 29-9). Resection of a benign process does not require wide mesenteric clearance.

Emergency Resection. Emergency resection may be required because of obstruction, perforation, or hemorrhage. In this setting, the bowel is almost always unprepared and the patient may be unstable. The surgical principles described earlier apply, and an attempt should be made to resect the involved segment along with its lymphovascular supply. If the resection involves the right colon or proximal transverse colon (right or extended right colectomy), a primary ileocolonic anastomosis can usually be performed safely as long as the remaining bowel appears healthy and the patient is stable. For left-sided tumors, the traditional approach has involved resection of the involved bowel and end colostomy, with or without a mucus fistula. However, there is an increasing body of data to suggest that a primary anastomosis without a bowel preparation or with an on-table lavage, with or without a diverting ileostomy, may be equally safe in this setting. If the proximal colon appears unhealthy (vascular compromise, serosal tears, perforation), a subtotal colectomy can be performed with a small bowel to rectosigmoid anastomosis. Resection and diversion (ileostomy or colostomy) remain safe and appropriate if the bowel appears compromised or if the patient is unstable, malnourished, or immunosuppressed.

Minimally Invasive Techniques of Resection. With advances in minimally invasive technology, many procedures that previously have required laparotomy can now be performed laparoscopically, with hand-assisted laparoscopy (HAL), or robotically.^{15,16} Potential advantages of minimally invasive surgery include improved cosmetic result, decreased postoperative pain, and earlier return of bowel function. Moreover, some experimental data suggest that minimally invasive

operations have less immunosuppressive impact on the patient and thus might improve postoperative outcome and even long-term survival. To date, most studies have demonstrated equivalence between laparoscopic, HAL, and open resection in terms of extent of resection. Return of bowel function and length of hospital stay are highly variable. Long-term outcome has yet to be determined; however, short-term quality of life appears to be improved by laparoscopy.^{17,18} Laparoscopic total mesorectal excision for rectal cancer, however, may not be appropriate. The most recent advances in minimally invasive surgery involve use of *robotics* and *telemanipulation* in which the surgeon operates from a console remote from the patient. These procedures have been rapidly gaining in popularity, especially for pelvic and rectal resections. Early studies suggest equivalence between robotic resections and laparoscopic/HAL resections.¹⁹

In addition, some proponents have suggested that robotic procedures may be easier to learn (a shorter “learning curve”) and that robotic surgery may be ergonomically better for the operating surgeon. Nevertheless, long-term superiority, or even equivalence, has yet to be demonstrated, and these advanced technologies are likely to be associated with significant cost.

Colectomy. A variety of terms are used to describe different types of colectomy (Fig. 29-10).

Ileocolic Resection An ileocolic resection describes a limited resection of the terminal ileum, cecum, and appendix. It is used to remove disease involving these segments of the intestine (e.g., ileocecal Crohn’s disease) and benign lesions or incurable cancers arising in the terminal ileum, cecum, and, occasionally, the appendix. If curable malignancy is suspected, more radical resections, such as a right hemicolectomy, are generally indicated. The ileocolic vessels are ligated and divided. A variable length of small intestine may be resected depending on the disease process. A primary anastomosis is created between the distal small bowel and the ascending colon. It is technically difficult to perform an anastomosis at or just proximal to the ileocecal valve; therefore, if the most distal ileum needs to be resected, the cecum is generally also removed.

Right Colectomy A right colectomy is used to remove lesions or disease in the right colon and is oncologically the most appropriate operation for curative intent resection of proximal colon carcinoma. The ileocolic vessels, right colic vessels, and right branches of the middle colic vessels are ligated and divided. Approximately 10 cm of terminal ileum are usually included in the resection. A primary ileal-transverse colon anastomosis is almost always possible.

Extended Right Colectomy An extended right colectomy may be used for curative intent resection of lesions located at the hepatic flexure or proximal transverse colon. A standard right colectomy is extended to include ligation of the middle colic vessels at their base. The right colon and proximal transverse colon are resected, and a primary anastomosis is created between the distal ileum and distal transverse colon. Such an anastomosis relies on the marginal artery of Drummond. If the blood supply to the distal transverse colon is questionable, the resection is extended distally beyond the splenic flexure to well-perfused descending colon where the ileocolic anastomosis can be performed safely.

Transverse Colectomy Lesions in the mid and distal transverse colon may be resected by ligating the middle colic vessels and resecting the transverse colon, followed by a colocolonic anastomosis. However, an extended right colectomy with an

Figure 29-9. Extent of resection for carcinoma of the colon. **A.** Cecal cancer. **B.** Hepatic flexure cancer. **C.** Transverse colon cancer. **D.** Splenic flexure cancer. **E.** Descending colon cancer. **F.** Sigmoid colon cancer.

anastomosis between the terminal ileum and descending colon may be a safer anastomosis with an equivalent functional result.

Left Colectomy For lesions or disease states confined to the distal transverse colon, splenic flexure, or descending colon, a left colectomy is performed. The left branches of the middle colic vessels, the left colic vessels, and the first branches of the sigmoid vessels are ligated. A colocolonic anastomosis can usually be performed.

Extended Left Colectomy An extended left colectomy is an option for removing lesions in the distal transverse colon. In this operation, the left colectomy is extended proximally to include the right branches of the middle colic vessels.

Sigmoid Colectomy Lesions in the sigmoid colon require ligation and division of the sigmoid branches of the inferior mesenteric artery. In general, the entire sigmoid colon should be resected to the level of the peritoneal reflection and an

Figure 29-10. Terminology of types of colorectal resections: A→C Ileocectomy; + A + B→D Ascending colectomy; + A + B→F Right hemicolectomy; + A + B→G Extended right hemicolectomy; + E + F→G + H Transverse colectomy; G→I Left hemicolectomy; F→I Extended left hemicolectomy; J + K Sigmoid colectomy; + A + B→J Subtotal colectomy; + A + B→K Total colectomy; + A + B→L Total proctocolectomy. (Reproduced with permission from Fielding LP, Goldberg SM: *Rob & Smith's Operative: Surgery of the Colon, Rectum, and Anus*. London: Elsevier; 1993.)

anastomosis created between the descending colon and upper rectum. Full mobilization of the splenic flexure is often required to create a tension-free anastomosis.

Total and Subtotal Colectomy Total or subtotal colectomy is occasionally required for patients with fulminant colitis, attenuated FAP, or synchronous colon carcinomas. In this procedure, the ileocolic vessels, right colic vessels, middle colic vessels, and left colic vessels are ligated and divided. The superior rectal vessels are preserved. If it is desired to preserve the sigmoid, the distal sigmoid vessels are left intact, and an anastomosis is created between the ileum and distal sigmoid colon (subtotal colectomy with ileosigmoid anastomosis). If the sigmoid is to be resected, the sigmoidal vessels are ligated and divided, and the ileum is anastomosed to the upper rectum (total abdominal colectomy with ileorectal anastomosis). If an anastomosis is contraindicated, an end ileostomy is created, and the remaining sigmoid or rectum is managed either as a mucus fistula or a Hartmann's pouch.

Proctocolectomy

Total Proctocolectomy In this procedure, the entire colon, rectum, and anus are removed, and the ileum is brought to the skin as a Brooke ileostomy.

Restorative Proctocolectomy (Ileal Pouch–Anal Anastomosis) The entire colon and rectum are resected, but the anal

sphincter muscles and a variable portion of the distal anal canal are preserved. Bowel continuity is restored by anastomosis of an ileal reservoir to the anal canal. The original technique included a transanal mucosectomy and hand-sewn ileoanal anastomosis. Proponents of this technique argue that mucosectomy guarantees removal of all of the diseased mucosa, including the anal transition zone, and therefore decreases the risk of ongoing disease, dysplasia, and carcinoma. Opponents cite the increased risk of incontinence after mucosectomy and argue that even meticulous technique invariably leaves behind mucosal “islands” that are subsequently hidden under the anastomosis. However, persistent or recurrent dysplasia in the anal transition zone is uncommon (4.5%), and cancers occur even more rarely.¹⁹ Moreover, the “double-staple” technique using the circular stapling devices is considerably simpler than mucosectomy and a hand-sewn anastomosis and may be associated with a better functional outcome (Fig. 29-11).²⁰⁻²² Regardless of the anastomotic technique, many surgeons recommend that patients undergo annual surveillance of the anastomosis and/or anal transition zone by digital rectal exam and anoscopy or proctoscopy.

The neorectum is made by anastomosis of the terminal ileum aligned in a “J,” “S,” or “W” configuration. Because functional outcomes are similar and because the J-pouch is the simplest to construct, it has become the most used configuration.

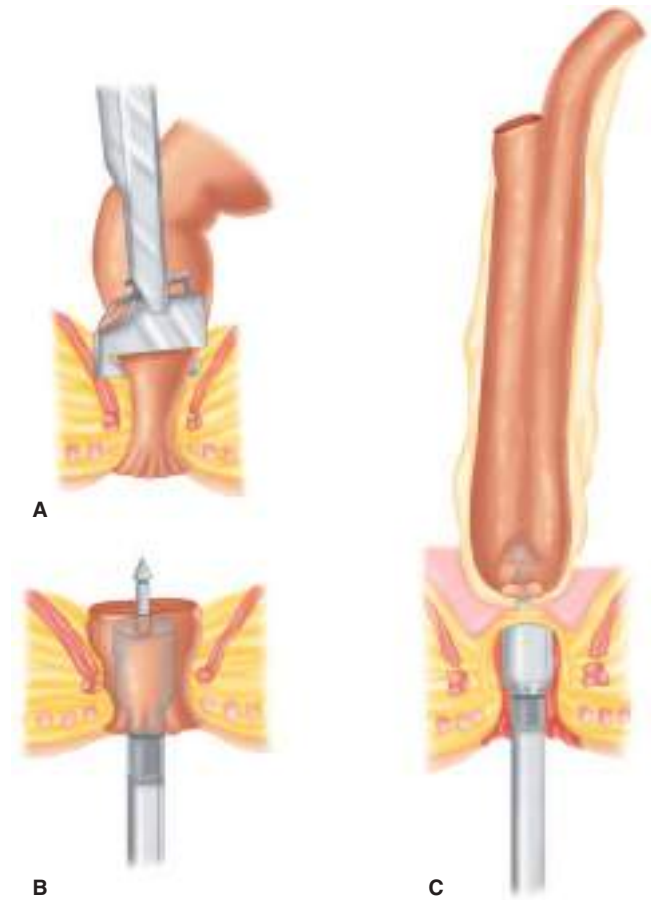

Figure 29-11. After a total colectomy and resection of the rectum (A), the anal canal with a short cuff of transitional mucosa and sphincter muscles is preserved (B). An ileal J-pouch has been constructed and is anastomosed to the anal canal using a double-staple technique (C). (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Figure 29-12. Ileal S-pouch anal anastomosis with temporary loop ileostomy. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

With increasing experience in laparoscopic and robotic colectomy, some centers have begun performing total proctocolectomy with ileal pouch–anal reconstruction using minimally invasive surgical techniques.¹⁵ Most surgeons perform a proximal ileostomy to divert succus from the newly created pouch in an attempt to minimize the consequences of leak and sepsis, especially in patients who are malnourished or immunosuppressed (Fig. 29-12). The ileostomy is then closed 6 to 12 weeks later, after a contrast study confirms the integrity of the pouch. In low-risk patients, however, there are reports of successful creation of an ileoanal pouch without a diverting stoma.

Anterior Resection. *Anterior resection* is the general term used to describe resection of the rectum from an abdominal approach to the pelvis with no need for a perineal, sacral, or other incision. Three types of anterior resection have been described.

High Anterior Resection A *high anterior resection* is the term used to describe resection of the distal sigmoid colon and upper rectum and is the appropriate operation for benign lesions and disease at the rectosigmoid junction such as diverticulitis. The upper rectum is mobilized, but the pelvic peritoneum is not divided and the rectum is not mobilized fully from the concavity

of the sacrum. The inferior mesenteric artery is ligated at its base, and the inferior mesenteric vein, which follows a different course than the artery, is ligated separately. A primary anastomosis (usually end-to-end) between the colon and rectal stump with a short cuff of peritoneum surrounding its anterior two thirds generally can be performed.

Low Anterior Resection. A *low anterior resection* is used to remove lesions in the upper and mid rectum. The rectosigmoid is mobilized, the pelvic peritoneum is opened, and the inferior mesenteric artery is ligated and divided either at its origin from the aorta or just distal to the takeoff of the left colic artery. The rectum is mobilized from the sacrum by sharp dissection under direct view within the endopelvic fascial plane. The dissection may be performed distally to the anorectal ring, extending posteriorly through the rectosacral fascia to the coccyx and anteriorly through Denonvilliers' fascia to the vagina in women or the seminal vesicles and prostate in men. The rectum and accompanying mesorectum are divided at the appropriate level, depending on the nature of the lesion. A low rectal anastomosis usually requires mobilization of the splenic flexure and ligation and division of the inferior mesenteric vein just inferior to the pancreas. Circular stapling devices have greatly facilitated the conduct and improved the safety of the colon to extraperitoneal rectal anastomosis.

Extended Low Anterior Resection An *extended low anterior resection* is necessary to remove lesions located in the distal rectum, but several centimeters above the sphincter. The rectum is fully mobilized to the level of the levator ani muscle just as for a low anterior resection, but the anterior dissection is extended along the rectovaginal septum in women and distal to the seminal vesicles and prostate in men. After resection at this level, a *coloanal anastomosis* can be created using one of a variety of techniques. An end-to-end stapled or hand-sewn anastomosis has traditionally been the procedure of choice. However, the functional consequences of a “straight” anastomosis have led to consideration for creation of a colon J-pouch to increase the capacity of the neorectal reservoir. A side-to-end anastomosis can be constructed by placing the anvil of an EEA stapler 3 to 4 cm away from the stapled end of the proximal colon, with similar functional outcomes to the colon J-pouch reconstruction.²⁰⁻²² Because the risk of an anastomotic leak and subsequent sepsis is higher when an anastomosis is created in the distal rectum or anal canal, creation of a temporary ileostomy should be considered in this setting, especially if the patient has received neoadjuvant radiation.²³

Although an anastomosis may be technically feasible very low in the rectum or anal canal, it is important to note that postoperative function may be poor. Because the descending colon lacks the distensibility of the rectum, the reservoir function may be compromised. Pelvic radiation, prior anorectal surgery, and obstetrical trauma may cause unsuspected sphincter damage. Finally, a very low anastomosis may involve and compromise the upper sphincter. Creation of a colon J-pouch or transverse coloplasty may improve function, but few long-term studies have addressed this issue.²⁰⁻²²

A history of sphincter damage or any degree of incontinence is a relative contraindication for a coloanal anastomosis.

▶ In such patients, an end colostomy may be a more satisfactory option.

Hartmann's Procedure and Mucus Fistula. Hartmann's procedure refers to a colon or rectal resection without an

anastomosis in which a colostomy or ileostomy is created and the distal colon or rectum is left as a blind pouch. The term is typically used when the left or sigmoid colon is resected and the closed off rectum is left in the pelvis. If the distal colon is long enough to reach the abdominal wall, a *mucus fistula* can be created by opening the defunctioned bowel and suturing the open lumen to the skin.

Abdominoperineal Resection. An abdominoperineal resection (APR) involves removal of the entire rectum, anal canal, and anus with construction of a permanent colostomy from the descending or sigmoid colon. The abdominal-pelvic portion of this operation proceeds in the same fashion as described for an extended low anterior resection. The perineal dissection can be performed with the patient in lithotomy position (often by a second surgeon) or in the prone position after closure of the abdomen and creation of the colostomy. For cancer, the perineal dissection is designed to excise the anal canal with a wide circumferential margin including a cylindrical cuff of the levator muscle. A deliberate resection of the levator muscles near their bony attachments, in order to avoid opening the space between the tumor and the levator ani, is known as the extralevator abdominoperineal resection (ELAPE). ELAPE is useful for low, locally advanced rectal cancers, but routine use for all rectal cancer has not been shown to improve cancer outcomes.²⁴ Primary wound closure is usually successful, but a large perineal defect, especially if preoperative radiation has been used, may require a vascularized flap closure in some patients.²⁵ For benign disease, proctectomy may be performed using an *intersphincteric dissection* between the internal and external sphincters. This approach minimizes the perineal wound, making it easier to close because the levator muscle remains intact.

Anastomoses

Anastomoses may be created between two segments of bowel in a multitude of ways. The geometry of the anastomosis may be *end-to-end*, *end-to-side*, *side-to-end*, or *side-to-side*. The anastomotic technique may be *hand-sewn* or *stapled* (Fig. 29-13). The submucosal layer of the intestine provides the strength of the bowel wall and must be incorporated in the anastomosis to assure healing. The choice of anastomosis depends on the operative anatomy and surgeon preference. Although many surgeons advocate one method over another, none has been proven to be superior. Accurate approximation of two well-vascularized, healthy limbs of bowel without tension in a normotensive, well-nourished patient almost always results in a good outcome. Anastomoses at highest risk of leak or stricture are those that are in the distal rectal or anal canal, involve irradiated or diseased intestine including perforation with peritoneal soilage, are inadvertently fashioned above a partial distal obstruction, or are performed in malnourished, immunosuppressed, or ill patient.

Anastomotic Configuration

End-to-End An end-to-end anastomosis can be performed when two segments of bowel are roughly the same caliber. This technique is most often employed in rectal resections, but may be used for colocolostomy or small bowel anastomoses.

End-to-Side An end-to-side configuration is useful when one limb of bowel is larger than the other. This most commonly occurs in the setting of chronic obstruction.

Side-to-End A side-to-end anastomosis is used when the proximal bowel is of smaller caliber than the distal bowel. Ileorectal

anastomoses commonly make use of this configuration. A side-to-end anastomosis may have a less tenuous blood supply than an end-to-end anastomosis.

Side-to-Side A side-to-side anastomosis allows a large, well-vascularized connection to be created on the antimesenteric side of two segments of intestine. This technique is commonly used in ileocolic and small bowel anastomoses.

Anastomotic Technique

Hand-Sutured Technique Any of the configurations described earlier may be created using a hand-sutured or stapled technique. Hand-sutured anastomoses may be *single layer*, using either running or interrupted stitches, or *double layer*. A double-layer anastomosis usually consists of a continuous inner layer and an interrupted outer layer. Suture material may be either permanent or absorbable. After distal rectal or anal canal resection, a transanal, hand-sewn coloanal anastomosis may be necessary to restore bowel continuity. This can be done in conjunction with an anal canal mucosectomy to allow the anastomosis to be created at the dentate line.

Stapled Techniques Linear cutting/stapling devices are used to divide the bowel and to create side-to-side anastomoses. The anastomosis may be reinforced with interrupted sutures if desired. Circular cutting/stapling devices can create end-to-end, end-to-side, or side-to-end anastomoses. These instruments are particularly useful for creating low rectal or anal canal anastomoses where the anatomy of the pelvis makes a hand-sewn anastomosis technically difficult or impossible.

Following resection of the colorectum, a stapled end-to-end colorectal, coloanal canal, or ileal pouch–anal anastomosis may be created by one of two techniques. With the *open purse-string technique*, the distal rectal stump purse-string is placed by hand, and the assembled circular stapler is inserted into the anus and guided up to the rectal purse-string. The stapler is opened, and the distal purse-string is tied. A purse-string is placed in the distal end of the proximal colon; the proximal colon is placed over the anvil and the purse-string tightened. The stapler is closed and fired (Fig. 29-14). With the alternative *double-staple technique*, the distal rectum or anal canal is closed with a transverse staple line. The circular stapler is inserted through the anus without its anvil until the cartridge effaces the transverse staple line. The stapler is opened, causing the trocar to perforate through the rectal stump adjacent to the transverse staple line. The anastomosis is then completed as described earlier (see Fig. 29-11). If the stapler cannot advance to the end of the rectal stump, further dissection of the stump may be necessary to optimize tissue apposition. After firing and removing the stapler, the resulting anastomotic rings should be inspected to ensure that they are full-thickness and concentric, and in cases of rectal cancer, the distal anastomotic ring should be sent to pathology as a specimen (true distal margin). A gap in an anastomotic ring suggests that the circular staple line is incomplete and the anastomosis should be reinforced with suture circumferentially, if technically feasible. A temporary proximal ileostomy may be indicated as well. Most surgeons will also *leak test* an anastomosis by instilling water or saline into the pelvis and insufflating the rectum with air via a proctoscope to looking or alternatively instilling methylene blue or betadine into the rectum to look for extravasation. A leak test strongly suggests a defect and/or disruption of the anastomosis. As such, the suture should line reinforced and sometimes may require reanastomosis.²³

Ostomies and Preoperative Stoma Planning

Depending on the clinical situation, a stoma may be temporary or permanent. It may be end-on or a loop. However, regardless of the indication for a stoma, placement and construction are crucial for function.

The preoperative preparation of a patient who is expected to require a stoma should include a consultation with an *enterostomal therapy (ET) nurse*. ET nurses are specially trained and credentialed by the Wound, Ostomy, and Continence Nurses Society. Preoperative planning includes counseling, education, and stoma siting. Postoperatively, the ET nurse assists with local skin care and pouching. Other considerations in stoma planning include evaluation of other medical conditions that may impact on a patient's ability to manage a stoma (e.g., eyesight, manual

dexterity). Family or other caregivers can prove invaluable in caring for these patients.

Preoperative stoma siting is crucial for a patient's postoperative function and quality of life. A poorly placed stoma can result in leakage and skin breakdown. Ideally, a stoma should be placed in a location that the patient can easily see and manipulate, within the rectus muscle, and below the belt line (Fig. 29-15). Because the abdominal landmarks in a supine, anesthetized patient may be dramatically different from those in an awake, standing, or sitting patient, the stoma site should always be marked with a tattoo, skin scratch, or permanent marker preoperatively, if possible. In an emergency operation where the stoma site has not been marked, an attempt should be made to place a stoma within the rectus muscle and away from

Figure 29-14. Technique of end-to-end colorectal anastomosis using a circular stapler. **A.** The patient is in modified lithotomy position. **B.** After resection of the rectosigmoid and placement of purse-string sutures proximally and distally, the stapler is inserted into the anal canal and opened. **C.** Rectal purse-string suture is tied to secure the rectal stump to the rod of the stapler, and the colonic purse-string is tied to secure the colon to the anvil of the stapler. **D.** The stapler is closed and fired. **E.** The stapler is removed, leaving a circular stapled end-to-end anastomosis.

both the costal margin and iliac crest. In emergencies, placement high on the abdominal wall is preferred to a more caudal site.

For all stomas, a circular skin incision is created, and the subcutaneous tissue is dissected to the level of the anterior rectus sheath. The anterior rectus sheath is incised in a cruciate fashion, the muscle fibers separated bluntly, and the posterior sheath identified and incised. Care should be taken to avoid injuring and causing bleeding from the inferior epigastric artery and vein. The size of the defect depends on the size of the bowel used to create the stoma, but it should be as small as possible without compromising the intestinal blood supply (usually the width of two to three fingers). The bowel is then brought through the defect and secured with sutures. The abdominal incision is usually closed and dressed prior to maturing the stoma to avoid contaminating the wound. In order to make appliance use easier, a protruding nipple is fashioned by everting the bowel. Three or four interrupted absorbable sutures are placed through the edge of the bowel, then through the serosa, approximately 2 cm proximal to the edge, and then through the dermis (Brooke technique). After the stoma is everted, the mucocutaneous junction is sutured circumferentially with interrupted absorbable suture (Fig. 29-16).

Ileostomy

Temporary Ileostomy A temporary ileostomy is often used to “protect” an anastomosis that is at risk for leakage (low in the rectum, in an irradiated field, in an immunocompromised or malnourished patient, and during some emergency operations). In this setting, the stoma is often constructed as a *loop ileostomy* (see Fig. 29-12). A segment of distal ileum is brought through the defect in the abdominal wall as a loop. An enterotomy is created and the stoma matured as described earlier. The loop may be secured with or without an underlying rod. A *divided loop* may also be created by firing a linear cutting/stapler across the distal limb of the loop flush with the skin followed by maturation of the proximal limb of the loop. This technique prevents incomplete diversion that occasionally occurs with a loop ileostomy.

The advantage of a loop or divided loop ileostomy is that subsequent closure can often be accomplished without a formal laparotomy. An elliptical incision is created around the stoma and the bowel gently dissected free of the subcutaneous tissues and fascia. A hand-sewn or stapled anastomosis can then be created and the intestine returned to the peritoneal cavity. This

Figure 29-16. Brooke ileostomy. **A.** Four sutures incorporating the cut end of the ileum, the seromuscular layer at the level of the anterior rectus fascia, and the subcuticular edge of the skin are placed at 90° to each other. **B.** The sutures are tied to produce stomal eversion, and **(C)** simple sutures from the cut edge of the bowel to the subcuticular tissue complete the maturation of the ileostomy. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

avoids a long laparotomy incision and generally is well tolerated. The timing of ileostomy closure should take into account anastomotic healing as well as the patient's overall condition. A flexible endoscopy exam and a contrast enema (Gastrografin) are recommended prior to closure to ensure that the anastomosis has not leaked and is patent. A patient's nutritional status should be optimized. Because the timing of adjuvant chemotherapy affects survival, cancer patients receiving adjuvant chemotherapy usually should defer ileostomy closure until completion of treatment.

Permanent Ileostomy A permanent ileostomy is sometimes required after total proctocolectomy or in patients with obstruction. An *end ileostomy* is the preferred configuration for a permanent ileostomy because a symmetric protruding nipple can be fashioned more easily than with a loop ileostomy (see Fig. 29-16). The end of the small intestine is brought through the abdominal wall defect and matured. Stitches are often used to secure the bowel to the posterior fascia.

Complications of Ileostomy Stoma necrosis may occur in the early postoperative period and is usually caused by skeletonizing the distal small bowel and/or creating an overly tight fascial defect. Limited mucosal necrosis above the fascia may be treated expectantly, but necrosis below the level of the fascia requires surgical revision. Stoma retraction may occur early or late and may be exacerbated by obesity. Local revision may be necessary. The creation of an ileostomy bypasses the fluid-absorbing capability of the colon, and dehydration with fluid and electrolyte abnormalities is not uncommon. Ideally, ileostomy output should be maintained at less than 1500 mL/d to avoid this problem. Bulk agents and opioids (Lomotil, Imodium, tincture of opium) are useful. The somatostatin analogue, octreotide, has been used with varying success in this setting. Skin irritation can also occur, especially if the stoma appliance fits poorly. Skin-protecting agents and custom pouches can help to solve this problem. Obstruction may occur intra-abdominally or at the site where the stoma exits the fascia. Parastomal hernia is less common after an ileostomy than after a colostomy but can cause poor appliance fitting, pain, obstruction, or strangulation. In general, symptomatic parastomal hernias should be repaired. A variety of techniques to repair these hernias have been described, including local repair (either with or without mesh), laparoscopic repair, and stoma resiting. Prolapse is a rare, late complication and is often associated with a parastomal hernia.

Colostomy. Most colostomies are created as *end colostomies* rather than *loop colostomies* (Fig. 29-17). The bulkiness of the colon makes a loop colostomy awkward for use of an appliance, and prolapse is more likely with this configuration. Most colostomies are created on the left side of the colon. An abdominal wall defect is created and the end of the colon mobilized through it. Because a protruding stoma is considerably easier to pouch, colostomies should also be matured in a Brooke fashion. The distal bowel may be brought through the abdominal wall as a *mucus fistula* or left intra-abdominally as a *Hartmann's pouch*. Tacking the distal end of the colon to the abdominal wall or tagging it with permanent suture can make identification of the stump easier if the colostomy is closed at a later date. Closure of an end colostomy has traditionally required a laparotomy, but increasingly minimally invasive techniques have been adopted. The stoma is dissected free of the abdominal wall and the distal bowel identified. An end-to-end anastomosis is then created.

Figure 29-17. Intraperitoneal end colostomy.

Complications of Colostomy *Colostomy necrosis* may occur in the early postoperative period and results from an impaired vascular supply (skeletonization of the distal colon or a tight fascial defect). Like ileostomy necrosis, limited suprafascial necrosis may be followed expectantly, but necrosis below the fascia requires surgery. *Retraction* may also occur but is less problematic with a colostomy than with an ileostomy because the stool is less irritating to the skin than *succus entericus*. *Obstruction* is unusual, but may also occur. *Parastomal hernia* is the most common late complication of a colostomy and requires repair if it is symptomatic. *Prolapse* occurs rarely, but is more common with a loop colostomy. Interestingly, it is almost always the efferent limb of the loop that prolapses. Dehydration is rare after colostomy, and skin irritation is less common than with ileostomy.

Functional Results

Function following segmental colonic resection and primary anastomosis is generally excellent. A small percentage of patients following subtotal or total colectomy and ileosigmoid or ileorectal anastomosis may experience diarrhea and bowel frequency. This is especially true if the patient is elderly, if significant length of small bowel has been resected, and if residual proctocolitis is poorly controlled. In general, the more distal the anastomosis, the greater is the risk of troublesome diarrhea and frequency. However, some patients develop significant diarrhea after right colectomy due to malabsorption of bile acids; in these cases, bile acid binding resins (e.g., cholestyramine) sometimes can be helpful.

Function following anterior resection is highly dependent on the level of anastomosis, the use of pre- or postoperative pelvic radiation, and underlying sphincter function. Following low anterior or extended low anterior resection, some surgeons prefer to construct a short (5-cm) colon J-pouch to anastomose to the distal rectum or anal canal in order to increase the capacity of the neorectum. The reservoirs are thought to lessen urgency, frequency, and incontinence, but some patients have difficulty initiating defecation, and long-term superiority over a “straight” anastomosis has yet to be proven. In addition, these reservoirs can be technically difficult, especially in an obese male with a narrow pelvis.²⁰⁻²²

The physical and psychological problems associated with a permanent Brooke ileostomy led to development of the continent Kock pouch ileostomy. Unfortunately, complications, especially complications related to valve slippage, are common. Despite variations of technique designed to improve the function of the continent ileostomy, most surgeons have abandoned this operation and instead perform restorative proctocolectomy with ileal pouch–anal anastomosis.

Although ileal pouch–anal reconstruction is anatomically appealing, functional outcome is far from perfect.^{26,27} Patients should be counseled to expect 8 to 10 bowel movements per day. Up to 50% have some degree of nocturnal incontinence. Pouchitis (see the following paragraph) occurs in nearly 50% of patients who undergo the operation for chronic ulcerative colitis, and small bowel obstruction is not uncommon. Other less common complications include difficulties with pouch evacuation, pouch-perineal and/or pouch-vaginal fistula, and anal stricture. Pouch failure rate averages 5% to 10%. Patients who are subsequently diagnosed with Crohn’s disease have a considerably higher pouch failure rate (approximately 50%), whereas patients with indeterminate colitis have an intermediate pouch failure rate (15–20%). Despite these drawbacks, the vast majority of patients are satisfied and prefer ileal pouch–anal reconstruction to permanent ileostomy.^{26,27}

Pouchitis is an inflammatory condition that affects both ileoanal pouches and continent ileostomy reservoirs. The incidence of pouchitis ranges from 30% to 55%. Symptoms include increased diarrhea, hematochezia, abdominal pain, fever, and malaise. Diagnosis is made endoscopically with biopsies. Differential diagnosis includes infection and undiagnosed Crohn’s disease. The etiology of pouchitis is unknown. Some believe pouchitis results from fecal stasis within the pouch, but emptying studies are not confirmatory. Antibiotics (metronidazole ± ciprofloxacin) are the mainstays of therapy, and most patients will respond rapidly to either oral preparations or enemas. Some patients develop chronic pouchitis that necessitates ongoing suppressive antibiotic therapy. Salicylate and corticosteroid enemas have also been used with some success.²⁸⁻³¹ Biologic agents targeting TNF α (infliximab, vedolizumab, ustekinumab) are also being studied.³²⁻³⁴ Reintroduction of normal flora by ingestion of *probiotics* and/or an elemental diet have been suggested as a possible treatment in refractory cases. Occasionally, pouch excision is necessary to control the symptoms of chronic pouchitis.³⁰

Anesthesia Considerations

Local Anesthesia. Many anorectal procedures can be performed with local anesthetic alone. Intravenous sedation is often provided to calm the patient. Injection of 0.5% lidocaine (short acting) and 0.25% bupivacaine (long acting) into the perianal skin, sphincter, and area around the pudendal nerves usually provides an adequate block. The addition of dilute epinephrine decreases bleeding and prolongs the anesthetic effect.

Regional Anesthesia. Epidural, spinal, and caudal anesthetics can be used for anorectal procedures and transanal resections. In patients with severe medical comorbidity, regional anesthesia may occasionally be used for laparotomy and colectomy. Postoperative epidural anesthesia provides excellent pain relief and improves pulmonary function especially after an open operation.

General Anesthesia. General anesthesia is required for the vast majority of intra-abdominal procedures. Patients should

undergo a thorough preoperative cardiovascular evaluation. In patients with significant comorbid disease, an anesthesia consultation may be appropriate.

Positioning. Most abdominal colectomies can be performed in the supine position. Anterior resection and APR require lithotomy positioning to facilitate the pelvic dissection and mobilization of the splenic flexure. Adequate padding should be provided for the patient's sacrum, and care should be taken to avoid stirrup pressure on the peroneal nerves.

Anorectal procedures may be performed in lithotomy or in the prone jackknife position. Some surgeons prefer the prone jackknife position because exposure may be better, especially for anterior lesions. Distal posterior lesions can usually be accessed from either position, but more proximal posterior lesions are better accessed in the prone position.

Operative Preliminaries

Bowel Preparation. The rationale for bowel preparation is that decreasing the bacterial load in the colon and rectum will decrease the incidence of postoperative infection. *Mechanical bowel preparation* uses cathartics to rid the colon of solid stool the night before surgery. The most commonly used regimens include polyethylene glycol (PEG) solutions or magnesium citrate. PEG solutions require patients to drink a large volume of fluid and may cause bloating and nausea. Magnesium citrate solutions are generally better tolerated but are more likely to cause fluid and electrolyte abnormalities. Both are equally efficacious in bowel cleansing. Preparatory formulations have been recently introduced in tablet form in an attempt to improve tolerance. However, these methods of bowel cleansing require ingestion of 40 or more tablets with water over several hours. To date, these formulations have not been proven to be superior to the more traditional products. *Antibiotic prophylaxis* also is recommended. The addition of oral antibiotics to the preoperative mechanical bowel preparation has been thought to decrease postoperative infection by further decreasing the bacterial load of the colon. A recent analysis of the Surgical Care Improvement Project-1 (SCIP-1) suggests that oral antibiotics reduce postoperative wound infection, especially if a mechanical bowel preparation is not used.³⁵⁻³⁷

Longstanding, convincing data support the efficacy of parenteral antibiotic prophylaxis at the time of surgery. Broad-spectrum parenteral antibiotic(s) with activity against aerobic and anaerobic enteric pathogens should be administered just prior to the skin incision and redosed as needed depending on the length of the operation. There is no proven benefit to using antibiotics postoperatively after an uncomplicated colectomy.

Despite widespread use of mechanical bowel preparation, the necessity of bowel cleansing prior to colectomy has been questioned. European surgeons in particular have advocated abandoning this practice. Arguments against mechanical bowel preparation include dehydration and electrolyte abnormalities that often result from bowel cleansing, as well as the risk of spillage of liquid stool left over from the "prep." Arguments in favor of mechanical bowel preparation included easier manipulation of an "empty" colon (especially in minimally invasive procedures) and avoidance of a "stool column" above an anastomosis, especially in the pelvis. Interestingly, a recent meta-analysis of 14 randomized controlled trials suggested that mechanical bowel preparation does *not* prevent surgical site infection and should be abandoned in clinical practice.

However, these studies did not include the use of oral antibiotics in the mechanical preparation groups, and further studies will be needed to determine the optimal preparation regimen.³⁵⁻³⁷

Ureteral Stents. Ureteral stents may be useful for identifying the ureters intraoperatively and are placed via cystoscopy after the induction of general anesthesia and removed at the end of the operation. Stents can be invaluable during reoperative pelvic surgery or when there is significant retroperitoneal inflammation (such as complicated diverticulitis), as well as in obese patients. Lighted stents may be helpful in laparoscopic and robotic resections. Patients often have transient hematuria postoperatively, but major complications are rare.

Multidisciplinary Teams. Patients with complex colorectal disease often benefit from a multidisciplinary approach to their care. Patients with pelvic floor disorders (especially incontinence) often require evaluation by both a colorectal surgeon and a urologist or urogynecologist. Preoperative evaluation of cancer patients by a medical oncologist and/or radiation oncologist is crucial for planning either neoadjuvant or adjuvant therapy. Intraoperatively, complex pelvic resections often require the involvement of not only a colorectal surgeon but also a urologist, gynecologic oncologist, neurosurgeon, and/or plastic surgeon. Radiation oncologists should be involved in the operation if brachytherapy catheters are to be placed for intracavitary radiation or if intraoperative radiation therapy is planned. Rarely, psychiatric disorders may manifest as colorectal problems (especially functional disorders and chronic pain), and involvement of a psychiatrist or psychologist may be beneficial.

INFLAMMATORY BOWEL DISEASE

General Considerations

Epidemiology. Inflammatory bowel disease includes *ulcerative colitis*, *Crohn's disease*, and *indeterminate colitis*. *Ulcerative colitis* occurs in 8 to 15 people per 100,000 in the United States and Northern Europe. The incidence is considerably lower in Asia, Africa, and South America, and among the nonwhite population in the United States. *Ulcerative colitis* incidence peaks during the third decade of life and again in the seventh decade of life. The incidence of Crohn's disease is slightly lower, 1 to 5 people per 100,000. Crohn's disease also affects Northern European and Caucasian populations disproportionately. Crohn's disease has a similar bimodal incidence, with most cases occurring between ages 15 to 30 years and ages 60 to 70 years.³⁸ In 15% of patients with inflammatory bowel disease, differentiation between ulcerative colitis and Crohn's colitis is impossible; these patients are classified as having *indeterminate colitis*.

Etiology. Inflammatory bowel disease is a multifactorial condition that includes environmental, genetic, and immune causal elements; the variation in disease distributions and severity, as well as the differential responses to medical therapy, reflect a complex pathophysiology that is not reducible to a single cause. Nonetheless, there are several consistent observations among IBD populations that allow some degree of generalization. The consistent differences in IBD incidence between different geographic regions strongly suggest that environmental factors such as diet and exposure to microorganisms have a causal role. Alcohol and oral contraceptive use have also been implicated, as has tobacco use, in the etiology and exacerbation of Crohn's disease.

IBD is a genetic disease, though one that is polygenic, explaining why IBD frequently affects multiple family members across more than one generation, while also explaining the large number of genes implicated in the development of IBD. Most of the data on the genetics of IBD focus on Crohn's disease. Although ulcerative colitis has an association with at least 20 genetic loci based on genome-wide association studies (GWAS), this form of IBD has a weaker genetic link than does Crohn's disease. Approximately 10% to 30% of IBD patients will have at least one other family member also affected by IBD.^{39,40} Additionally, there is 50% disease concordance among monozygotic twins and a 10% disease concordance among dizygotic twins.⁴¹

Many of the genetic variants most consistently associated with IBD involve loci involved in innate immune function. These include NOD2 (nucleotide-binding oligomerization domain-containing protein 2), which is located on chromosome 16 and which is responsible for coordinating the function of several genes leading to the production of proinflammatory cytokines in response to gut microbes. This genetic variant is arguably the most strongly associated with IBD, being strongly connected with Crohn's disease, although it is also associated with severe pouchitis in patients with a history of ulcerative colitis.^{42,43}

The *ATG16L1* gene is located on chromosome 2, and its product is involved in the immune response to muramyl dipeptide, a component of both gram-positive and gram-negative bacteria that is recognized by the immune system. A related gene, *IRGM*, is located on chromosome 5, and its product is pivotal in the interferon-gamma-mediated clearance of intracellular pathogens. Variants in this gene are associated with a higher incidence of ileocolic resections in Crohn's disease patients.⁴²⁻⁴⁴

Patients with IBD appear to have a chronic immune dysregulation, which may lead to an interplay with gut microbes which are also present in non-IBD patients, but which elicit pathologic immune responses in the IBD population leading to chronic, idiopathic inflammation of the alimentary tract. Bacteria such as *Mycobacterium paratuberculosis* and *Listeria monocytogenes*, as well as viruses such as paramyxovirus and measles virus, have been suggested as having a role in the development of Crohn's disease. With the decreased cost of sequencing and with the expansion of reference databases for identification of organisms, microbiome studies have been applied to the study of IBD patients, both to learn about the pathogenesis of IBD as well as for disease prognostication. Recent studies have identified an abundance of *Serratia marcescens*, *E coli*, and *Candida tropicalis* in the guts of patients with Crohn's disease. In a study of 543 stool samples, patients with ulcerative colitis and primary sclerosing cholangitis (PSC) demonstrated a distinct bacterial community structure, with an enrichment of bacteria belonging to the *Veillonella* genus, which is associated with several diseases characterized by inflammation and fibrosis.⁴⁵⁻⁴⁹

A defect in the gut mucosal barrier, which increases exposure to intestinal microbes as well as proinflammatory substances, is a potential etiologic factor related to immune dysregulation. An autoimmune mechanism has also been postulated. Although there is no clear evidence linking an immunologic disorder to inflammatory bowel disease, the similarity of many of the extraintestinal manifestations to rheumatologic disorders has made this theory attractive. In summary, IBD is primarily characterized by intestinal inflammation, and medical therapy is focused on reducing or preventing that inflammation.⁴⁵⁻⁴⁹

Pathology and Differential Diagnosis. Although ulcerative colitis and Crohn's colitis share many pathologic and clinical similarities, these conditions can be differentiated in 85% of patients. Ulcerative colitis is a mucosal process in which the colonic mucosa and submucosa are infiltrated with inflammatory cells. The mucosa may be atrophic, and crypt abscesses are common. Endoscopically, the mucosa is frequently friable and may possess multiple inflammatory pseudopolyps. In long-standing ulcerative colitis, the colon may be foreshortened and the mucosa replaced by scar. In quiescent ulcerative colitis, the colonic mucosa may appear normal both endoscopically and microscopically. Ulcerative colitis may affect the rectum (proctitis), rectum and sigmoid colon (proctosigmoiditis), rectum and left colon (left-sided colitis), or the rectum and varying lengths of colon extending proximal to the splenic flexure (pancolitis). Ulcerative colitis does not primarily affect the small intestine, but the terminal ileum may demonstrate inflammatory changes ("backwash ileitis"). A key feature of ulcerative colitis is the continuous involvement of the rectum and colon; rectal sparing or skip lesions suggest a diagnosis of Crohn's disease. Symptoms are related to the degree of mucosal inflammation and the extent of colitis. Patients typically complain of bloody diarrhea and crampy abdominal pain. Proctitis may produce tenesmus. Severe abdominal pain and fever raise the concern of *fulminant colitis* or *toxic megacolon*. Physical findings are nonspecific and range from minimal abdominal tenderness and distention to frank peritonitis. In the nonemergent setting, the diagnosis is typically made by colonoscopy and mucosal biopsy.

In contrast to ulcerative colitis, Crohn's disease is a transmural inflammatory process that can affect any part of the gastrointestinal tract from mouth to anus. Mucosal ulcerations, an inflammatory cell infiltrate, and noncaseating granulomas are characteristic pathologic findings. Chronic inflammation may ultimately result in fibrosis, strictures, and fistulas in either the colon or small intestine. The endoscopic appearance of Crohn's colitis is characterized by deep serpiginous ulcers and a "cobblestone" appearance. Skip lesions and rectal sparing are common. Symptoms of Crohn's disease depend on the severity of inflammation and/or fibrosis and the location of inflammation in the gastrointestinal tract. Acute inflammation may produce diarrhea, crampy abdominal pain, and fever. Strictures may produce symptoms of obstruction. Weight loss is common, both because of obstruction and from protein loss. Perianal Crohn's disease may present with pain, swelling, and drainage from fistulas or abscesses. Physical findings are also related to the site and severity of disease.

In 15% of patients with colitis from inflammatory bowel disease, differentiation of ulcerative colitis from Crohn's colitis is impossible either grossly or microscopically (indeterminate colitis).⁵⁰ These patients typically present with symptoms similar to ulcerative colitis. Endoscopic and pathologic findings usually include features common to both diseases. Increasingly, serologic markers have been employed to differentiate ulcerative colitis from Crohn's disease. The anti-Saccharomyces cerevisiae antibody (ASCA) and perinuclear anticytoplasmic antibody (pANCA) may be useful in differentiating these two processes but require prospective study.⁵⁰ Further differential diagnoses include infectious colitides, especially cytomegalovirus (CMV), *Campylobacter jejuni*, *Entamoeba histolytica*, *toxigenic E Coli*, *C difficile*, *Neisseria gonorrhoeae*, *Salmonella*, and *Shigella* species.

Extraintestinal Manifestations. The liver is a common site of extracolonic disease in inflammatory bowel disease. Fatty infiltration of the liver is present in 40% to 50% of patients, and cirrhosis is found in 2% to 5%. Fatty infiltration may be reversed by medical or surgical treatment of colonic disease, but cirrhosis is irreversible. Primary sclerosing cholangitis is a progressive disease characterized by intra- and extrahepatic bile duct strictures. Forty percent to 60% of patients with primary sclerosing cholangitis have ulcerative colitis. Colectomy will not reverse this disease, and the only effective therapy is liver transplantation. Pericholangitis is also associated with inflammatory bowel disease and may be diagnosed with a liver biopsy. Bile duct carcinoma is a rare complication of long-standing inflammatory bowel disease. Patients who develop bile duct carcinoma in the presence of inflammatory bowel disease are, on average, 20 years younger than other patients with bile duct carcinoma.⁵¹

Arthritis also is a common extracolonic manifestation of inflammatory bowel disease, and the incidence is 20 times greater than in the general population. Arthritis usually improves with treatment of the colonic disease. Sacroiliitis and ankylosing spondylitis are associated with inflammatory bowel disease, although the relationship is poorly understood. Medical and surgical treatment of the colonic disease does not impact symptoms.⁵¹

Erythema nodosum is seen in 5% to 15% of patients with inflammatory bowel disease and usually coincides with clinical disease activity. Women are affected three to four times more frequently than men. The characteristic lesions are raised, red, and predominantly on the lower legs. Pyoderma gangrenosum is an uncommon but serious condition that occurs almost exclusively in patients with inflammatory bowel disease. The lesion begins as an erythematous plaque, papule, or bleb, usually located on the pretibial region of the leg and occasionally near a stoma. The lesions progress and ulcerate, leading to a painful, necrotic wound. Pyoderma gangrenosum may respond to resection of the affected bowel in some patients. In others, this disorder is unaffected by treatment of the underlying bowel disease. One of the challenges in managing pyoderma is that this manifestation of IBD exhibits pathergy, where the disease will manifest and have its severity exacerbated by the creation of surgical-sites. Depending on the circumstances, a history or the presence of pyoderma should prompt consideration for avoidance of a stoma.⁵¹

Up to 10% of patients with inflammatory bowel disease will develop ocular lesions. These include uveitis, iritis, episcleritis, and conjunctivitis, as well as macular degenerative, hyperpigmented pigmented epithelium (CHRPE). They usually develop during an acute exacerbation of the inflammatory bowel disease. The etiology is unknown.⁵¹

Principles of Nonoperative Management. Medical therapy for inflammatory bowel disease focuses on decreasing inflammation and alleviating symptoms, and many of the agents used are the same for both ulcerative colitis and Crohn's disease. In general, mild to moderate flares may be treated in the outpatient setting. More severe signs and symptoms mandate hospitalization. Pancolitis generally requires more aggressive therapy than limited disease. Because ulcerative proctitis and proctosigmoiditis are limited to the distal large intestine, topical therapy with salicylate and/or corticosteroid suppositories and enemas can be extremely effective. Systemic therapy is rarely required in these patients.

Salicylates Sulfasalazine (Azulfidine), 5-acetyl salicylic acid (5-ASA), and related compounds are first-line agents in the medical treatment of mild to moderate inflammatory bowel disease. These compounds decrease inflammation by inhibition of cyclooxygenase and 5-lipoxygenase in the gut mucosa. They require direct contact with affected mucosa for efficacy. Multiple preparations are available for administration to different sites in the small intestine and colon (sulfasalazine, mesalamine [Pentasa, Asacol, Rowasa]).

Antibiotics Antibiotics are often used to decrease the intraluminal bacterial load in Crohn's disease. Metronidazole has been reported to improve Crohn's colitis and perianal disease, but the evidence is weak. Fluoroquinolones may also be effective in some cases. In the absence of fulminant colitis or toxic megacolon, antibiotics are not used to treat ulcerative colitis.

Corticosteroids Corticosteroids (either oral or parenteral) are a key component of treatment for an acute exacerbation of either ulcerative colitis or Crohn's disease. Corticosteroids are nonspecific inhibitors of the immune system, and 75% to 90% of patients will improve with the administration of these drugs. However, corticosteroids have a number of serious side effects, and use of these agents should be limited to the shortest course possible. In addition, corticosteroids should be used judiciously in children because of the potential adverse effect on growth. Failure to wean corticosteroids is a relative indication for surgery.

Because of the systemic effects of corticosteroids, an effort has been made to develop drugs that act locally and have limited systemic absorption. Agents such as budesonide, beclomethasone dipropionate, and tixocortol pivalate undergo rapid hepatic degradation that significantly decreases systemic toxicity. Budesonide is available as an oral preparation. Corticosteroid enemas provide effective local therapy for proctitis and proctosigmoiditis and have fewer side effects than systemic corticosteroids.

Immunomodulating Agents Azathioprine and 6-mercaptopurine (6-MP) are antimetabolite drugs that interfere with nucleic acid synthesis and thus decrease proliferation of inflammatory cells. These agents are useful for treating ulcerative colitis and Crohn's disease in patients who have failed salicylate therapy or who are dependent on, or refractory to, corticosteroids. It is important to note, however, that the onset of action of these drugs takes 6 to 12 weeks, and concomitant use of corticosteroids almost always is required.

Cyclosporine is an immunosuppressive agent that interferes with T-lymphocyte function. While cyclosporine is not routinely used to treat inflammatory bowel disease, up to 80% of patients with an acute flare of ulcerative colitis will improve with its use. However, the majority of these patients will ultimately require colectomy. Cyclosporine is also occasionally used to treat exacerbations of Crohn's disease, and approximately two-thirds of patients will note some improvement. Improvement is generally apparent within 2 weeks of beginning cyclosporine therapy. Long-term use of cyclosporine is limited by its significant toxicities (e.g., nephrotoxicity, hirsutism, gum hypertrophy).

Methotrexate is a folate antagonist that also has been used to treat inflammatory bowel disease. Although the efficacy of this agent is unproven, there are reports that more than 50% of patients will improve with administration of this drug.⁵²

Biologic Agents In an effort to improve treatment for steroid-refractory inflammatory bowel disease, a class of agents has been developed based on inhibition of tumor necrosis factor alpha (TNF- α). Intravenous infusion of these agents decreases inflammation systemically. Infliximab is a monoclonal antibody directed against TNF- α and was the first biologic agent used to treat Crohn's disease. More than 50% of patients with moderate to severe Crohn's disease will improve with infliximab therapy. Infliximab is a chimeric monoclonal antibody directed against TNF- α and it was the first biologic agent used to treat Crohn's disease. Based on the ACCENT I and II trials, infliximab was associated with a greater incidence of clinical remission, the ability to discontinue corticosteroids, and a longer length of remission compared to placebo.^{53,54} There are also multiple studies demonstrating an improvement in fistulizing perianal Crohn's disease, although studies define "improvement" in a variety of ways, some of which do not require fistula to completely involute.⁵³⁻⁵⁶

Because infliximab is a chimera partially consisting of mouse antibody, human antibodies directed against infliximab can mitigate the efficacy of this drug. For this reason, adalimumab and certolizumab, that have no nonhuman component, were developed. These two drugs can be administered by subcutaneous injection, allowing patients to self-administer these therapies and to avoid the cost and inconvenience of presenting to an infusion center. The ultimate goal of biologic agents, just as with other medical therapies for IBD, is mucosal healing.

The use of biologic agents for the treatment of ulcerative colitis is an area where opinions between gastroenterologists and surgeons are more divergent. Unlike in the case of Crohn's disease, there is a putative surgical cure for ulcerative colitis, which casts the risks of long-term immunosuppression in a different light than in the setting of Crohn's where there is no curative therapy available. For patients with moderate to severe ulcerative colitis not responding to other medical therapies, there is evidence supporting the use of infliximab (UC SUCCESS) and adalimumab (ULTRA I AND II). The use of infliximab as rescue therapy for inpatients with severe, steroid-dependent ulcerative colitis has more recently been investigated. Though gastroenterologists may view this intervention as maintenance therapy that begins in an inpatient setting only to be continued following hospital discharge, it is still unclear whether inpatient infliximab is even a reliable bridge to elective surgery. Many of the studies supporting inpatient rescue therapy with infliximab did not focus their analyses on patients with extensive (pan) colitis, the group at highest risk for requiring an unplanned admission due to a disease flare, and the subgroup of ulcerative colitis patients most likely to fail rescue therapy and to require colectomy.⁵⁷⁻⁶²

Whether the preoperative use of biologics is associated with a higher incidence of postoperative complications is a matter of contention. There are individual studies demonstrating a higher incidence of postoperative sepsis, intra-abdominal abscess and readmissions for patients undergoing ileocelectomy for Crohn's disease who also received preoperative infliximab within three months of surgery. Systematic reviews on this topic, primarily focusing on Crohn's disease, have concluded that perioperative infliximab may or may not be associated with a higher incidence of postoperative complications, with most of these complications being infectious in nature.⁶³

Nutrition Patients with inflammatory bowel disease are often malnourished. Abdominal pain and obstructive symptoms may

decrease oral intake. Diarrhea can cause significant protein loss. Ongoing inflammation produces a catabolic physiologic state. Parenteral nutrition should be strongly considered early in the course of therapy for either Crohn's disease or ulcerative colitis. The nutritional status of the patient also should be considered when planning operative intervention, and nutritional parameters such as serum albumin, prealbumin, and transferrin should be assessed. In extremely malnourished patients, especially those who are also being treated with corticosteroids, creation of a stoma is often safer than a primary anastomosis.

Ulcerative Colitis

Ulcerative colitis is a dynamic disease characterized by remissions and exacerbations. The clinical spectrum ranges from an inactive or quiescent phase to low-grade active disease to fulminant disease. The onset of ulcerative colitis may be insidious, with minimal bloody stools, or the onset can be abrupt, with severe diarrhea and bleeding, tenesmus, abdominal pain, and fever. The severity of symptoms depends on the degree and extent of inflammation. Although anemia is common, massive hemorrhage is rare. Physical findings are often nonspecific.

The diagnosis of ulcerative colitis is almost always made endoscopically. Because the rectum is invariably involved, proctoscopy may be adequate to establish the diagnosis. The earliest manifestation is mucosal edema, which results in a loss of the normal vascular pattern. In more advanced disease, characteristic findings include mucosal friability and ulceration. Pus and mucus may also be present. While mucosal biopsy is often diagnostic in the chronic phase of ulcerative colitis, biopsy in the acute phase will often reveal only nonspecific inflammation. Evaluation with colonoscopy or barium enema during an acute flare is contraindicated because of the risk of perforation.

Barium enema has been used to diagnose chronic ulcerative colitis and to determine the extent of disease. However, this modality is less sensitive than colonoscopy and may not detect early disease. In long-standing ulcerative colitis, the colon is foreshortened and lacks haustral markings ("lead pipe" colon). Because the inflammation in ulcerative colitis is purely mucosal, strictures are highly uncommon. Any stricture diagnosed in a patient with ulcerative colitis must be presumed to be malignant until proven otherwise.

Indications for Surgery. Indications for surgery in ulcerative colitis may be emergent or elective. Emergency surgery is required for patients with massive life-threatening *hemorrhage*, *toxic megacolon*, or *fulminant colitis* who fail to respond rapidly to medical therapy. Patients with signs and symptoms of fulminant colitis should be treated aggressively with bowel rest, hydration, broad-spectrum antibiotics, and parenteral corticosteroids. Colonoscopy and barium enema are contraindicated, and antidiarrheal agents should be avoided. Deterioration in clinical condition or failure to improve within 24 to 48 hours mandates surgery.

Indications for elective surgery include intractability despite maximal medical therapy and high-risk development of major complications of medical therapy such as aseptic necrosis of joints secondary to chronic steroid use. Elective surgery also is indicated in patients at significant risk of developing colorectal carcinoma. The risk of malignancy increases with pancolon disease and the duration of symptoms and is approximately 2% after 10 years, 8% after 20 years, and 18% after 30 years. Unlike sporadic colorectal cancers, carcinoma developing in the context of ulcerative colitis is more likely to arise from areas of

flat dysplasia and may be difficult to diagnose at an early stage. For this reason, it is recommended that patients with longstanding ulcerative colitis undergo colonoscopic surveillance with multiple (40–50), random biopsies to identify dysplasia before invasive malignancy develops. However, the adequacy of this type of screening is controversial. Recently, magnifying chromoendoscopy has been used to improve sensitivity. This technique uses topical dyes that are applied to the colonic mucosa at the time of endoscopy (Lugol's solution, methylene blue, indigo carmine, and others). These dyes highlight contrast between normal and dysplastic epithelium, allowing more precise biopsy of suspicious areas.^{64,65} Surveillance is recommended annually after 8 years in patients with pancolitis, and annually after 15 years in patients with left-sided colitis. Although low-grade dysplasia was long thought to represent minimal risk, more recent studies show that invasive cancer may be present in up to 20% of patients with low-grade dysplasia. For this reason, any patient with dysplasia should be advised to undergo proctocolectomy. Controversy exists over whether prophylactic proctocolectomy should be recommended for patients who have had chronic ulcerative colitis for greater than 10 years in the absence of dysplasia. Proponents of this approach note that surveillance colonoscopy with multiple biopsies samples only a small fraction of the colonic mucosa, and dysplasia and carcinoma are often missed. Opponents cite the relatively low risk of progression to carcinoma (approximately 2.4%) if all biopsies lack dysplasia. Neither approach has been shown definitively to decrease mortality from colorectal cancer.

Operative Management

Emergent Operation In a patient with fulminant colitis or toxic megacolon, total abdominal colectomy with end ileostomy (with or without a mucus fistula), rather than total proctocolectomy, is recommended. Although the rectum is invariably diseased, most patients improve dramatically after an abdominal colectomy, and this operation avoids a difficult and time-consuming pelvic dissection in a critically ill patient. Rarely, a loop ileostomy and decompressing colostomy may be necessary if the patient is too unstable to withstand colectomy. Definitive surgery may then be undertaken at a later date once the patient has recovered. Complex techniques, such as an ileal pouch–anal reconstruction, generally are contraindicated in the emergent setting. However, massive hemorrhage that includes bleeding from the rectum may necessitate proctectomy and creation of either a permanent ileostomy or an ileal pouch–anal anastomosis.

Elective Operation Elective resection for ulcerative colitis usually is performed for refractory inflammation and/or the risk of malignancy (dysplasia). Because of the risk of ongoing inflammation, the risk of malignancy, and the availability of restorative proctocolectomy, most surgeons recommend operations that include resection of the rectum. *Total proctocolectomy with end ileostomy* has been the “gold standard” for treating patients with chronic ulcerative colitis. This operation removes the entire affected intestine and avoids the functional disturbances associated with ileal pouch–anal reconstruction. Most patients function well physically and psychologically after this operation. *Total proctocolectomy with continent ileostomy (Kock's pouch)* was developed to improve function and quality of life after total proctocolectomy, but morbidity is significant, and restorative proctocolectomy is generally preferred today. Since its introduction in 1980, *restorative proctocolectomy with ileal pouch–anal anastomosis* has become the procedure

of choice for most patients who require total proctocolectomy but wish to avoid a permanent ileostomy (see Figs. 29-11 and 29-12).⁶⁶ Abdominal colectomy with ileorectal anastomosis may be appropriate for a patient with indeterminate colitis and rectal sparing.

Crohn's Disease

Similar to ulcerative colitis, Crohn's disease is characterized by exacerbations and remissions. Crohn's disease, however, may affect any portion of the intestinal tract, from mouth to anus. Diagnosis may be made by colonoscopy or esophagogastroduodenoscopy or by barium small bowel study or enema, depending on which part of the intestine is most affected. The presence of skip lesions is key in differentiating Crohn's colitis from ulcerative colitis, and rectal sparing occurs in approximately 40% of patients. The most common site of involvement of Crohn's disease is the terminal ileum and cecum (*ileocolic Crohn's disease*), followed by the small bowel, and then by the colon and rectum. Perianal and anal canal Crohn's disease manifest by complex anal fistulae and/or abscesses, anal ulcers, and large skin tags may be the initial site of presentation in up to 4% of cases.

Indications for Surgery. Because Crohn's disease is currently incurable and because it can affect any part of the gastrointestinal tract, the therapeutic rationale is fundamentally different from that of ulcerative colitis. Ulcerative colitis may be cured by removal of the affected intestinal segment (the colon and rectum). In Crohn's disease, it is impossible to remove all the at-risk intestine; therefore, surgical therapy is reserved for complications of the disease.

Crohn's disease may present as an *acute inflammatory* process or as a *chronic fibrotic* process. During the acute inflammatory phase, patients may present with intestinal inflammation complicated by fistulae and/or intra-abdominal abscesses. Maximal medical therapy should be instituted, including anti-inflammatory medications, bowel rest, and antibiotics. Parenteral nutrition should be considered if the patient is malnourished. Most intra-abdominal abscesses can be drained percutaneously with the use of CT scan guidance. Although the majority of these patients will ultimately require surgery to remove the diseased segment of bowel, these interventions allow the patient's condition to stabilize, nutrition to be optimized, and inflammation to decrease prior to embarking on a surgical resection. Once an operation is undertaken, fistulae generally require resection of the segment of bowel with active Crohn's disease; the secondary sites of the fistula are often otherwise normal and do not generally require resection after division of the fistula. Simple closure of the secondary fistula site usually suffices.

Chronic fibrosis may result in strictures in any part of the gastrointestinal tract. Because the fibrotic process is gradual, free perforation proximal to the obstructing stricture is rare. Chronic strictures almost never improve with medical therapy. Strictures may be treated with *resection* or *stricturoplasty*. Distal ileal strictures are sometimes amenable to colonoscopic balloon dilatation. Optimal timing for surgery should take into account the patient's underlying medical and nutritional status.

Once an operation is undertaken for Crohn's disease, several principles should guide intraoperative decision making. In general, a laparotomy for Crohn's disease should be performed through a *midline incision* because of the possible need for a stoma. *Laparoscopy* is also increasingly used in this setting. Because many patients with Crohn's disease often will require multiple operations, *the length of bowel removed should be*

minimized. Bowel should be resected to an area with *grossly normal margins*; frozen sections are not necessary. Finally, a primary anastomosis may be created safely if the patient is medically stable, nutritionally replete, and taking few immunosuppressive medications. *Creation of a stoma should be strongly considered* in any patient who is hemodynamically unstable, septic, malnourished, or receiving high-dose immunosuppressive therapy and among patients with extensive intra-abdominal contamination.

Ileocolic and Small Bowel Crohn's Disease. The terminal ileum and cecum are involved in Crohn's disease in up to 41% of patients; the small intestine is involved in up to 35% of patients. The most common indications for surgery are *internal fistula or abscess* (30–38% of patients) and *obstruction* (35–37% of

patients). *Psoas abscess* may result from ileocolic Crohn's disease. Sepsis should be controlled with percutaneous drainage of abscess(es) and antibiotics, if possible. Parenteral nutrition may be necessary in patients with chronic obstruction. The extent of resection depends on the amount of involved intestine. Short segments of inflamed small intestine and right colon should be resected and a primary anastomosis created if the patient is stable, nutrition is adequate, and immunosuppression is minimal. Isolated chronic strictures should also be resected. In patients with multiple fibrotic strictures that would require extensive small bowel resection, *stricturoplasty* is a safe and effective alternative to resection. Short strictures are amenable to a transverse stricturoplasty, while longer strictures may be treated with a side-to-side small bowel anastomosis (Fig. 29-18).

Figure 29-18. Alternative stricturoplasty techniques. **A.** A short stricture is opened along the antimesenteric surface of the bowel wall. **B.** The enterotomy is closed transversely. **C.** A long stricture is opened along the antimesenteric surface of the bowel wall. **D.** The bowel is folded into an inverted “U.” **E.** A side-to-side anastomosis is made. (Reproduced with permission from Corman ML. *Colon & Rectal Surgery*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1989.)

Risk of recurrence after resection for ileocolic and small bowel Crohn's disease is high. More than 50% of patients will experience a recurrence within 10 years, and the majority of these will require a second operation.

Crohn's Colitis. Crohn's disease of the large intestine may present as *fulminant colitis* or *toxic megacolon*. In this setting, treatment is identical to treatment of fulminant colitis and toxic megacolon secondary to ulcerative colitis. Resuscitation and medical therapy with bowel rest, broad-spectrum antibiotics, and parenteral corticosteroids should be instituted. If the patient's condition worsens or fails to rapidly improve, total abdominal colectomy with end ileostomy is recommended. An elective proctectomy may be required if the patient has refractory Crohn's proctitis. Alternatively, if the rectum is spared, an ileorectal anastomosis may be appropriate once the patient has recovered.

Other indications for surgery in chronic Crohn's colitis are *intractability*, *complications of medical therapy*, and *risk of or development of malignancy*. Unlike ulcerative colitis, Crohn's colitis may be segmental, and rectal sparing is often observed. A segmental colectomy may be appropriate if the remaining colon and/or rectum appear normal. An isolated colonic stricture may also be treated by segmental colectomy. Although it was long thought that Crohn's disease did not increase the risk of colorectal carcinoma, it is now recognized that Crohn's colitis (especially pancolitis) carries nearly the same risk for cancer as ulcerative colitis. Annual surveillance colonoscopy with multiple biopsies is recommended for patients with long-standing Crohn's colitis (>7 years in duration). As in ulcerative colitis, dysplasia is an indication for total proctocolectomy. Ileal pouch–anal reconstruction is not recommended in these patients because of the risk for development of Crohn's disease within the pouch and the high risk of complications, such as fistula, abscess, stricture, pouch dysfunction, and pouch failure.

Anal and Perianal Crohn's Disease. Anal and perianal manifestations of Crohn's disease are very common and occur in 35% of all patients with Crohn's disease. Isolated anal Crohn's disease is uncommon, affecting only 3% to 4% of patients. Detection of anal Crohn's disease, therefore, should prompt evaluation of the remainder of the gastrointestinal tract.

The most common perianal lesions in Crohn's disease are *skin tags* that are minimally symptomatic. *Fissures* are also common. Typically, a fissure from Crohn's disease is particularly deep or broad and perhaps better described as an anal ulcer. These fissures are often multiple and located in a lateral position rather than anterior or posterior midline as seen in an idiopathic fissure in ano. A classic-appearing fissure in ano located laterally should raise the suspicion of Crohn's disease. *Perianal abscess and fistulas* are common and can be particularly challenging. Fistulas tend to be complex and often have multiple tracts (Fig. 29-19). *Hemorrhoids* are not more common in patients with Crohn's disease than in the general population, although many patients tend to attribute any anal or perianal symptom to "hemorrhoids."

Treatment of anal and perianal Crohn's disease focuses on alleviation of symptoms. Perianal skin irritation from diarrhea often responds to medical therapy directed at small bowel or colonic disease. In general, skin tags and hemorrhoids should *not* be excised unless they are extremely symptomatic because of the risk of creating chronic, nonhealing wounds. Fissures may respond to local or systemic therapy; sphincterotomy

Figure 29-19. Photograph of a patient with multiple perianal fistulas secondary to Crohn's disease.

is relatively contraindicated because of the risk of creating a chronic, nonhealing wound and because of the increased risk of incontinence in a patient with diarrhea from underlying colitis or small bowel disease. Anal ulcers associated with Crohn's disease are usually not very painful unless there is an underlying abscess. Thus, in patients with significant anal pain, an examination under anesthesia is indicated to exclude an underlying abscess or fistula and to assess the rectal mucosa. In the absence of active Crohn's proctitis, one can proceed cautiously with a partial internal sphincterotomy if the examination under anesthesia reveals a classic-appearing posterior or anterior fissure and anal stenosis.

Recurrent abscess(es) or complex anal fistulae should raise the possibility of Crohn's disease. Treatment focuses on *control of infection*, *delineation of complex anatomy*, *treatment of underlying mucosal disease*, and *sphincter preservation*. Abscesses often can be drained locally, and mushroom catheters are useful for maintaining drainage. Endoanal ultrasound and pelvic MRI are useful for mapping complex fistulous tracts. Liberal use of setons can control many fistulas and avoid division of the sphincter. Many patients with anal Crohn's disease function well with multiple setons left in place for years. Endoanal advancement flaps may be considered for definitive therapy if the rectal mucosa is uninvolved but will not heal due to rectal inflammation. In 10% to 15% of cases, intractable perianal sepsis requires proctectomy.

Rectovaginal fistula can be a particularly difficult problem in these patients. A rectal or vaginal mucosal advancement flap may be used if the rectal mucosa appears healthy and scarring of the rectovaginal septum is minimal. Occasionally, proctectomy is the best option for women with highly symptomatic rectovaginal fistulae. Although proximal diversion is often employed to protect complex perianal reconstruction, there is no evidence that diversion alone increases healing of anal and perianal Crohn's disease.

Medical treatment of underlying proctitis with salicylate and/or corticosteroid enemas may be helpful; however, control of infection is the primary goal of therapy. Metronidazole has been used with some success in this setting. Anti-TNF- α agents (infliximab and adalimumab) have shown some efficacy in healing chronic fistulas secondary to Crohn's disease. The success of these agents has led to a concerted effort to identify other

immunomodulators that might prove useful. Proinflammatory cytokines such as interleukin-12 and interferon- γ are potential targets. Inhibition of immune cell migration has also been suggested as an approach. However, it is of paramount importance to drain any and all abscesses before initiating immunosuppressive therapy such as corticosteroids or anti-TNF- α monoclonal antibodies.⁵⁴⁻⁵⁵

Indeterminate Colitis

Approximately 15% of patients with inflammatory bowel disease manifest clinical and pathologic characteristics of both ulcerative colitis and Crohn's disease. Endoscopy, barium enema, and biopsy may be unable to differentiate ulcerative colitis from Crohn's colitis in this setting. The indications for surgery are the same as those for ulcerative colitis: *intractability, complications of medical therapy, and risk of or development of malignancy*. In the setting of indeterminate colitis in a patient who prefers a sphincter-sparing operation, a *total abdominal colectomy with end ileostomy* may be the best initial procedure. Pathologic examination of the entire colon may then allow a more accurate diagnosis. If the diagnosis suggests ulcerative colitis, an ileal pouch–anal anastomosis procedure can be performed. If the diagnosis remains in question, the safest surgical option is completion proctectomy with end ileostomy (similar to Crohn's colitis). Ileal pouch–anal reconstruction may also be considered with the understanding that the pouch failure rate is between 15% and 20%.⁵⁰

DIVERTICULAR DISEASE

Diverticular disease is a clinical term used to describe the presence of symptomatic diverticula. *Diverticulosis* refers to the presence of diverticula without inflammation. *Diverticulitis* refers to inflammation and infection associated with diverticula. The majority of colonic diverticula are *false diverticula* in which the mucosa and muscularis mucosa have herniated through the colonic wall. These diverticula occur between the teniae coli, at points where nutrient arterial blood vessels penetrate the colonic wall (presumably creating an area of relative weakness in the colonic muscle). They are thought to be *pulsion diverticula* resulting from high intraluminal pressure. *Diverticular bleeding* can be massive but usually is self-limited. *True diverticula*, which comprise all layers of the bowel wall, are rare and are usually congenital in origin.

Diverticulosis is extremely common in the United States and Europe. It is estimated that half of the population older than age 50 years has colonic diverticula. The sigmoid colon is the most common site of diverticulosis (Fig. 29-20). Diverticulosis is thought to be an acquired disorder, but the etiology is poorly understood. The most accepted theory is that a lack of dietary fiber results in smaller stool volume, requiring high intraluminal pressure and high colonic wall tension for propulsion. Chronic contraction then results in muscular hypertrophy and development of the process of segmentation in which the colon acts like separate segments instead of functioning as a continuous tube. As segmentation progresses, the high pressures are directed radially toward the colon wall rather than to development of propulsive waves that move stool distally. The high radial pressures directed against the bowel wall create *pulsion diverticula*. A loss of tensile strength and a decrease in elasticity of the bowel wall with age have also been proposed etiologies. Although none of these theories has been proven, a high-fiber diet does appear to

Figure 29-20. Diverticulosis of sigmoid colon on barium enema. (Reproduced with permission from James EC, Corry RJ, Perry JCF: Basic Surgical Practice. Philadelphia, PA: Hanley & Belfus; 1987.)

decrease the incidence of diverticulosis. Although diverticulosis is common, most cases are asymptomatic, and complications occur in the minority of people with this condition.

Inflammatory Complications (Diverticulitis)

Diverticulitis refers to inflammation and infection associated with a diverticulum and is estimated to occur in 10% to 25% of people with diverticulosis. Peridiverticular and pericolic infection results from a perforation (either macroscopic or microscopic) of a diverticulum, which leads to contamination, inflammation, and infection. The spectrum of disease ranges from mild, uncomplicated diverticulitis that can be treated in the outpatient setting, to free perforation and diffuse peritonitis that requires emergency laparotomy. Most patients present with left-sided abdominal pain, with or without fever, and leukocytosis. A mass may be present. Plain radiographs are useful for detecting free intra-abdominal air. CT scan is extremely useful for defining pericolic inflammation, phlegmon, or abscess. Contrast enemas and/or endoscopy are relatively contraindicated because of the risk of perforation. The differential diagnosis includes malignancy, ischemic colitis, infectious colitis, and inflammatory bowel disease.

Uncomplicated Diverticulitis. *Uncomplicated diverticulitis* is characterized by left lower quadrant pain and tenderness. CT findings include pericolic soft tissue stranding, colonic wall thickening, and/or phlegmon. Most patients with uncomplicated diverticulitis will respond to outpatient therapy with broad-spectrum oral antibiotics and a low-residue diet. Antibiotics should be continued for 7 to 10 days. About 10% to 20% of patients with more severe pain, tenderness, fever, and leukocytosis are treated in the hospital with parenteral antibiotics

and bowel rest. Most patients improve within 48 to 72 hours. Failure to improve may suggest abscess formation. CT can be extremely useful in this setting, and many pericolic abscesses can be drained percutaneously. Deterioration in a patient's clinical condition and the development of peritonitis are indications for laparotomy.

Most patients with uncomplicated diverticulitis will recover without surgery, and 50% to 70% will have no further episodes. It has long been believed that the risk of complications increases with recurrent disease. For this reason, elective sigmoid colectomy has often been recommended after the second episode of diverticulitis, especially if the patient has required hospitalization. Resection has often been recommended after the first episode in very young patients and is often recommended after the first episode of *complicated diverticulitis*. These general guidelines have been questioned in recent years, and more recent studies suggest that the risk of complications and/or need for emergent resection does *not* increase with recurrent disease. Moreover, the rate of complications is rare after elective surgery and recurrences do not increase the rate of complications. As such, the rate of resection in all patients, including young patients and those with complicated disease, has decreased.⁶⁷⁻⁷¹

Many surgeons now will not advise colectomy even after two documented episodes of diverticulitis assuming the patient is completely asymptomatic and that carcinoma has been excluded by colonoscopy. Immunosuppressed patients are generally still advised to undergo colectomy after a single episode of documented diverticulitis. Medical comorbidities should be considered when evaluating a patient for elective resection, and the risks of recurrent disease should be weighed against the risks of the operation.^{69,70} Because colon carcinoma may present in an identical fashion to diverticulitis (either complicated or uncomplicated), all patients must be evaluated for malignancy after resolution of the acute episode. Colonoscopy is recommended 4 to 6 weeks after recovery. Inability to exclude malignancy is another indication for resection.

In the elective setting, a *sigmoid colectomy with a primary anastomosis* is the procedure of choice. The resection should always be extended to the rectum distally because the risk of recurrence is high if a segment of sigmoid colon is retained.

The proximal extent of the resection should include all thickened or inflamed bowel; however, resection of all diverticula is unnecessary. Increasingly, laparoscopy is being used for elective sigmoid colectomy for diverticular disease.

Complicated Diverticulitis. *Complicated diverticulitis* includes diverticulitis with abscess, obstruction, diffuse peritonitis (free perforation), or fistulas between the colon and adjacent structures. Colovesical, colovaginal, and coloenteric fistulas are long-term sequelae of complicated diverticulitis. The *Hinchey staging system* is often used to describe the severity of complicated diverticulitis: Stage I includes colonic inflammation with an associated pericolic abscess; stage II includes colonic inflammation with a retroperitoneal or pelvic abscess; stage III is associated with purulent peritonitis; and stage IV is associated with fecal peritonitis. Treatment depends on the patient's overall clinical condition and the degree of peritoneal contamination and infection. Small abscesses (<2 cm in diameter) may be treated with parenteral antibiotics. Larger abscesses are best treated with CT-guided percutaneous drainage (Fig. 29-21) and antibiotics.⁷² Many of these patients will ultimately require resection, but percutaneous drainage may allow a one-stage, elective procedure and may obviate the need for colectomy if full recovery follows the drainage.

Urgent or emergent laparotomy may be required if an abscess is inaccessible to percutaneous drainage, if the patient's condition deteriorates or fails to improve, or if the patient presents with free intra-abdominal air or peritonitis. In almost all cases, an attempt should be made to resect the affected segment of bowel. Patients with small, localized pericolic or pelvic abscesses (Hinchey stages I and II) may be candidates for a sigmoid colectomy with a primary anastomosis (a one-stage operation). Among patients with larger abscesses, peritoneal soiling, or peritonitis, sigmoid colectomy with end colostomy and Hartmann's pouch is the most commonly used procedure.⁷¹ Success also has been reported after sigmoid colectomy, primary anastomosis, with or without on-table lavage, and proximal diversion (loop ileostomy). This option may be appropriate in stable patients and offers the great advantage that the subsequent operation to restore bowel continuity is simpler than is

A

B

takedown of a Hartmann's pouch. The presence of inflammation and phlegmon may increase the risk of ureteral damage during mobilization of the sigmoid colon, and preoperative placement of ureteral catheters can be invaluable. In extremely unstable patients, or in the presence of such severe inflammation that resection would harm adjacent organs, proximal diversion and local drainage have been employed. However, this approach is generally avoided because of high morbidity and mortality rates, along with the requirement for multiple operations. More recently, several studies have suggested that laparoscopic lavage and drainage without bowel resection may be safe and effective even in the presence of free perforation. However, a 20% risk of surgical reoperation can be expected.^{73,74}

Obstructive symptoms occur in approximately 67% of patients who develop acute diverticulitis, and complete obstruction occurs in 10%. Patients with incomplete obstruction often respond to fluid resuscitation, nasogastric suction, and gentle, low-volume water or Gastrografin enemas. Relief of obstruction allows full bowel preparation and elective resection. A high-volume oral bowel preparation is contraindicated in the presence of obstructive symptoms. Obstruction that does not rapidly respond to medical management mandates laparotomy. Sigmoid colectomy with end colostomy is the safest procedure to perform in this setting. However, colectomy and primary anastomosis, with or without on-table lavage (depending on extent of fecal load in the proximal colon), and proximal diversion may be appropriate if the patient is stable and the proximal and distal bowel appear healthy.

Approximately 5% of patients with complicated diverticulitis develop fistulas between the colon and an adjacent organ. *Colovesical* fistulas are most common, followed by *colovaginal* and *coloenteric* fistulas. *Colocutaneous* fistulas are a rare complication of diverticulitis. Two key points in the evaluation of fistulas are to *define the anatomy of the fistula* and *exclude other diagnoses*. Contrast enema and/or small bowel studies are extremely useful in defining the course of the fistula. CT scan can identify associated abscesses or masses. The differential diagnosis includes *malignancy*, *Crohn's disease*, and *radiation-induced fistulas*. While Crohn's disease and radiation injury may be suspected based on the patient's medical history, colonoscopy or sigmoidoscopy usually is required to rule out malignancy. In addition, in a patient who has received radiation therapy, a fistula must be considered to be recurrent cancer until proven otherwise. Once the anatomy of the fistula has been defined and other diagnoses excluded, operative management should include resection of the affected segment of the colon involved with diverticulitis (usually with a primary anastomosis) and simple repair of the secondarily involved organ. Suspicion of carcinoma may mandate a wider, en bloc resection.

Hemorrhage

Bleeding from a diverticulum results from erosion of the peridiverticular arteriole and may result in massive hemorrhage. Most significant lower gastrointestinal hemorrhage occurs in elderly patients in whom both diverticulosis and angiodysplasia are common. Consequently, the exact bleeding source may be difficult to identify. Fortunately, in 80% of patients, bleeding stops spontaneously. Clinical management should focus on resuscitation and localization of the bleeding site as described for lower gastrointestinal hemorrhage. Colonoscopy may occasionally identify a bleeding diverticulum that may then be treated with epinephrine injection or cautery. Angiography may

be diagnostic and therapeutic in this setting. In the rare instance in which diverticular hemorrhage persists or recurs, laparotomy and segmental colectomy may be required.

Giant Colonic Diverticulum

Giant colonic diverticula are extremely rare. Most occur on the antimesenteric side of the sigmoid colon. Patients may be asymptomatic or may present with vague abdominal complaints such as pain, nausea, or constipation. Plain radiographs may suggest the diagnosis. Barium enema is usually diagnostic. Complications of a giant diverticulum include perforation, obstruction, and volvulus. Resection of the involved colon and diverticulum is recommended.

Right-Sided Diverticula

The cecum and ascending colon infrequently are involved in diverticulosis coli. Even more uncommon is a true solitary diverticulum, which contains all layers of the bowel wall and is thought to be congenital in origin. Right-sided diverticula occur more often in younger patients than do left-sided diverticula and are more common in people of Asian descent than in other populations. Most patients with right-sided diverticula are asymptomatic. However, diverticulitis does occur occasionally. Because patients are young and present with right lower quadrant pain, they are often thought to suffer from acute appendicitis, and the diagnosis of right-sided diverticulitis is subsequently made in the operating room. If there is a single large diverticulum and minimal inflammation, a diverticulectomy may be performed, but an ileocecal resection is usually the preferred operation in this setting. Hemorrhage rarely occurs and should be treated in the same fashion as hemorrhage from a left-sided diverticulum.

ADENOCARCINOMA AND POLYPS

Incidence

Colorectal carcinoma is the most common malignancy of the gastrointestinal tract. Over 130,000 new cases are diagnosed annually in the United States, and more than 50,000 patients die of this disease each year, making colorectal cancer the third most lethal cancer in the United States.⁷⁵

The incidence is similar in men and women and has remained fairly constant over the past 20 years; however, the widespread adoption of current national screening programs is gradually decreasing the incidence of this common and lethal disease in people over 50 years of age. However, people younger than 50 have been experiencing and increase incidence and worse mortality.⁷⁵ Early detection and improvements in medical and surgical care are thought to be responsible for the decreasing mortality of colorectal cancer observed in recent years.

Epidemiology (Risk Factors)

Identification of risk factors for development of colorectal cancer is essential to establish screening and surveillance programs in appropriately targeted populations.

Aging. Aging is the dominant risk factor for colorectal cancer, with incidence rising steadily after age 50 years. More than 90% of cases diagnosed are in people older than age 50 years. This is the rationale for initiating screening tests of asymptomatic patients at average risk of developing colorectal cancer at age 50 years. However, individuals of any age can develop colorectal cancer, so symptoms such as a significant change in bowel

habits, rectal bleeding, melena, unexplained anemia, or weight loss require a thorough evaluation.

Hereditary Risk Factors. Approximately 80% of colorectal cancers occur sporadically, while 20% arise in patients with a known family history of colorectal cancer. Advances in the understanding of these familial disorders have led to interest in early diagnosis using genetic testing. Because of the medical, legal, and ethical considerations that are involved in this type of testing, all patients should be offered genetic counseling if a familial syndrome is suspected.

Environmental and Dietary Factors. The observation that colorectal carcinoma occurs more commonly in populations that consume diets high in animal fat and low in fiber has led to the hypothesis that dietary factors contribute to carcinogenesis. A diet high in saturated or polyunsaturated fats increases risk of colorectal cancer, while a diet high in oleic acid (olive oil, coconut oil, fish oil) does not increase risk. Animal studies suggest that fats may be directly toxic to the colonic mucosa and thus may induce early malignant changes. In contrast, a diet high in *vegetable fiber* appears to be protective. A correlation between alcohol intake and incidence of colorectal carcinoma has also been suggested. Ingestion of calcium; selenium; vitamins A, C, and E; carotenoids; and plant phenols may decrease the risk of developing colorectal cancer. Obesity and sedentary lifestyle dramatically increase cancer-related mortality in a number of malignancies, including colorectal carcinoma. This knowledge is the basis for primary prevention strategies to eliminate colorectal cancer by altering diet and lifestyle.⁷⁶

Inflammatory Bowel Disease. Patients with long-standing colitis from inflammatory bowel disease are at increased risk for the development of colorectal cancer. It is hypothesized that chronic inflammation predisposes the mucosa to malignant changes, and there is some evidence that degree of inflammation influences risk. In general, the duration and extent of colitis correlate with risk. Other factors thought to increase risk include the presence of primary sclerosing cholangitis and family history of colorectal cancer.

Other Risk Factors. Cigarette smoking is associated with an increased risk of colonic adenomas, especially after more than 35 years of use. Patients with ureterosigmoidostomy may also be at increased risk for both adenoma and carcinoma formation.⁷⁷

Acromegaly, which is associated with increased levels of circulating human growth hormone and insulin-like growth factor-1, increases risk as well. Pelvic irradiation may increase the risk of developing rectal carcinoma. However, it is unclear whether this represents a direct effect of radiation damage or is instead a correlation between the development of rectal cancer and a history of another pelvic malignancy; for example, among

patients who develop prostate cancer and are treated with radiation, the risk of rectal cancer increases significantly.⁷⁸

Pathogenesis of Colorectal Cancer

Genetic Defects. An intense research effort has focused on elucidating the genetic defects and molecular abnormalities associated with the development and progression of colorectal adenomas and carcinoma. Mutations may cause *activation of oncogenes (K-ras)* and/or *inactivation of tumor suppressor genes (APC, deleted in colorectal carcinoma [DCC], p53)*. Colorectal carcinoma is thought to develop from adenomatous polyps by accumulation of these mutations in what has come to be known as the *adenoma-carcinoma sequence* (Fig. 29-22).^{9,79}

Defects in the *APC* gene were first described in patients with Familial Adenomatous Polyposis (FAP). By investigating these families, characteristic mutations in the *APC* gene were identified. They are now known to be present in 80% of sporadic colorectal cancers as well.

The *APC* gene is a *tumor suppressor gene*. Mutations in both alleles are necessary to initiate polyp formation. The majority of mutations are premature stop codons, which result in a truncated *APC* protein. In FAP, the site of mutation correlates with the clinical severity of the disease. For example, mutations in either the 3' or 5' end of the gene result in attenuated forms of FAP (AFAP), whereas mutations in the center of the gene result in more virulent disease. Thus, knowledge of the specific mutation in a family may help guide clinical decision-making.¹⁰

APC inactivation alone does not result in a carcinoma. Instead, this mutation sets the stage for the accumulation of genetic damage that results in malignancy. Additional mutations may include activation or inactivation of a variety of genes.

One of the most commonly involved genes in colorectal cancer is *K-ras*. *K-ras*, a signaling molecule in the epidermal growth factor receptor (EGFR) pathway, is classified as a *proto-oncogene* because mutation of only one allele will perturb the cell cycle. The *K-ras* gene product is a G-protein involved in intracellular signal transduction. When active, *K-ras* binds guanosine triphosphate (GTP); hydrolysis of GTP to guanosine diphosphate (GDP) then inactivates the G-protein. Mutation of *KRAS* results in an inability to hydrolyze GTP, thus leaving the G-protein permanently in the active form. It is thought that this then leads to uncontrolled cell division. Because *K-ras* mutation results in uncontrolled downstream signaling, anti-EGFR agents are ineffective in treating *K-ras* mutant tumors. As such, *K-ras* mutation status is important in deciding when to utilize anti-EGFR therapies. Other EGFR signaling molecules such as *BRAF* have also been implicated in colorectal cancer pathogenesis and progression, and ongoing research is focusing on elucidating their roles in this disease.

Figure 29-22. Schematic showing progression from normal colonic epithelium to carcinoma of the colon.

Another common mutation occurs in the *MYH* gene on chromosome 1p. *MYH* is a base excision repair gene, and biallelic deletion results in changes in other downstream molecules. Since its discovery, *MYH* mutations have been associated with an AFAP phenotype in addition to sporadic cancers. Unlike *APC* gene mutations that are expressed in an autosomal dominant pattern, the requirement for biallelic mutation in *MYH* results in an autosomal recessive pattern of inheritance.^{80,81}

The tumor suppressor gene *p53* has been well characterized in a number of malignancies. The p53 protein appears to be crucial for initiating apoptosis in cells with irreparable genetic damage. Mutations in *p53* are present in 75% of colorectal cancers.

Deletion of the tumor suppressor phosphatase and tensin homolog (*PTEN*) appears to be involved in a number of hamartomatous polyposis syndromes. Deletions in *PTEN* have been identified in juvenile polyposis, Peutz-Jeghers syndrome, Cowden's syndrome, and *PTEN* hamartoma syndrome, in addition to multiple endocrine neoplasia type IIB. Peutz-Jeghers syndrome is also associated with mutation in *STK11*, a serine-threonine kinase gene. The genetic changes that underlie serrated polyposis syndrome(s) are currently poorly understood.⁹

Genetic Pathways. The mutations involved in colorectal cancer pathogenesis and progression are now recognized to accumulate via one of three major genetic pathways: the *loss of heterozygosity (LOH; chromosomal instability)* pathway, the *microsatellite instability (MSI)* pathway, and the *CpG island methylation (CIMP; serrated methylated)* pathway.

The Loss of Heterozygosity Pathway The LOH pathway is characterized by chromosomal deletions and tumor aneuploidy. Eighty percent of colorectal carcinomas appear to arise from mutations in the LOH pathway. This pathway was first described in patients with FAP in whom mutations of the *APC* gene were found to be inherited.

Another example of LOH occurs in the region of chromosome 18q. This region has been found to be deleted in up to 70% of colorectal cancers. Two tumor suppressor genes, *DCC* and *SMAD4*, are located in this region, and as such, *deletion of 18q* may result in the loss of one or both of these genes. *DCC* is a tumor suppressor gene, and loss of both alleles is required for malignant degeneration. The main role of this molecule appears to be in the central nervous system, where it is involved in neural differentiation and axonal migration. This observation has led to the hypothesis that *DCC* may be involved in differentiation and cellular adhesion in colorectal cancer, but this theory remains unproven. *DCC* mutations are present in more than 70% of colorectal carcinomas and may negatively impact prognosis. *SMAD4* functions in the signaling cascade of transforming growth factor beta and beta-catenin (also a downstream effector of the *APC* gene). Loss of either of these genes is thought to promote cancer progression.⁸²

The Microsatellite Instability Pathway. Many of the remaining colorectal carcinomas are thought to arise from mutations in the MSI pathway, which is characterized by errors in mismatch repair during DNA replication. These errors in mismatch repair were first described in Hereditary Nonpolyposis Colon Cancer (HNPCC; Lynch syndrome) Lynch 9, but are now recognized to be present in many sporadic tumors as well. A number of genes have been identified that appear to be crucial for recognizing and repairing DNA replication errors. These *mismatch repair genes* include *MSH2*, *MLH1*, *PMS1*, *PMS2*, and *MSH6/GTBP*.

A mutation in one of these genes predisposes a cell to mutations, which may occur in proto-oncogenes or tumor suppressor genes. Accumulation of these errors then leads to genomic instability and ultimately to carcinogenesis.

Microsatellites are regions of the genome in which short base-pair segments are repeated several times, regions that are particularly prone to replication error. Consequently, a mutation in a mismatch repair gene produces variable lengths of these repetitive sequences, a finding that has been described as MSI.

Tumors associated with MSI appear to have different biologic characteristics than do tumors that result from the LOH pathway. Tumors with MSI are more likely to be in the right colon and possess diploid DNA and are associated with a better prognosis than tumors that arise from the LOH pathway that are microsatellite stable. Tumors arising from the LOH pathway tend to occur in the more distal colon, often have chromosomal aneuploidy, and are associated with a poorer prognosis.

CpG Island Methylation Pathway In the CIMP pathway, genes do not accumulate mutations (deletions or insertions of bases), but instead are activated or inactivated by methylation. This process has been called *epigenetic alteration* to differentiate it from the more traditional genetic alterations or true mutations. In normal cells, methylation is critical for regulation of gene expression. In cancer, aberrant methylation (either hyper- or hypomethylation), usually of a promoter region, results in abnormal activation or inactivation of genes. This gene silencing or, alternatively, activation results in a phenotype similar to that present with a true gene mutation. This pathway has also been called the *serrated methylated pathway* because of the observation that *serrated polyps* often harbor aberrant methylation in contrast to adenomatous polyps that are more often associated with mutations in the *APC* gene (LOH pathway).⁸³

Although these classifications are useful for understanding the mechanisms underlying carcinogenesis, they are not mutually exclusive. For example, a mismatch repair gene may be inactivated by methylation. Errors in mismatch repair may then allow mutations to inactivate a tumor suppressor gene. In addition, there is considerable interest in targeting molecules in each of these pathways in order to design better anticancer agents. Finally, ongoing research is focusing on the utility of molecular profiling in predicting prognosis and/or response to treatment.¹⁰

Polyps

It is now well accepted that the majority of colorectal carcinomas evolve from adenomatous polyps; this sequence of events is the *adenoma-carcinoma sequence*. *Polyp* is a nonspecific clinical term that describes any projection from the surface of the intestinal mucosa regardless of its histologic nature. Colorectal polyps may be classified as *neoplastic (tubular adenoma, villous adenoma, tubulovillous adenomas, serrated adenomas/polyps)*, *hyperplastic*, *hamartomatous (juvenile, Peutz-Jeghers, Cronkite-Canada)*, or *inflammatory (pseudopolyp, benign lymphoid polyp)*.

Neoplastic Polyps. Adenomatous polyps are common, occurring in up to 25% of the population older than 50 years of age in the United States. By definition, these lesions are dysplastic. The risk of malignant degeneration is related to both the size and type of polyp. Tubular adenomas are associated with malignancy in only 5% of cases, whereas villous adenomas may harbor cancer in up to 40%. Tubulovillous adenomas are at intermediate risk (22%). Invasive carcinomas are rare in

polyps smaller than 1 cm; the incidence of invasive carcinoma increases with size. The risk of carcinoma in a polyp larger than 2 cm is 35% to 50%. Although most neoplastic polyps do not evolve to cancer, most colorectal cancers originate as a polyp. It is this fact that forms the basis for secondary prevention strategies to eliminate colorectal cancer by targeting the neoplastic polyp for removal before malignancy develops.

Polyps may be *pedunculated* or *sessile*. Most pedunculated polyps are amenable to colonoscopic snare excision. Removal of sessile polyps is often more challenging. Special colonoscopic techniques, including saline lift, piecemeal snare excision, and endoscopic mucosal resection facilitate successful removal of many sessile polyps. For rectal sessile polyps, transanal operative excision is preferred because it produces an intact, single pathology specimen that can be used to determine the need for further therapy. Interpretation of the precise depth of invasion of a cancer arising in a sessile polyp after piecemeal excision is often impossible. The site of sessile polypectomies should be marked by tattoo marking to guide subsequent endoscopic surveillance and to facilitate identification of the involved bowel segment should operative resection be necessary.⁸⁴ Colectomy is reserved for cases in which colonoscopic removal is impossible, such as large, flat lesions, or if a focus of invasive cancer is confirmed in the specimen.

Complications of polypectomy include *perforation* and *bleeding*. A small perforation (*microperforation*) in a fully prepared, stable patient may be managed with bowel rest, broad-spectrum antibiotics, and close observation. Signs of sepsis, peritonitis, or deterioration in clinical condition are indications for laparotomy. Bleeding may occur immediately after polypectomy or may be delayed. The bleeding will usually stop spontaneously, but colonoscopy may be required to apply endoscopic clips, resnare a bleeding stalk, cauterize the lesion, or inject/apply epinephrine. Occasionally angiography and infusion of vasopressin may be necessary. Rarely, colectomy is required.

Hyperplastic Polyps. Hyperplastic polyps are extremely common in the colon. These polyps are usually small (<5 mm) and show histologic characteristics of hyperplasia without any dysplasia. They are not considered premalignant, but they cannot be distinguished from adenomatous polyps colonoscopically and are therefore often removed. In contrast, large hyperplastic polyps (>2 cm) may have a risk of malignant degeneration. *Hyperplastic polyposis* is a rare disorder in which multiple large hyperplastic polyps occur in young adults. These patients are at increased risk for the development of colorectal cancer.

Serrated Polyps. Serrated polyps, including sessile serrated adenomas and traditional serrated adenomas, are a recently recognized, histologically distinct group of neoplastic polyps. Endoscopically they are flat lesions and frequently difficult to visualize. These lesions were long thought to be similar to hyperplastic polyps with minimal malignant potential. However, it has become clear that some of these polyps will develop into invasive cancers. In addition, a familial *serrated polyposis syndrome* has been described. Serrated polyps should be treated like adenomatous polyps.⁸⁵

Hamartomatous Polyps (Juvenile Polyps). In contrast to adenomatous and serrated polyps, hamartomatous polyps (juvenile polyps) usually are not premalignant. These lesions are the characteristic polyps of childhood but may occur at any age. Bleeding is a common symptom, and intussusception and/or obstruction may occur. Because the gross appearance of these

polyps is identical to adenomatous polyps, these lesions should also be treated by polypectomy. In contrast to adenomatous polyposis syndromes, these conditions are often associated with mutation in *BMPRIA* and *SMAD4*.

Familial juvenile polyposis is an autosomal dominant disorder in which patients develop hundreds of polyps in the colon and rectum. Unlike solitary juvenile polyps, these lesions may degenerate into adenomas and eventually carcinoma. Annual screening should begin between the ages of 10 and 12 years. Treatment is surgical and depends in part on the degree of rectal involvement. If the rectum is relatively spared, a total abdominal colectomy with ileorectal anastomosis may be performed with subsequent close surveillance of the retained rectum. If the rectum is carpeted with polyps, total proctocolectomy is the more appropriate operation. These patients are candidates for ileal pouch–anal reconstruction to avoid a permanent stoma.

Peutz-Jeghers syndrome is characterized by polyposis of the small intestine and, to a lesser extent, polyposis of the colon and rectum. Characteristic melanin spots are often noted on the buccal mucosa and lips of these patients. The polyps of Peutz-Jeghers syndrome are generally considered to be hamartomas and are not thought to be at significant risk for malignant degeneration. However, carcinoma may occasionally develop. Because the entire length of the gastrointestinal tract may be affected, surgery is reserved for symptoms such as obstruction or bleeding or for patients in whom polyps develop adenomatous features. Screening consists of a baseline colonoscopy and upper endoscopy at age 20 years, followed by annual flexible sigmoidoscopy thereafter. Clinicians should ensure patients are screened for associated extraintestinal malignancies (breast, upper gastrointestinal tract, pancreas, cervix, ovaries, and testicles).

Cronkite-Canada syndrome is a disorder in which patients develop gastrointestinal polyposis in association with alopecia, cutaneous pigmentation, and atrophy of the fingernails and toenails. Diarrhea is a prominent symptom, and vomiting, malabsorption, and protein-losing enteropathy may occur. Most patients die of this disease despite maximal medical therapy, and surgery is reserved for complications of polyposis such as obstruction.

Cowden's syndrome is an autosomal dominant disorder with hamartomas of all three embryonal cell layers. Facial trichilemmomas, breast cancer, thyroid disease, and gastrointestinal polyps are typical of the syndrome. Patients should be screened for cancers. Treatment is otherwise based on symptoms.

Inflammatory Polyps (Pseudopolyps). Inflammatory polyps occur most commonly in the context of inflammatory bowel disease, but they may also occur after amebic colitis, ischemic colitis, and schistosomal colitis. These lesions are not premalignant, but they cannot be distinguished from adenomatous polyps based on gross appearance and therefore should be removed. Microscopic examination shows islands of normal, regenerating mucosa (the polyp) surrounded by areas of mucosal loss. Polyposis may be extensive, especially in patients with severe colitis, and may mimic FAP.

Inherited Colorectal Carcinoma

Many of the genetic defects originally described in hereditary cancers have subsequently been found in sporadic tumors. Although the majority of colorectal cancer is sporadic, several hereditary syndromes provide paradigms for the study of this disease. Insight gained from studying inherited colorectal cancer

syndromes has led to better understanding of the genetics of colorectal carcinoma.

Familial Adenomatous Polyposis. This rare autosomal dominant condition accounts for only about 1% of all colorectal adenocarcinomas. Nevertheless, this syndrome has provided tremendous insight into the molecular mechanisms underlying colorectal carcinogenesis. The genetic abnormality in FAP is a mutation in the *APC* gene, located on chromosome 5q. Of patients with FAP, *APC* mutation testing is positive in 75% of cases. While most patients with FAP will have a known family history of the disease, up to 25% present without other affected family members. Clinically, patients develop hundreds to thousands of adenomatous polyps shortly after puberty. The lifetime risk of colorectal cancer in FAP patients approaches 100% by age 50 years.

Flexible sigmoidoscopy of first-degree relatives of FAP patients beginning at age 10 to 15 years has been the traditional mainstay of screening. Today, following genetic counseling, *APC* gene testing may be used to screen family members, providing an *APC* mutation has been identified. If *APC* testing is positive in a relative of a patient with a known *APC* mutation, annual flexible sigmoidoscopy beginning at age 10 to 15 years is done until polyps are identified. If *APC* testing is negative, the relative can be screened starting at age 50 years per average-risk guidelines. If *APC* testing is refused or unavailable, or if a mutation cannot be identified, annual flexible sigmoidoscopy beginning at age 10 to 15 years is performed until age 24 years. Screening flexible sigmoidoscopy is then done every 2 years until age 34 years, every 3 years until age 44 years, and then every 3 to 5 years.

FAP patients are also at risk for the development of adenomas anywhere in the gastrointestinal tract, particularly in the duodenum. Periampullary carcinoma is a particular concern. Upper endoscopy is therefore recommended for surveillance every 1 to 3 years beginning at age 25 to 30 years.

Once the diagnosis of FAP has been made and polyps are developing, treatment is surgical. Four factors affect the choice of operation: age of the patient; presence and severity of symptoms; extent of rectal polyposis; and presence and location of cancer or desmoid tumors. Three operative procedures can be considered: total proctocolectomy with an end (Brooke) ileostomy; total abdominal colectomy with ileorectal anastomosis; and restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA) with or without a temporary ileostomy. Most patients elect to have an ileal pouch–anal anastomosis in the absence of a distal rectal cancer, a mesenteric desmoid tumor that prevents the ileum from reaching the anus, or poor sphincter function. Mucosectomy has been advocated in patients with FAP undergoing ileal pouch–anal anastomosis because of the risk of neoplasia in the anal transition zone, but the requirement for this procedure remains controversial.^{86,87} Although patient satisfaction with IPAA remains high, function may not be ideal, and up to 50% of patients experience some degree of incontinence. Total abdominal colectomy with an ileorectal anastomosis is also an option in these patients, but requires vigilant surveillance of the retained rectum for development of rectal cancer. There is increasing data suggesting that the administration of cyclooxygenase-2 (COX-2) inhibitors (celecoxib, sulindac) may slow or prevent the development of polyps.^{88,89}

FAP may be associated with extraintestinal manifestations such as congenital hypertrophy of the retinal pigmented

epithelium, desmoid tumors, epidermoid cysts, mandibular osteomas (Gardner's syndrome), and central nervous system tumors (Turcot's syndrome). Although they arise in a minority of FAP patients, desmoid tumors in particular can make surgical management difficult and are a source of major morbidity and mortality in these patients. These lesions arise from fibroblasts, and although technically benign, can be highly locally invasive. These tumors often involve the bowel mesentery, pelvis, and abdominal wall. In some cases, surgery is thought to be the "trigger." Local recurrence after attempted resection is common; therefore, surgery is to be avoided if at all possible. Desmoid tumors are often hormone responsive, and growth may be inhibited in some patients with tamoxifen. COX-2 inhibitors and nonsteroidal, anti-inflammatory drugs may also be beneficial in this setting. A recent report suggests that imatinib may also be effective.^{90,91}

Attenuated Familial Adenomatous Polyposis. AFAP is a recognized variant of FAP. Patients present later in life with fewer polyps (usually 10–100) predominantly located in the right colon, when compared to classic FAP. Colorectal carcinoma develops in more than 50% of these patients, but occurs later (average age, 55 years). Patients are also at risk for duodenal polyposis. However, in contrast to FAP, *APC* gene mutations are present in only about 30% of patients with AFAP. When present, these mutations are expressed in an autosomal dominant pattern.

Mutations in *MYH* also result in the AFAP phenotype but are expressed in an autosomal recessive pattern. It has been suggested that *MYH* mutations may be responsible for AFAP in patients who do not have a detectable *APC* gene mutation.^{80,81}

Genetic testing is often offered to patients with suspected AFAP. When positive, genetic counseling and testing may be used to screen at-risk family members. If the family mutation is unknown, screening colonoscopy is recommended beginning at age 13 to 15 years, then every 4 years to age 28 years, and then every 3 years. These patients are often candidates for a total abdominal colectomy with ileorectal anastomosis because the limited polyposis in the rectum can usually be treated by colonoscopic snare excision.⁹² Prophylaxis with COX-2 inhibitors also may be appropriate. Because of the more subtle phenotype in these patients, it is important to rule out other familial syndromes such as HNPCC (Lynch syndrome) and the more common familial colorectal cancer.

Lynch Syndrome (Hereditary Nonpolyposis Colon Cancer; HNPCC). Lynch syndrome is more common than FAP, but it is still extremely rare (1–3% of all colon cancers). The genetic defects associated with Lynch syndrome arise from errors in *mismatch repair*, the phenotypic result being MSI. Lynch syndrome is inherited in an autosomal dominant pattern and is characterized by the development of colorectal carcinoma at an early age (average age, 40–45 years). Approximately 70% of affected individuals will develop colorectal cancer. Cancers appear in the proximal colon more often than in sporadic colorectal cancer and have a better prognosis regardless of stage. The risk of synchronous or metachronous colorectal carcinoma is 40%. Lynch syndrome may also be associated with extracolonic malignancies, including endometrial carcinoma, which is most common in women, and ovarian, pancreas, stomach, small bowel, biliary, and urinary tract carcinomas. The diagnosis is made based on family history. The *Amsterdam I criteria* for clinical diagnosis of Lynch syndrome are three affected relatives

with histologically verified adenocarcinoma of the large bowel (one must be a first-degree relative of one of the others) in two successive generations of a family with one patient diagnosed before age 50 years. The presence of other related carcinomas should raise the suspicion of this syndrome. Revised criteria *Amsterdam II* requires three or more relatives with an HNPCC related malignancy in which at least one is a first degree relative of the others, two generations are affected, at least one cancer occurred before age 50, FAP has been excluded, and pathology of the tumors has been reviewed and confirmed. In a patient with an established diagnosis of colorectal cancer, tumor testing for presence of mismatch repair gene products (immunohistochemistry) and/or MSI can sometimes serve as screening for this syndrome.^{10,93,94}

Lynch syndrome results from mutations in mismatch repair genes, and like FAP, specific mutations are associated with different phenotypes. For example, mutations in *PMS2* or *MSH6* result in a more attenuated form of Lynch syndrome when compared to mutations in other genes. *MSH6* inactivation also appears to be associated with a higher risk for endometrial cancer. Further significance of these specific mutations remains to be determined.

Screening colonoscopy is recommended annually for at-risk patients beginning at either age 20 to 25 years or 10 years younger than the youngest age at diagnosis in the family, whichever comes first. Because of the high risk of endometrial carcinoma, transvaginal ultrasound or endometrial aspiration biopsy is also recommended annually after age 25 to 35 years. Because there is a 40% risk of developing a second colon cancer, total colectomy with ileorectal anastomosis is recommended once adenomas or a colon carcinoma is diagnosed. Annual proctoscopy is necessary because the risk of developing rectal cancer remains high. Similarly, prophylactic hysterectomy and bilateral salpingo-oophorectomy should be considered in women who have completed childbearing.⁹³⁻⁹⁵

Familial Colorectal Cancer. Nonsyndromic familial colorectal cancer accounts for 10% to 15% of patients with colorectal cancer. The lifetime risk of developing colorectal cancer increases with a family history of the disease. The lifetime risk of colorectal cancer in a patient with no family history of this disease (average-risk population) is approximately 6%, but rises to 12% if one first-degree relative is affected and to 35% if two first-degree relatives are affected. Age of onset also impacts risk, and a diagnosis before the age of 50 years is associated with a higher incidence in family members. Screening colonoscopy is recommended every 5 years beginning at age 40 years or beginning 10 years before the age of the earliest diagnosed patient in the pedigree. While there are no specific genetic abnormalities that are associated with familial colorectal cancer, any of the defects found in either the LOH pathway or MSI pathway may be present in these patients.

Prevention: Screening and Surveillance

Because the majority of colorectal cancers are thought to arise from adenomatous polyps, preventive measures focus on identification and removal of these premalignant lesions. In addition, many cancers are asymptomatic, and screening may detect these tumors at an early and curable stage (Table 29-1). Although screening for colorectal cancer decreases the incidence of cancer and cancer-related mortality, the optimal method of screening remains controversial. Screening guidelines are meant for asymptomatic patients.⁹⁵⁻⁹⁸ Any patient with a gastrointestinal

complaint (bleeding, change in bowel habits, pain, etc) requires a complete evaluation, usually by colonoscopy.

Fecal Occult Blood Testing and Fecal Immunohistochemical Testing. FOBT is known to reduce colorectal cancer mortality by 33% and metastatic disease by 50%. However, FOBT is relatively insensitive, missing up to 50% of cancers and the majority of adenomas. Its specificity is low because 90% of patients with positive tests do not have colorectal cancer. FIT is more sensitive and specific for cancer. Mortality benefits for its use are inferred from FOBT literature. Compliance with annual testing is low and costs are significant if one includes the colonoscopy examinations done to evaluate patients with positive FOBT/FIT. Nonetheless, the direct evidence that FOBT screening is efficacious and decreases both the incidence and mortality of colorectal cancer is so strong that national guidelines recommend annual FOBT/FIT screening for asymptomatic, average-risk Americans older than 50 years of age as one of several accepted strategies. A positive FOBT/FIT should be followed by colonoscopy.⁹⁷⁻¹⁰⁰

Stool DNA. Neoplastic lesions of the colon shed cells into the lumen posing an opportunity for detection via DNA testing. A commercially available multitarget stool DNA test evaluates stool samples for mutant *KRAS*, methylated *BMP3* and the promoter region of *NDRG4*. In a large North American prospective study, this test has recently been found to be 92% sensitive for detection of colorectal cancer. Compared to FIT, stool DNA testing has a lower specificity (74%) raising concerns about how to manage stool DNA-positive patients who have a negative colonoscopic evaluation. Sensitivity for advanced precancerous lesions was 42%.^{100,101} This test, in combination with FIT, is supported as a screening modality every 1 to 3 years by the U.S. Preventative Task Force, and every 3-year utilization is supported by NCCN guidelines.¹⁰⁰ Nevertheless, additional studies will be necessary to determine if these tests are comparable or superior to more traditional methods has been techniques.

Flexible Sigmoidoscopy. Screening by flexible sigmoidoscopy every 5 years may lead to a 60% to 70% reduction in mortality from colorectal cancer, chiefly by identifying high-risk individuals with adenomas. However, it is important to recognize that lesions in the proximal colon cannot be identified, and for this reason, flexible sigmoidoscopy has often been paired with *air-contrast barium enema* to detect transverse and right colon lesions. Patients found to have a polyp, cancer, or other lesion on flexible sigmoidoscopy will require colonoscopy.¹⁰¹⁻¹⁰²

Fecal Occult Blood Testing and Flexible Sigmoidoscopy. Several trials have shown that FOBT screening is least effective at detecting rectosigmoid cancers.⁹⁷⁻⁹⁹ This is precisely the area screened by flexible sigmoidoscopy; thus, the combination of the two tests has been suggested as a reasonable screening strategy. Winawer and colleagues, in a study of 12,479 subjects, showed that the combination of FOBT annually with flexible sigmoidoscopy every 5 years resulted in lower mortality from colorectal cancer and better survival in patients with colorectal cancer.⁹⁹ A similar benefit was confirmed in long-term (11-year) follow-up from the Norwegian Colorectal Cancer Prevention Trial. Such data led to the American Cancer Society recommendations that one of the acceptable screening regimens for average-risk Americans is the combination of FOBT/FIT annually and flexible sigmoidoscopy every 5 years; this combination was preferred over either test alone. Recent NCCN guidelines offer the option of flexible sigmoidoscopy with stool-based testing

Table 29-1

Advantages and disadvantages of screening modalities for asymptomatic individuals

	ADVANTAGES	DISADVANTAGES
Fecal occult blood testing (FOBT)	Ease of use and noninvasive Low cost Good sensitivity with repeat testing	May not detect most polyps Low specificity Colonoscopy required for positive result Poor compliance with serial testing Three successive stools required
Fecal immunohistochemical test (FIT)	Ease of use and noninvasive Low cost More sensitive and specific than FOBT Only one stool sample required	May not detect most polyps Colonoscopy required for positive result
Multitarget stool DNA	Ease of use and noninvasive More sensitive than FIT	May not detect most polyps Colonoscopy required for positive result Less specific than FIT
Sigmoidoscopy	Examines colon most at risk Very sensitive for polyp detection in left colon Does not require full bowel preparation (enemas only)	Invasive Uncomfortable Slight risk of perforation or bleeding May miss proximal lesions Colonoscopy required if polyp identified
Colonoscopy	Examines entire colon Highly sensitive and specific Therapeutic	Most invasive Uncomfortable and requires sedative Requires bowel preparation Risk of perforation or bleeding Costly
Double-contrast barium enema	Examines entire colon Good sensitivity for polyps >1 cm Examines entire colon	Requires bowel preparation Less sensitivity for polyps <1 cm May miss lesions in the sigmoid colon Colonoscopy required for positive result
Computed tomography colonography (virtual colonoscopy)	Noninvasive Sensitivity may be as good as colonoscopy	Requires bowel preparation Insensitive for small polyps Minimal experience and data Colonoscopy required for positive result

every 10 years. The addition of air-contrast barium enema to assess the proximal colon may improve sensitivity as well.⁹⁶

Colonoscopy. Colonoscopy is currently the most accurate and most complete method for examining the large bowel. This procedure is highly sensitive for detecting even small polyps (<1 cm) and allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. However, colonoscopy does require mechanical bowel preparation, and the discomfort associated with the procedure requires conscious sedation in most patients. Colonoscopy is also considerably more expensive than other screening modalities and requires a well-trained endoscopist. The risk of a major complication after colonoscopy (perforation and hemorrhage) is extremely low (0.2–0.3%). Nevertheless, deaths have been reported.

Air-Contrast Barium Enema. Air-contrast barium enema is also highly sensitive for detecting polyps greater than 1 cm in diameter (90% sensitivity). Unfortunately, there are no studies proving its efficacy for screening large populations. Accuracy is greatest in the proximal colon but may be compromised in the sigmoid colon if there is significant diverticulosis. The major disadvantages of barium enema are the need for mechanical bowel preparation and the requirement for colonoscopy if a lesion is discovered.

Computed Tomography Colonography (Virtual Colonoscopy). Advances in imaging technology have created a number of less invasive, but highly accurate tools for screening. CT colonography makes use of helical CT technology and three-dimensional reconstruction to image the intraluminal colon. At present, patients require a mechanical bowel preparation. The colon is then insufflated with air, a spiral CT is performed, and both two-dimensional and three-dimensional images are generated. In the hands of a qualified radiologist, sensitivity appears to be as good as colonoscopy for colorectal cancers and polyps greater than 1 cm in size.¹⁰³ Colonoscopy is required if a lesion is identified. CT colonography has also been used for imaging the proximal colon in cases of obstruction or if a colonoscopy cannot be completed in selected patients. Limitations of this technique include false-positive results from retained stool, diverticular disease, haustral folds, motion artifacts, and an inability to detect flat adenomas.

Guidelines for Screening. Current American Cancer Society guidelines advocate screening for the average-risk population (asymptomatic, no family history of colorectal carcinoma, no personal history of polyps or colorectal carcinoma, no familial syndrome) beginning at age 50 years. Recommended procedures include yearly FOBT/FIT, flexible sigmoidoscopy every

Table 29-2

Screening guidelines for colorectal cancer

POPULATION	INITIAL AGE	RECOMMENDED SCREENING TEST
Average risk	50 y	Annual FOBT or Flexible sigmoidoscopy every 5 y or Annual FOBT and flexible sigmoidoscopy every 5 y or Air-contrast barium enema every 5 y or Colonoscopy every 10 y
Adenomatous polyps	50 y	Colonoscopy at first detection; then colonoscopy in 3 y If no further polyps, colonoscopy every 5 y If polyps, colonoscopy every 3 y Annual colonoscopy for >5 adenomas
Colorectal cancer	At diagnosis	Pretreatment colonoscopy; then at 12 mo after curative resection; then colonoscopy after 3 y; then colonoscopy every 5 y, if no new lesions
Ulcerative colitis, Crohn's colitis	At diagnosis; then after 8 y for pancolitis, after 15 y for left-sided colitis	Colonoscopy with multiple biopsies every 1–2 y
FAP	10–12 y	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 y after polyps appear
Attenuated FAP	20 y	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 y after polyps appear
HNPCC	20–25 y	Colonoscopy every 1–2 y Endometrial aspiration biopsy every 1–2 y
Familial colorectal cancer first-degree relative	40 y or 10 y before the age of the youngest affected relative	Colonoscopy every 5 y Increase frequency if multiple family members are affected, especially before 50 y

FAP = familial adenomatous polyposis; FOBT = fecal occult blood testing; HNPCC = hereditary nonpolyposis colon cancer. Data from Smith et al,⁷⁹ Pignone et al,⁹⁷ and Levin et al.⁶⁷

5 years, FOBT/FIT and flexible sigmoidoscopy in combination, air-contrast barium enema every 5 years, or colonoscopy every 10 years. Patients with other risk factors should be screened earlier and more frequently (Table 29-2).^{93-96,104,105}

Routes of Spread and Natural History

Carcinoma of the colon and rectum arises in the mucosa. The tumor subsequently invades the bowel wall and eventually adjacent tissues and other viscera. Tumors may become bulky and circumferential, leading to colon obstruction. Local invasion (especially in the rectum or sigmoid colon) may occasionally cause obstruction of other organs such as the ureter.

Regional lymph node involvement is the most common form of spread of colorectal carcinoma and usually precedes distant metastasis or the development of carcinomatosis. The likelihood of nodal metastasis increases with tumor size, poorly differentiated histology, lymphovascular invasion, and depth of invasion. The T stage (depth of invasion) is the single most significant predictor of lymph node spread. Carcinoma in situ (Tis) in which there is no penetration of the muscularis mucosa (basement membrane) has also been called *high-grade dysplasia* and should carry no risk of lymph node metastasis. Small lesions confined to the bowel wall (T1 and T2) are associated with lymph node metastasis in 5% to 20% of cases, whereas larger tumors that invade through the bowel wall or into adjacent organs (T3 and T4) are likely to have lymph node metastasis in more than 50% of cases. The number of lymph nodes with metastases correlates with the presence of distant disease

and inversely with survival. Four or more involved lymph nodes (N2 disease) predict a poor prognosis. In colon cancer, lymphatic spread usually follows the major venous outflow from the involved segment of the colon. Lymphatic spread from the rectum follows two routes. In the upper rectum, drainage ascends along the superior rectal vessels to the inferior mesenteric nodes. In the lower rectum, lymphatic drainage may course along the middle rectal vessels. Nodal spread along the inferior rectal vessels to the internal iliac nodes or groin is rare unless the tumor involves the anal canal or the proximal lymphatics are blocked with tumor (Fig. 29-23).

The most common site of distant metastasis from colorectal cancer is the liver. These metastases arise from hematogenous spread via the portal venous system. Like lymph node metastasis, the risk of hepatic metastasis increases with tumor size and tumor grade. However, even small tumors may produce distant metastasis. The lung is also a site of hematogenous spread, but this rarely occurs in isolation. Carcinomatosis (diffuse peritoneal metastases) occurs by peritoneal seeding and has a dismal prognosis.

Staging and Preoperative Evaluation

Clinical Presentation. Symptoms of colon and rectal cancers are nonspecific and generally develop when the cancer is locally advanced. The classic first symptoms are a change in bowel habits and rectal bleeding. Abdominal pain, bloating, and other signs of obstruction typically occur with larger tumors and

Figure 29-23. Lymphatic drainage of the rectum. a. = artery.

suggest more advanced disease. Because of the caliber of the bowel and the consistency of the stool, left-sided tumors are more likely to cause obstruction than are right-sided tumors. Rectal tumors may cause bleeding, tenesmus, and pain. However, it is important to note that many patients may be asymptomatic and/or present with unexplained anemia, weight loss, or poor appetite.

Staging. Colorectal cancer staging is based on tumor depth and the presence or absence of nodal or distant metastases. Older staging systems, such as the Dukes' Classification and its Astler-Coller modification, have been replaced by the tumor-node-metastasis (TNM) staging system described by the American Joint Committee on Cancer (AJCC). The AJCC TNM classification has recently been updated to reflect survival outcomes based upon the Surveillance Epidemiology and End Results (SEER) registry (Table 29-3).¹⁰⁶⁻¹⁰⁹ Stage I disease includes adenocarcinomas that are invasive through the muscularis mucosa but are confined to the submucosa (T1) or the muscularis propria (T2) in the absence of nodal metastases. Stage II disease consists of tumors that invade through the bowel wall into the subserosa or nonperitonealized pericolic or perirectal tissues (T3) or into other organs or tissues or through the visceral peritoneum (T4) without nodal metastases. Stage III disease includes any T stage with nodal metastases, and stage IV disease denotes distant metastases.

The preoperative imaging evaluation usually identifies stage IV disease. In colon cancer, differentiating stages I, II, and III depends on histologic examination of the resected specimen. In rectal cancer, endorectal ultrasound or MRI may predict the stage (ultrasound stage, uTxNx) preoperatively, but the final determination depends on pathologic examination of the resected tumor and adjacent lymph nodes (pathologic stage, pTxNx). Disease stage correlates with 5-year survival. Patients with stages I and II disease can expect excellent survival rates. The presence of nodal metastases (stage III) decreases survival. In rectal cancer, staging has been further refined, and outcomes suggest that subgroups of patients within each stage may have very different prognoses. If the mesorectum around a rectal cancer is

involved or threatened (only 1–2 mm of clearance), there is a very high likelihood of local recurrence and a poor prognosis. This circumferential or radial margin is probably best assessed preoperatively by MRI. Although nodal involvement is the single most important prognostic factor in colorectal carcinoma, tumor characteristics, such as degree of differentiation, mucinous or signet-ring cell histology, vascular invasion, and DNA aneuploidy, also adversely affect prognosis. Preoperative CEA also has been suggested to be a prognostic indicator.⁸ Molecular profiling is currently being studied in an effort to further improve prognostic indicators.¹¹⁰ The 5-year survival rate with stage IV disease is low. However, in well-selected patients, metastasectomy, especially of isolated liver or lung lesions, can result in cure. In these patients, the involvement of a multidisciplinary team and/or tumor board is highly recommended (Fig. 29-24).

Preoperative Evaluation. Once a colon or rectal carcinoma has been diagnosed, a staging evaluation should be undertaken. The colon must be evaluated for synchronous tumors, usually by colonoscopy. Synchronous disease will be present in up to 5% of patients. For rectal cancers, digital rectal examination and rigid or flexible proctoscopy with biopsy should be performed to assess tumor size, location, morphology, histology, and fixation. Endorectal ultrasound or MRI can be invaluable in staging rectal cancer and is used to classify the ultrasound T and N stage of rectal cancers (see Fig. 29-24). A chest/abdominal/pelvic CT scan should be obtained to evaluate for distant metastases. Pelvic CT scan, and sometimes MRI, can be useful in large rectal tumors and in recurrent disease to determine the extent of local invasion. Among patients with obstructive symptoms, a water-soluble contrast study (Gastrografin enema) may be useful for delineating the degree of obstruction. It is important to avoid mechanical bowel preparation (for either colonoscopy or surgery) in a patient who appears to be obstructed. PET scan may be useful in evaluating lesions seen on CT scan and in patients in whom a risky or highly morbid operation is planned (pelvic exenteration, sacrectomy). Preoperative CEA is often obtained and may be useful for postoperative follow-up.

Therapy for Colonic Carcinoma

Principles of Resection. The objective in treatment of carcinoma of the colon is to remove the primary tumor along with its lymphovascular supply. Because the lymphatics of the colon accompany the main arterial supply, the length of bowel resected depends on which vessels are supplying the segment involved with the cancer. Any adjacent organ or tissue, such as the omentum, that has been invaded should be resected en bloc with the tumor. If all of the tumor cannot be removed, a palliative procedure should be considered, although it is important to note that “debulking” is rarely effective in colorectal adenocarcinoma.

The presence of synchronous cancers or adenomas or a strong family history of colorectal neoplasms suggests that the entire colon is at risk for carcinoma (often called a *field defect*), and a subtotal or total colectomy should be considered. Metachronous tumors (a *second primary colon cancer*) identified during follow-up studies should be treated similarly. However, the surgeon must be aware of which mesenteric vessels have been ligated at the initial colectomy because that may influence the viability of the remaining colon and the choice of procedure.

The number of lymph nodes recovered in the surgical specimen has long served as a proxy for the oncologic adequacy of resection. A number of studies previously have suggested that

Table 29-3

TNM Staging of colorectal carcinoma

	DEFINITION		
Tumor Stage (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma <i>in situ</i> , intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)		
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)		
T2	Tumor invades the muscularis propria		
T3	Tumor invades through the muscularis propria into pericorectal tissues		
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure		
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)		
T4b	Tumor directly invades or adheres to adjacent organs or structures		
Nodal Stage (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring ≥ 0.2 mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative		
N1a	One regional lymph node is positive		
N1b	Two or three regional lymph nodes are positive		
N1c	No regional lymph nodes are positive, but there are tumor deposits in the <ul style="list-style-type: none"> • subserosa • mesentery • or nonperitonealized pericolic, or perirectal/mesorectal tissues. 		
N2	Four or more regional nodes are positive		
N2a	Four to six regional lymph nodes are positive		
N2b	Seven or more regional lymph nodes are positive		
Distant Metastasis (M)			
M0	No distant metastasis by imaging, etc.; no evidence of tumor in distant sites or organs (This category is not assigned by pathologists.)		
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified		
M1a	Metastasis to one site or organ is identified without peritoneal metastasis		
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis		
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases		
STAGE	T	N	M
0	Tis	N0	M0
I	T1, T2	N0	M0
IIA	T3	N0	M0
IIB	T4a	N0	M0
IIC	T4b	N0	M0
IIIA	T1–T2	N1/N1c	M0
IIIA	T1	N2a	M0
IIIB	T3–T4a	N1/N1c	M0
IIIB	T2–T3	N2a	M0
IIIB	T1–T2	N2b	M0
IIIC	T4a	N2a	M0
IIIC	T3–T4a	N2b	M0
IIIC	T4b	N1–N2	M0
IVA	Any T	Any N	M1a
IVB	Any T	Any N	M1b
IVC	Any T	Any N	M1c

Figure 29-24. A. Endorectal ultrasonography showing a T3 rectal carcinoma. The dotted line is being used to measure the diameter of the lesion. B. Rectal cancer MRI. (A, Used with permission from Charles O. Finne III, MD, Minneapolis, MN.)

a minimum of 12 lymph nodes in the resected specimen are necessary for adequate staging. In addition, patients in whom more nodes are harvested have better long-term outcome. As such, a 12-node minimum has been suggested as an appropriate benchmark for assessing quality of care. However, several investigators recently have called this into question, noting that the number of lymph nodes examined does not correlate with staging, use of adjuvant chemotherapy, or patient survival. Others have suggested that the number of negative lymph nodes and/or the lymph node ratio (positive lymph nodes to total lymph nodes) may further improve staging.^{106,111-114}

If unexpected metastatic disease is encountered at the time of a laparotomy, the decision about whether to proceed with resection of the primary tumor depends on the volume of distant disease, location and size of the primary tumor, the operation required to remove the primary tumor, and the operative

approach. If the metastatic disease is low volume (isolated or potentially resectable liver lesions) and the resection of the primary tumor is straightforward (segmental abdominal colectomy), it is probably reasonable to proceed with resection. On the other hand, if the metastatic disease is high volume (carcinomatosis), especially if the primary tumor is minimally symptomatic, the operation should be aborted in order to facilitate early systemic chemotherapy. Some centers favor starting the operation with a diagnostic laparoscopy in cases where risk of discovering metastasis is high in order to minimize the magnitude of the operation should surgery be aborted. With recent advances in chemotherapy, many of these patients will never develop a complication from the primary tumor requiring surgical intervention. Other palliative approaches include a bypass or proximal stoma for obstructing lesions.^{115,116}

Stage-Specific Therapy

Stage 0 (Tis, N0, M0) Polyps containing carcinoma in situ (high-grade dysplasia) carry no risk of lymph node metastasis. However, the presence of high-grade dysplasia increases the risk of finding an invasive carcinoma within the polyp. For this reason, these polyps should be excised completely, and pathologic margins should be free of dysplasia. Most pedunculated polyps and many sessile polyps may be completely removed endoscopically. These patients should be followed with frequent colonoscopy to ensure that the polyp has not recurred and that an invasive carcinoma has not developed. In cases where the polyp cannot be removed entirely, a segmental resection is recommended.

Stage I: The Malignant Polyp (T1, N0, M0) Occasionally a polyp that was thought to be benign will be found to harbor invasive carcinoma after polypectomy. Treatment of a *malignant polyp* is based on the risk of local recurrence and the risk of lymph node metastasis.⁵⁹ The risk of lymph node metastases depends primarily on the depth of invasion. Invasive carcinoma in the head of a pedunculated polyp with no stalk involvement carries a low risk of metastasis (<1%) and may be completely resected endoscopically. For sessile polyps, the depth of invasion predicts risk of lymphovascular spread. A recent classification stratifies risk by depth of submucosal spread. Superficial lesions (submucosa 1; Sm1) are low risk, whereas Sm2 and Sm3 are intermediate and high risk.¹¹⁷ Lymphovascular invasion, poorly differentiated histology, tumor budding, or tumor within 1 mm of the resection margin greatly increases the risk of local recurrence and metastatic spread. Segmental colectomy is then indicated. Invasive carcinoma arising in a sessile polyp extending into the submucosa and is usually best treated with segmental colectomy (Fig. 29-25).

Stages I and II: Localized Colon Carcinoma (T1-3, N0, M0)

The majority of patients with stages I and II colon cancer will be cured with surgical resection. Few patients with completely resected stage I disease will develop either local or distant recurrence, and adjuvant chemotherapy does not improve survival in these patients.¹¹⁷ However, up to 46% of patients with completely resected stage II disease will ultimately die from colon cancer. For this reason, adjuvant chemotherapy has been suggested for selected patients with stage II disease (young patients, tumors with “high-risk” histologic findings). It remains controversial as to whether chemotherapy improves survival rates in these patients. In some cases, molecular profiling may predict prognosis, although it is important to note that these tools have not been shown to predict response to therapy. At present,

Figure 29-25. Levels of invasive carcinoma in pedunculated and sessile polyps. ca = carcinoma.

molecular profiling for selecting patients to receive chemotherapy remains unproven.

Stage III: Lymph Node Metastasis (Tany, N1, M0) Patients with lymph node involvement are at significant risk for both local and distant recurrence, and adjuvant chemotherapy has been recommended routinely in these patients. 5-Fluorouracil-based regimens (with leucovorin) and oxaliplatin (FOLFOX) reduce recurrences and improve survival in this patient population. It is important to note, however, that a subgroup of patients with stage III disease will do well without chemotherapy. MSI status in particular predicts good prognosis. Subset analysis from the CRYSTAL trial has shown that patients with MSI-high stage III disease do not benefit from 5-fluorouracil-based chemotherapy. Molecular profiling, therefore, may be helpful in determining which stage III patients can safely avoid systemic chemotherapy.¹¹⁸

Stage IV: Distant Metastasis (Tany, Nany, M1) Survival is extremely limited in stage IV colon carcinoma. Systemic chemotherapy is recommended in almost all cases of distant spread. However, unlike many other malignancies, highly selected patients with isolated, resectable metastases may benefit from resection (metastasectomy). The most common site of metastasis is the liver. Of patients with systemic disease, approximately 15% will have metastases limited to the liver. Of these, 20% are potentially resectable for cure. Survival is improved in these patients (20–40% 5-year survival) when compared to patients who do not undergo resection. Hepatic resection of synchronous metastases from colorectal carcinoma may be performed as a combined procedure or in two stages. The second most common site of metastasis is the lung, occurring in approximately 20% of patients with colorectal carcinoma. Although very few of these patients will be potentially resectable, among those who are (about 1–2% of all colorectal cancer patients), long-term survival benefit is approximately 30% to 40%. There are limited reports of successful resection of metastases in other sites (ovary and retroperitoneum are most common). Cytoreductive surgery and intraperitoneal chemotherapy (HIPEC) has been suggested for patients with carcinomatosis, but remains unproven for colorectal cancer and carries high morbidity.^{119,120}

The remainder of patients with stage IV disease cannot be cured surgically, and therefore, the focus of treatment should be palliation. Methods such as colonic stenting for obstructive lesions of the left colon also provide good palliation. More

limited surgical intervention such as a diverting stoma or bypass procedure may be appropriate in patients with stage IV disease who develop obstruction. Hemorrhage in an unresectable tumor can sometimes be controlled with angiographic embolization. External beam radiation also has been used for palliation. The involvement of a palliative care team in the management of these patients is critical.¹¹⁶

Therapy for Rectal Carcinoma

Principles of Resection. The biology of rectal adenocarcinoma is thought to be similar to the biology of colonic adenocarcinoma, and the operative principles of complete resection of the primary tumor, its lymphatic bed, and any other involved organ apply to surgical resection of rectal carcinoma. However, the anatomy of the pelvis and proximity of other structures (ureters, bladder, prostate, vagina, iliac vessels, and sacrum) make resection more challenging and often require a different approach than for colonic adenocarcinoma. Moreover, it is more difficult to achieve negative radial margins in rectal cancers that extend through the bowel wall because of the anatomic limitations of the pelvis. Therefore, local recurrence is higher than with similar stage colon cancers. However, unlike the intraperitoneal colon, the relative paucity of small bowel and other radiation-sensitive structures in the pelvis makes it easier to treat rectal tumors with radiation. Therapeutic decisions, therefore, are based on the location and depth of the tumor and its relationship to other structures in the pelvis.

Local Therapy. The distal 10 cm of the rectum are accessible transanally. For this reason, several local approaches have been proposed for treating rectal neoplasms. *Transanal excision* (full thickness or mucosal) is an excellent approach for noncircumferential, benign, villous adenomas of the rectum. *Transanal endoscopic microsurgery (TEM)* and *transanal minimally invasive surgery (TAMIS)* make use of a specially designed proctoscope, magnifying system, and instruments similar to those used in laparoscopy to allow local excision of lesions higher in the rectum (up to 15 cm). Although this technique has been used for selected T1, and some T2, carcinomas, local excision does not allow pathologic examination of the lymph nodes and might therefore understage patients. Moreover, local recurrence rates are high after transanal excision, and salvage surgery, while often curative, has been reported to be associated with poorer survival than with initial radical surgery. Current recommendation is to limit local excision of T1 lesions to patients with well to moderately differentiated small lesions (<3 cm) and/or in patients medically unfit for radical resection. In general, local excision of any rectal neoplasm should be considered an *excisional biopsy* because final pathologic examination of the specimen may reveal an invasive carcinoma that then mandates more radical therapy.^{120,121}

Ablative techniques, such as electrocautery or endocavitary radiation, also have been used. The disadvantage of these techniques is that no pathologic specimen is retrieved to confirm the tumor stage. Fulguration is generally reserved for extremely high-risk, symptomatic patients with a limited life span who cannot tolerate more radical surgery.¹²⁰

Radical Resection. Radical resection is preferred to local therapy for most rectal carcinomas. Radical resection involves removal of the involved segment of the rectum along with its lymphovascular supply. Although any microscopically negative margin has been suggested to be adequate, most surgeons

still attempt to obtain a 2-cm distal mural margin for curative resections.

Total mesorectal excision (TME) is a technique that uses sharp dissection along anatomic planes to ensure complete resection of the rectal mesentery during low and extended low anterior resections. For upper rectal or rectosigmoid resections, a partial mesorectal excision of at least 5 cm distal to the tumor appears adequate. TME both decreases local recurrence rates and improves long-term survival rates. Moreover, this technique is associated with less blood loss and less risk to the pelvic nerves and presacral plexus than is blunt dissection. The principles of TME should be applied to all radical resections for rectal cancer.

Recurrence of rectal cancer generally has a poor prognosis. Extensive involvement of other pelvic organs (usually occurring in the setting of tumor recurrence) may require a *pelvic exenteration*. The rectal and perineal portions of this operation are similar to an APR, but en bloc resection of the ureters, bladder, and prostate or uterus and vagina are also performed. A permanent colostomy and an ileal conduit to drain the urinary tract may be necessary. The sacrum may also be resected if necessary (*sacrectomy*) up to the level of the S2-S3 junction. These operations are best performed in tertiary centers with multidisciplinary teams consisting of a colon and rectal surgeon, urologist, neurosurgeon, and plastic surgeon.

Stage-Specific Therapy (Fig. 29-26). Pretreatment staging of rectal carcinoma often relies on endorectal ultrasound or MRI

to determine the T and N status of a rectal cancer. Ultrasound is highly accurate at assessing tumor depth, but it is less accurate in diagnosing nodal involvement. Ultrasound evaluation can guide choice of therapy in most patients. MRI is useful to assess mesorectal involvement. When the radial margin is threatened or involved, neoadjuvant chemoradiation is recommended.¹²²

Stage 0 (Tis, N0, M0) Villous adenomas harboring carcinoma in situ (high-grade dysplasia) are ideally treated with local excision. A 1-cm margin should be obtained. Rarely, radical resection will be necessary if transanal excision is not technically possible (large circumferential lesions).

Stage I: Localized Rectal Carcinoma (T1-2, N0, M0)

Although local excision has been used for small, favorable sessile uT1N0 and uT2N0 rectal cancers, local recurrence rates may be as high as 20% and 40%, respectively. Local excision increasingly is offered to patients with small, low-risk lesions, but it does not allow physicians to assess regional lymph nodes. For this reason, radical resection is recommended in all good-risk patients. Lesions with unfavorable histologic characteristics and those located in the distal third of the rectum, in particular, are prone to recurrence. In high-risk patients and in patients who refuse radical surgery because of the risk of need for a permanent colostomy, local excision may be adequate, but strong consideration should be given to adjuvant or neoadjuvant chemoradiation to improve local control. The efficacy of adjuvant or neoadjuvant chemoradiation followed by transanal excision in patients who can tolerate radical surgery has been

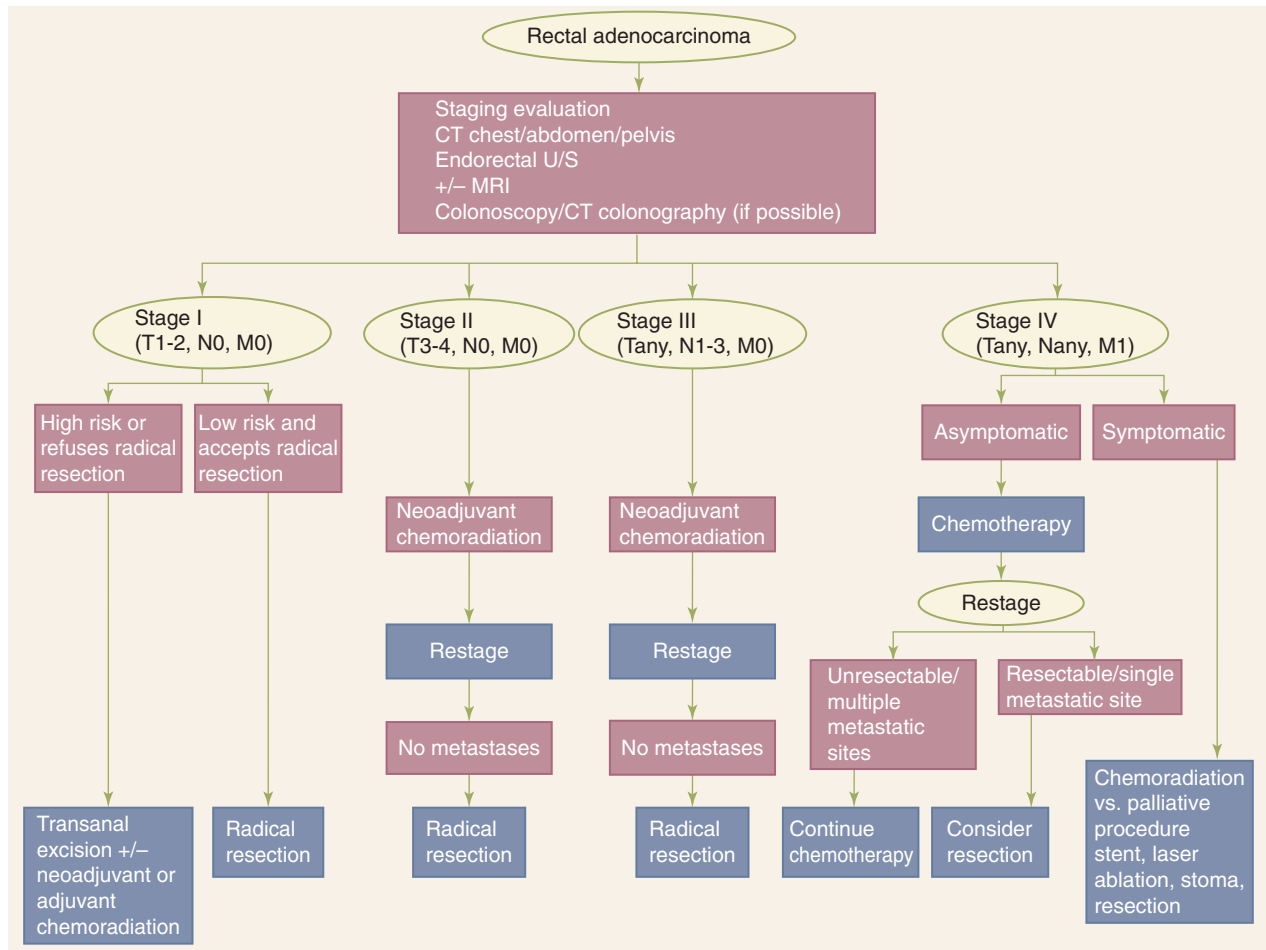

Figure 29-26. Diagnostic algorithm for rectal cancer. CT = computed tomography; MRI = magnetic resonance imaging; U/S = ultrasound.

controversial. Early results from ACOSOG Z6041, in which patients with T2 rectal cancers received neoadjuvant chemoradiation followed by transanal excision, showed a pathologic complete response rate of 44%.¹²³ At 3 years, disease-free survival was 88%, which is comparable to cancer outcomes after a formal resection. However, population-based data suggests that survival after local excision for rectal cancer is suboptimal and should not be offered as a matter of routine.¹²⁴

Locally Advanced Rectal Cancer (Stages II and III)

Stage II: Localized Rectal Carcinoma (T3-4, N0, M0). Larger rectal tumors, especially if located in the distal rectum, are more likely to recur locally. There are two schools of thought, each differing in their approach, concerning how to control local recurrences. Advocates of total mesorectal resection suggest that optimization of operative technique will obviate the need for any adjuvant chemoradiation to control local recurrence after resection of stages I, II, and III rectal cancers. The opposing school suggests that stages II and III rectal cancers will benefit from chemoradiation. They argue that such therapy reduces local recurrences and prolongs survival whether given preoperatively or postoperatively. The advantages of preoperative chemoradiation include tumor shrinkage, increased likelihood of resection and of a sphincter-sparing procedure, tumor downstaging by treating locally involved lymph nodes, and decreased risk to the small intestine. Disadvantages include possible overtreatment of early-stage tumors, impaired wound healing, and pelvic fibrosis increasing the risk of operative complications. Postoperative radiation allows accurate pathologic staging of the resected tumor and lymph nodes and avoids the wound healing problems associated with preoperative radiation. However, bulky tumors, tumors involving adjacent organs, and very low rectal tumors may be much more difficult to resect without preoperative radiation and may require a more extensive operation.¹²⁴⁻¹²⁷

Stage III: Lymph Node Metastasis (Tany, N1, M0). Many surgeons now recommend chemotherapy and radiation either pre- or postoperatively for node-positive rectal cancers. The advantages and disadvantages are similar to those listed for stage II disease, except that the likelihood of overtreating an early-stage lesion is considerably less.

Over the past two decades, a wide variety of studies have addressed the issue of adjuvant and neoadjuvant therapy for locally advanced rectal cancer. Many of these studies demonstrated both improved local control and prolonged survival and resulted in the 1990 National Institutes of Health (NIH) consensus conference recommendation for postoperative chemoradiation therapy in these patients. There is little controversy regarding chemoradiation therapy for stage III (node-positive) disease. However, advances in surgical technique, such as TME, for locally advanced node-negative cancers (T3-4, N0; stage II) have improved local control with surgery alone, prompting some to abandon adjuvant chemoradiation in these patients, especially for those with cancers in the proximal rectum. Although the data from these studies are intriguing, other reports have shown that chemoradiation improves local control and survival even in patients who undergo TME. Thus, most colorectal surgeons in the United States continue to recommend adjuvant or neoadjuvant therapy for patients with locally advanced disease. Many European surgeons now rely heavily on MRI staging to determine the need for neoadjuvant chemoradiation. They use neoadjuvant chemoradiation if the radial margin is threatened

or involved by the cancer or if anal sphincter or other local organ invasion is present. In the United States, chemoradiation therapy is still recommended for all patients with stage III disease and the majority of patients with stage II disease. In select patients with T3 tumors, favorable histology, and negative radial margins, chemoradiation may not be necessary, but larger prospective studies are required before this approach can be recommended.¹²⁵⁻¹²⁷

Appropriate timing of chemoradiation for locally advanced rectal cancer has been debated. Historically, preoperative chemoradiation has been advocated based on tumor shrinkage/downstaging, improved resectability, and the possibility of performing a sphincter-sparing operation in some patients. In addition, the absence of small bowel adhesions in the pelvis may decrease toxicity. However, preoperative radiation therapy may increase operative complications and impairs wound healing. Although preoperative endorectal ultrasound and MRI have improved our ability to stage rectal cancer, clinical “overstaging” can be problematic, and neoadjuvant therapy may therefore overtreat patients with pT1-2, N0 tumors. Advocates of postoperative radiation therapy cite more accurate pathologic staging and fewer operative/postoperative complications. However, large, bulky tumors may be unresectable or require a more extensive operation (APR, pelvic exenteration) without preoperative therapy. In addition, postoperative pelvic radiation may compromise function of the neorectum.

Comparisons of perioperative toxicity and oncologic outcome have been addressed by the German CAO/ARO/AIO-94 trial. In this study, pre- and postoperative chemoradiation were associated with equivalent acute toxicity and equivalent postoperative complication rates. Postoperative chemoradiation, however, doubled the risk of postoperative stricture formation. In addition, preoperative chemoradiation halved the risk of local recurrence (6% vs. 12%). Based on these data, most surgeons consider preoperative chemoradiation to be the most appropriate therapy for locally advanced rectal cancer.¹²⁶ In the United States, this generally consists of 5-FU based chemotherapy and 5 to 6 weeks of external beam radiation (“long course”) followed by surgery 6 to 8 weeks later. It is important to note, however, that many European centers utilize a “short course” preoperative radiation regimen consisting of 5 days of radiation followed by surgery within 1 to 2 weeks. At present, these modalities have not been compared in any randomized, prospective trial.^{125,127}

With advances in chemoradiation, an increasing number of patients with locally advanced rectal cancer will have complete shrinkage of their tumor (a clinical complete response; cCR). In light of the potential morbidity of proctectomy, it has been suggested that select patients can be managed nonoperatively (“watch and wait”). However, data from current studies are contradictory and concern remains about the ability to predict which patients with clinical complete response actually have a pathologic complete response.¹²⁸ Patients selected for nonoperative management must be examined by a surgeon at a frequent intervals. Additional adjuvant chemotherapy administered after the decision for a nonoperative approach is another important consideration.^{128,129} At present, this approach is not recommended outside of a specialty center and/or clinical trial.

Stage IV: Distant Metastasis (Tany, Nany, M1) Like stage IV colon carcinoma, survival is limited in patients with distant metastasis from rectal carcinoma. Isolated hepatic

and/or pulmonary metastases are rare, but when present may be resected for cure in selected patients.^{119,120} Some patients will require palliative procedures. Radical resection may be required to control pain, bleeding, or tenesmus, but highly morbid procedures such as pelvic exenteration and sacrectomy should generally be avoided in this setting. Local therapy using cautery, endocavitary radiation, or laser ablation may be adequate to control bleeding or prevent obstruction. Intraluminal stents may be useful in the uppermost rectum but often cause pain and tenesmus lower in the rectum. Occasionally, a proximal diverting colostomy will be required to alleviate obstruction. A mucus fistula should be created if possible to vent the distal colon. It is critical that the morbidity of any procedure be realistically weighed against potential benefit in these patients with limited life expectancy. The assistance of a palliative care team can be invaluable in this setting.¹¹⁶

Follow-Up and Surveillance

Patients who have been treated for one colorectal cancer are at risk for the development of recurrent disease (either locally or systemically) or metachronous disease (a second primary tumor). In theory, metachronous cancers should be preventable by using surveillance colonoscopy to detect and remove polyps before they progress to invasive cancer. For most patients, a colonoscopy should be performed within 12 months after the diagnosis of the original cancer (or sooner if the colon was not examined in its entirety prior to the original resection). If that study is normal, colonoscopy should be repeated every 3 to 5 years thereafter.

The optimal method of following patients for recurrent cancer remains controversial. The goal of close follow-up observation is to *detect resectable recurrence* and to *improve survival*. Re-resection of local recurrence and resection of distant metastasis to liver, lung, or other sites are often technically challenging and highly morbid, with only a limited chance of achieving long-term survival. Thus, only selected patients who would tolerate such an approach should be followed intensively. Because most recurrences occur within 2 years of the original diagnosis, surveillance focuses on this time period. Patients who have undergone local resection of rectal tumors also should be followed with frequent endoscopic examinations (every 3–6 months for 3 years, then every 6 months for 2 years). CEA is often followed every 3 to 6 months for 2 years. CT scans are often performed annually for 5 years, but there are few data to support this practice. More intensive surveillance is appropriate in high-risk patients such as those with possible Lynch syndrome or T3, N+ cancers. Although intensive surveillance improves detection of resectable recurrences, it is important to note that a survival benefit has never been proven. Therefore, the risks and benefits of intensive surveillance must be weighed and treatment individualized.

Treatment of Recurrent Colorectal Carcinoma

Between 20% and 40% of patients who have undergone curative intent surgery for colorectal carcinoma will eventually develop recurrent disease. Most recurrences occur within the first 2 years after the initial diagnosis, but preoperative chemoradiation therapy may delay recurrence. While most of these patients will present with distant metastases, a small proportion will have isolated local recurrence and may be considered for *salvage surgery*. Recurrence after colon cancer resection usually occurs at the local site within the abdomen or in the

liver or lungs. Resection of other involved organs may be necessary. Recurrence of rectal cancer can be considerably more difficult to manage because of the proximity of other pelvic structures. If the patient has not received chemotherapy and radiation, then adjuvant therapy should be administered prior to salvage surgery. Radical resection may require extensive resection of pelvic organs (pelvic exenteration with or without sacrectomy). Ideally, the aim of a salvage operation should be to resect all of the tumor with negative margins. However, if the ability to achieve a negative margin is in question, the addition of intraoperative radiation therapy (usually brachytherapy) can help improve local control. Pelvic MRI is useful for identifying tumor extension that would prevent successful resection (extension of tumor into the pelvic sidewall, involvement of the iliac vessels or bilateral sacral nerves, sacral invasion above the S2-S3 junction). Patients should also undergo a thorough preoperative evaluation to identify distant metastases (CT of chest, abdomen, and pelvis, and PET scan) before undergoing such an extensive procedure. Nevertheless, radical salvage surgery can prolong survival in selected patients.

Minimally Invasive Techniques for Resection

Laparoscopic colectomy for cancer has been controversial. Early reports of high port site recurrence dampened enthusiasm for this technique.¹³⁰ The ability to perform an adequate oncologic resection for cancer has also been questioned. Several trials have laid to rest many of these fears. The Clinical Outcomes of Surgical Therapy (COST) Study Group, the Colon Carcinoma Laparoscopic or Open Resection (COLOR) trial, and the United Kingdom Medical Research Council Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASSIC) trial all have shown oncologic equivalence between open and laparoscopic techniques. In these multi-institutional studies, the rates of cancer recurrence, survival, and quality of life were similar, suggesting that, in the hands of an appropriately trained surgeon, laparoscopic colectomy is appropriate for colon cancer.¹³¹⁻¹³⁶ The recent introduction of robotic surgery offers an additional minimally invasive approach. Early studies suggest that robotic surgery may be the oncologic equivalent to laparoscopic surgery for colon cancer.¹³⁷

Laparoscopic surgery for rectal cancer has been more controversial. Multiple studies of laparoscopic total mesorectal excision for rectal cancer have demonstrated decreased blood loss, earlier return of bowel function and shorter length of stay compared with open TME. While a laparoscopic approach to mobilization of the left colon and splenic flexure can be used in rectal resection procedures, laparoscopic TME refers to completion of the pelvic dissection laparoscopically and not through the abdominal extraction site. Technical challenges in the retraction of the rectum and surrounding soft tissues and transection of the distal rectum mandate careful evaluation oncologic outcomes. Two recent randomized controlled trials from the United States (ACOSOG Z6051)¹³⁸ and Australia and New Zealand (ALaCaRT: Australasian Laparoscopic Cancer of the Rectum Trial)¹³⁹ have shown that laparoscopic surgery is not superior to open surgery in this regard. When the totality of evidence from nine randomized trials is evaluated, CRM was positive in 7.9% of laparoscopic and 6.1% of open rectal resections, a difference that was not statistically significant.¹⁷ In trials that reported the completeness of mesorectal excision (n = 5), inadequate TME was significantly more likely in laparoscopic (13.2%) compared with open (10.4%) resections. Long-term recurrence and

survival data from ACOSOG and ALaCaRT studies will be needed to determine what role laparoscopy should play in rectal cancer surgery. Two earlier trials, COLOR (COlon cancer Laparoscopic or Open Resection) II¹³⁴ and COREAN (Comparison of Open *versus* laparoscopic surgery for mid and low Rectal cancer After Neoadjuvant chemoradiotherapy),¹³⁵ have shown equivalent 3-year recurrence and survival. It is possible that specific subsets of patients are more appropriate for open surgery. For example, ALaCaRT authors thought laparoscopic surgery may be less successful in patients who had neoadjuvant therapy, larger T3 tumors, or higher BMIs, but their study was underpowered to make definitive conclusions in these patients. A laparoscopic approach should not be considered for T4 tumors.

The inferior quality of laparoscopic rectal cancer surgery suggested by recent randomized trials is attributed to technical limitations, leading to the suggestion that robotic surgery, with its wristed instruments, fixed platform, and potentially improved visualization could offer an improvement. The results of the ROLARR (Robotic vs Laparoscopic Resection for Rectal Cancer) randomized trial will offer more data on the quality of TME and margins after robotic surgery; however, a trial comparing open to robotic dissection will also be important.¹⁴¹

OTHER NEOPLASMS

Rare Colorectal Tumors

Neuroendocrine Tumors. Neuroendocrine tumors occur most commonly in the gastrointestinal tract, and up to 25% of these tumors are found in the rectum. Well-differentiated neuroendocrine tumors (also known as carcinoid tumors) are commonly identified on colonoscopy as small (<1 cm) nodules and have a benign clinical course, with overall survival is greater than 80%. However, the risk of malignancy increases with size, and more than 60% of tumors greater than 2 cm in diameter are associated with distant metastases. Rectal neuroendocrine tumors appear to be less likely to secrete vasoactive substances than carcinoids in other locations, and carcinoid syndrome is uncommon in the absence of hepatic metastases. Small carcinoids can be locally resected transanally. Larger tumors, poorly differentiated tumors (such as small cell or large cell neuroendocrine carcinomas), and those with obvious invasion into the muscularis require more radical surgery. Neuroendocrine tumors in the proximal colon are less common and are more likely to be malignant. Size also correlates with risk of malignancy, and tumors less than 2 cm in diameter rarely metastasize. However, the majority of neuroendocrine tumors in the proximal colon present as bulky lesions, and up to two-thirds of patients will have metastatic spread at the time of diagnosis. These tumors should usually be treated with radical resection. Because well-differentiated neuroendocrine tumors are typically slow growing, patients with distant metastases may expect reasonably long survival. Symptoms of carcinoid syndrome can often be alleviated with somatostatin analogues (octreotide) and/or interferon- α . Tumor debulking can offer effective palliation in selected patients.¹⁴²⁻¹⁴⁴

Mixed Adenoneuroendocrine Carcinomas. Mixed adenoneuroendocrine carcinomas, also known as composite carcinoid carcinomas, adenocarcinoids tumors, amphicrine or collision tumors, have histologic features of both neuroendocrine tumors and adenocarcinomas. The natural history of these tumors more closely parallels that of adenocarcinomas than neuroendocrine tumors, and regional and systemic metastases are common.

Carcinoid carcinoma of the colon and rectum should be treated according to the same oncologic principles as followed for management of adenocarcinoma.

Lipomas. Lipomas are benign lesions that occur most commonly in the submucosa of the colon and rectum. The majority of lipomas are asymptomatic and discovered incidentally. Small asymptomatic lesions do not require resection. However, larger lesions may occasionally cause bleeding, obstruction, or intussusception, especially when greater than 2 cm in diameter. Larger lipomas should be resected by colonoscopic techniques or by a colotomy and enucleation or limited colectomy.¹⁴⁴

Lymphoma. Gastrointestinal lymphoma may be primary or generalized/secondary. Primary GI lymphomas occur most frequently in the terminal ileum and cecum. Lymphoma involving the colon and rectum is rare, but it accounts for about 10% of all gastrointestinal lymphomas. Presentation, treatment and prognosis differ between patients with lymphoma occurring as a localized entity in the colon and rectum versus those occurring in patients who have generalized lymphoma with colorectal involvement. Symptoms in isolated rectal lymphoma include bleeding, obstruction, and pain, and these tumors may be clinically indistinguishable from adenocarcinomas. The cecum is most often involved, probably as a result of spread from the terminal ileum. Symptoms include bleeding and obstruction. Bowel resection is the treatment of choice for isolated colorectal lymphoma. Adjuvant therapy may be given based on the stage of disease.¹⁴⁴

Leiomyoma and Leiomyosarcoma. Leiomyomas are benign tumors of the smooth muscle of the bowel wall and occur most commonly in the upper gastrointestinal tract. Most patients are asymptomatic, and lesions are often diagnosed incidentally when a mass is seen on endoscopy or felt on digital rectal examination. However, large lesions can cause bleeding or obstruction. Because it is difficult to differentiate a benign leiomyoma from a malignant leiomyosarcoma, these lesions should be resected. Recurrence is common after local resection, but most small leiomyomas can be adequately treated with limited resection. Lesions larger than 5 cm should be treated with radical resection because the risk of malignancy is high.

Leiomyosarcoma is rare in the gastrointestinal tract. When this malignancy occurs in the large intestine, the rectum is the most common site. Leiomyosarcoma of the rectum is usually low grade, and, as such, can be difficult to differentiate from leiomyoma. Definitive diagnosis is usually made after resection. Symptoms, when they occur, are usually bleeding or obstruction. A radical resection is indicated for most of these tumors. Despite complete resection, recurrence is not uncommon, and prognosis is generally poor.¹⁴⁴

Gastrointestinal Stromal Tumor (GIST). Gastrointestinal Stromal Tumors (GIST) are most common in the proximal GI tract but do occasionally occur in the colorectum (5–10%) and may be mistaken for leiomyomas. GISTs are mesenchymal tumors that arise from the interstitial cells of Cajal. The vast majority (>95%) of GISTs express CD117 (KIT), and as such, are sensitive to tyrosine kinase inhibitors (TKIs), such as imatinib mesylate and sunitinib malate. Risk stratification is based on tumor size and mitotic activity, and 30% to 50% are malignant. Although small GISTs may be asymptomatic and discovered incidentally, larger lesions can cause bleeding, obstruction, or abdominal pain. Treatment of choice is surgical resection (either local excision or radical resection) with

microscopically negative margins, if possible; however, local recurrence is common. For larger marginally resectable tumors, TKIs (imatinib) can be used to shrink the tumor. These agents can also be considered for adjuvant therapy after resection and are useful for treating metastatic disease.¹⁴⁴

Retrorectal/Presacral Tumors

Tumors occurring in the retrorectal space are rare. This region lies between the upper two-thirds of the rectum and the sacrum above the rectosacral fascia. It is bound by the rectum anteriorly, the presacral fascia posteriorly, and the endopelvic fascia laterally (lateral ligaments). The retrorectal space contains multiple embryologic remnants derived from a variety of tissues (neuroectoderm, notochord, and hindgut). As such, tumors that develop in this space are often heterogeneous.

Congenital lesions are most common, comprising almost two-thirds of retrorectal lesions. The remainder are classified as neurogenic, osseous, inflammatory, or miscellaneous lesions. Malignancy is more common in the pediatric population than in adults, and solid lesions are more likely to be malignant than are cystic lesions. Inflammatory lesions may be solid or cystic (abscess) and usually represent extensions of infection either in the perirectal space or in the abdomen.

Developmental cysts constitute the majority of congenital lesions and may arise from all three germ cell layers. Dermoid and epidermoid cysts are benign lesions that arise from the ectoderm. Enterogenous cysts arise from the primitive gut. Anterior meningocele and myelomeningocele arise from herniation of the dural sac through a defect in the anterior sacrum. A “scimitar sign” (sacrum with a rounded, concave border without any bony destruction) is the pathognomonic radiographic appearance of this condition.

Solid lesions include teratomas, chordomas, neurologic tumors, or osseous lesions. Teratomas are true neoplasms and contain tissue from each germ cell layer. They often contain both cystic and solid components. Teratomas are more common in children than in adults, but when found in adults, 30% are malignant. Chordomas arise from the notochord and are the most common malignant tumor in this region. These are slow-growing, invasive cancers that show characteristic bony destruction. Neurogenic tumors include neurofibromas and sarcomas, neurilemmomas, ependymomas, and ganglioneuromas. Osseous lesions include osteomas and bone cysts, as well as neoplasms such as osteogenic sarcoma, Ewing’s tumor, chondromyxosarcoma, and giant cell tumors.

Patients may present with pain (lower back, pelvic, or lower extremity), gastrointestinal symptoms, or urinary tract symptoms. Most lesions are palpable on digital rectal examination. While plain X-rays and CT scans often are used to evaluate these lesions, pelvic MRI is the most sensitive and specific imaging study. Myelogram is occasionally necessary if there is central nervous system involvement. Treatment is almost always surgical resection. The approach depends in part on the nature of the lesion and its location. Lesions high in the pelvis may be approached via a transabdominal route, whereas low lesions may be resected transsacrally. Intermediate lesions may require a combined abdominal and sacral operation. Although survival is excellent after resection of benign lesions, local recurrence is not uncommon. Prognosis after resection of malignant lesions is highly variable and reflects the biology of the underlying tumor.

The role of biopsy in this setting has been controversial. Historically, the recommendation was to *avoid* biopsy because

of the risk of infection or needle tract seeding. This recommendation has recently been challenged, especially for large and/or unusual tumors that would be better treated with multimodality neoadjuvant therapy (GIST, sarcoma, metastatic adenocarcinoma). A recent study confirmed the utility of needle biopsy of solid lesions and refuted concerns about needle tract seeding. As such, most solid lesions should be biopsied regardless of resectability. Biopsy or aspiration of cystic lesions, especially meningoceles, should still be avoided because of the risk of infection.¹⁴⁴⁻¹⁴⁷

Anal Canal and Perianal Tumors

Cancers of the anal canal are uncommon and account for approximately 2% of all colorectal malignancies. Neoplasms of the anal canal have traditionally been divided into those affecting the *anal margin* (distal to the dentate line) and those affecting the *anal canal* (proximal to the dentate line) based on lymphatic drainage patterns. Lymphatics from the anal canal proximal to the dentate line drain cephalad via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along both the middle rectal vessels and inferior rectal vessels through the ischiorectal fossa to the internal iliac nodes. Lymph from the anal canal distal to the dentate line usually drains to the inguinal nodes. It can also drain to the superior rectal lymph nodes or along the inferior rectal lymphatics to the ischiorectal fossa if primary drainage routes are blocked with tumor (Fig. 29-27).

A more clinically useful classification divides anal lesions into those that are *perianal* (can be completely visualized with gentle eversion of the buttocks) and those that are *intra-anal* (cannot be completely visualized with gentle eversion of the buttocks). In many cases, therapy depends on whether the tumor is perianal or intra-anal.

Squamous Intraepithelial Lesions. Anal canal and perianal dysplasia have long had a potpourri of nomenclature. Anal intraepithelial neoplasia (AIN), Bowen’s disease, and carcinoma in situ all refer to human papillomavirus (HPV)-induced

Figure 29-27. Lymphatic drainage of the anal canal. a. = artery.

dysplasia. Because these entities are pathologically identical, there has been an effort to standardize nomenclature. *High-grade squamous intraepithelial lesions (HSIL)* include high- and intermediate-grade dysplasia, AINII and AINIII, Bowen's disease, and carcinoma in situ. *Low-grade squamous intraepithelial lesions (LSIL)* includes low-grade dysplasia and AINI. Recently, the terms *High-grade AIN (HGAIN; AINIII)* and *low-grade AIN (LGAIN; AIN I/II)* have been suggested.¹⁴⁶⁻¹⁴⁸ Both high- and low-grade lesions are associated with infection with HPV, especially types 16 and 18.

High-grade lesions are precursors to invasive squamous cell carcinoma (epidermoid carcinoma) and may appear as a plaque or may only be apparent with high-resolution anoscopy and application of acetic acid and/or Lugol's iodine solution. The incidence of both squamous intraepithelial lesions and epidermoid carcinoma of the anus has increased dramatically among human immunodeficiency virus (HIV)-positive men who have sex with men. This increase is thought to result from increased rates of HPV infection along with HIV-induced immunosuppression. Treatment of high-grade dysplasia is *ablation*. Because of a high recurrence and/or reinfection rate, these patients require close surveillance. High-risk patients should be followed with frequent anal Papanicolaou (Pap) smears every 3 to 6 months. An abnormal Pap smear should be followed by an examination under anesthesia and anal mapping using high-resolution anoscopy. High-resolution anoscopy shows areas with abnormal telangiectasias that are consistent with high-grade dysplasia. Many centers now consider this technique for repeated ablation of high-grade lesions to be the optimal method for following these patients.¹⁴⁸⁻¹⁵⁰ It should be noted, however, that the practice has not been universally adopted, and it is unclear whether close surveillance in lower-risk (nonimmunosuppressed) patients is necessary. Rarely, extensive disease may require resection with flap closure. Medical therapy for HPV has also been proposed. Topical immunomodulators such as imiquimod (Aldara) have been shown to induce regression in some series.¹⁵¹ Topical 5-fluorouracil has also been used in this setting. Finally, the introduction of a vaccine against HPV may help decrease the incidence of this disease in the future.

Epidermoid Carcinoma. Epidermoid carcinoma of the anus includes squamous cell carcinoma, cloacogenic carcinoma, transitional carcinoma, and basaloid carcinoma. The clinical behavior and natural history of these tumors are similar. Epidermoid carcinoma is a slow-growing tumor and usually presents as an intra-anal or perianal mass. Pain and bleeding may be present. Perianal epidermoid carcinoma may be treated in a similar fashion as squamous cell carcinoma of the skin in other locations because wide local excision can usually be achieved without resecting the anal sphincter. Intra-anal epidermoid carcinoma cannot be excised locally, and first-line therapy relies on chemotherapy and radiation (the *Nigro protocol*: 5-fluorouracil, mitomycin C, and 30 Gy of external beam radiation). This regimen cures 70% to 80% of these tumors. It is important to note that epidermoid carcinomas continue to respond after completion of chemoradiation. Lesions that persist greater than 3 to 6 months after therapy may represent persistent disease and should be biopsied. Recurrence usually requires radical resection (APR). Metastasis to inguinal lymph nodes is a poor prognostic sign.¹⁴⁸

Verrucous Carcinoma (Buschke-Lowenstein Tumor, Giant Condyloma Acuminata). Verrucous carcinoma is a locally

aggressive form of condyloma acuminata. Although these lesions do not metastasize, they can cause extensive local tissue destruction and may be grossly indistinguishable from epidermoid carcinoma. Wide local excision is the treatment of choice when possible, but radical resection may sometimes be required. Topical immunomodulators such as imiquimod (Aldara) may shrink some tumors, but they are almost never curative.¹⁵¹ Very large lesions may respond to external beam radiation, but resection is almost always required.

Basal Cell Carcinoma. Basal cell carcinoma of the anus is rare and resembles basal cell carcinoma elsewhere on the skin (raised, pearly edges with central ulceration). This is a slow-growing tumor that rarely metastasizes. Wide local excision is the treatment of choice, but recurrence occurs in up to 30% of patients. Radical resection and/or radiation therapy may be required for large lesions.

Adenocarcinoma. Adenocarcinoma of the anus is extremely rare and usually represents downward spread of a low rectal adenocarcinoma. Adenocarcinoma may occasionally arise from the anal glands or may develop in a chronic fistula. Radical resection, usually after neoadjuvant chemoradiation, is usually required.

Extramammary perianal *Paget's disease* is *adenocarcinoma in situ* arising from the apocrine glands of the perianal area. The lesion is typically plaque-like and may be indistinguishable from high-grade intraepithelial lesions. Characteristic *Paget's cells* are seen histologically. These tumors are often associated with a synchronous gastrointestinal adenocarcinoma, so a complete evaluation of the intestinal tract should be performed. Wide local excision is usually adequate treatment for perianal Paget's disease.

Melanoma. Anorectal melanoma is rare, comprising less than 1% of all anorectal malignancies and 1% to 2% of melanomas. Diagnosis is often delayed, and symptoms are attributed to hemorrhoidal disease. Despite many advances in the treatment of cutaneous melanoma, prognosis for patients with anorectal disease remains poor. Overall 5-year survival is less than 10%, and many patients present with systemic metastasis and/or deeply invasive tumors at the time of diagnosis. A few patients with anorectal melanoma, however, present with isolated local or locoregional disease that is potentially resectable for cure, and both radical resection (APR) and wide local excision have been advocated. Recurrence is common and usually occurs systemically regardless of the initial surgical procedure. Local resection with free margins does not increase the risk of local or regional recurrence, and APR offers no survival advantage over local excision. Because of the morbidity associated with APR, wide local excision is recommended for initial treatment of localized anal melanoma. In some patients, wide local excision may not be technically feasible, and APR may be required if the tumor involves a significant portion of the anal sphincter or is circumferential. The addition of adjuvant chemotherapy, biochemotherapy, vaccines, or radiotherapy may be of benefit in some patients, but efficacy remains unproven.^{152,153}

OTHER BENIGN COLORECTAL CONDITIONS

Rectal Prolapse and Solitary Rectal Ulcer Syndrome

Rectal Prolapse. Rectal prolapse refers to a circumferential, full-thickness protrusion of the rectum through the anus and has also been called "first-degree" prolapse, "complete" prolapse, or

proctidentia. Internal prolapse occurs when the rectal wall intussuscepts but does not protrude and is probably more accurately described as internal intussusception. Mucosal prolapse is a partial-thickness protrusion often associated with hemorrhoidal disease and is usually treated with banding or hemorrhoidectomy.

In adults, this condition is far more common among women, with a female-to-male ratio of 6:1. Prolapse becomes more prevalent with age in women and peaks in the seventh decade of life. In men, prevalence is unrelated to age. Symptoms include tenesmus, a sensation of tissue protruding from the anus that may or may not spontaneously reduce, and a sensation of incomplete evacuation. Mucus discharge and leakage may accompany the protrusion. Patients also present with a myriad of functional complaints, from incontinence and diarrhea to constipation and outlet obstruction.

A thorough preoperative evaluation, including colonic transit studies, anorectal manometry, tests of pudendal nerve terminal motor latency, EMG, and cinedefecography, may be useful. The colon should be evaluated by colonoscopy, air-contrast barium enema, or CT colonography to exclude neoplasms or diverticular disease. Cardiopulmonary condition should be thoroughly evaluated because comorbidities may influence the choice of surgical procedure.

The primary therapy for rectal prolapse is surgery, and more than 100 different procedures have been described to treat this condition. Operations can be categorized as either *abdominal* or *perineal*. Abdominal operations have taken three major approaches: (a) reduction of the perineal hernia and closure of the cul-de-sac (*Moschowitz repair*); (b) fixation of the rectum, either with a prosthetic mesh or fascia lata sling (*Ripstein* and *Wells rectopexy*; *ventral rectopexy*) or by *suture rectopexy*; or (c) resection of redundant sigmoid colon (Fig. 29-28). In some cases, resection is combined with rectal fixation (*resection rectopexy*). The recently described ventral rectopexy involves dissection of the anterior rectum down to the pelvic floor. Mesh is sutured to the anterior rectum at one end and anchored to the sacral promontory at the other end.¹⁵⁴ Abdominal procedures for rectal prolapse are increasingly performed laparoscopically or robotically. Perineal approaches have focused on tightening the anus with a variety of prosthetic materials, reefing the rectal mucosa (*Delorme procedure*), or resecting the prolapsed bowel from the perineum (*perineal rectosigmoidectomy* or *Altemeier procedure*) (Fig. 29-29).

Because rectal prolapse occurs most commonly in elderly women, the choice of operation depends in part on the patient's overall medical condition. Abdominal rectopexy (with or without sigmoid resection) offers the most durable repair, with recurrence occurring in less than 10% of patients. Perineal

rectosigmoidectomy avoids an abdominal operation and may be preferable in high-risk patients but is associated with a higher recurrence rate. Reefing the rectal mucosa is effective for patients with limited prolapse. Anal encirclement procedures generally have been abandoned.

Solitary Rectal Ulcer Syndrome. Solitary rectal ulcer syndrome and colitis cystica profunda are commonly associated with internal intussusception. Patients may complain of pain, bleeding, mucus discharge, or outlet obstruction. In solitary rectal ulcer syndrome, one or more ulcers are present in the distal rectum, usually on the anterior wall. In colitis cystica profunda, nodules or a mass may be found in a similar location. Evaluation should include anorectal manometry, defecography, and either colonoscopy or barium enema to exclude other diagnoses. Biopsy of an ulcer or mass is mandatory to exclude malignancy or infection due to cytomegalovirus (CMV) in an immunosuppressed patient. Nonoperative therapy (high-fiber diet, defecation training to avoid straining, and laxatives or enemas) is effective in the majority of patients. Biofeedback has also been reported to be effective in some patients. Surgery (either abdominal or perineal repair of prolapse as described earlier) is reserved for highly symptomatic patients who have failed all medical interventions.

Volvulus

Volvulus occurs when an air-filled segment of the colon twists about its mesentery. The sigmoid colon is involved in up to 90% of cases, but volvulus can involve the cecum (<20%) or transverse colon. A volvulus may reduce spontaneously, but more commonly produces bowel obstruction, which can progress to strangulation, gangrene, and perforation. Chronic constipation may produce a large, redundant colon (*chronic megacolon*) that predisposes to volvulus, especially if the mesenteric base is narrow.

The symptoms of volvulus are those of acute bowel obstruction. Patients present with abdominal distention, nausea, and vomiting. Symptoms rapidly progress to generalized abdominal pain and tenderness. Fever and leukocytosis are heralds of gangrene and/or perforation. Occasionally, patients will report a long history of intermittent obstructive symptoms and distention, suggesting intermittent chronic volvulus.

Sigmoid Volvulus. Sigmoid volvulus can often be differentiated from cecal or transverse colon volvulus by the appearance of plain X-rays of the abdomen. Sigmoid volvulus produces a characteristic *bent inner tube* or *coffee bean* appearance, with the convexity of the loop lying in the right upper quadrant (opposite the site of obstruction). Gastrografin enema shows a

Figure 29-28. Transabdominal proctopexy for rectal prolapse. The fully mobilized rectum is sutured to the presacral fascia. **A.** Anterior view. **B.** Lateral view. If desired, a sigmoid colectomy can be performed concomitantly to resect the redundant colon.

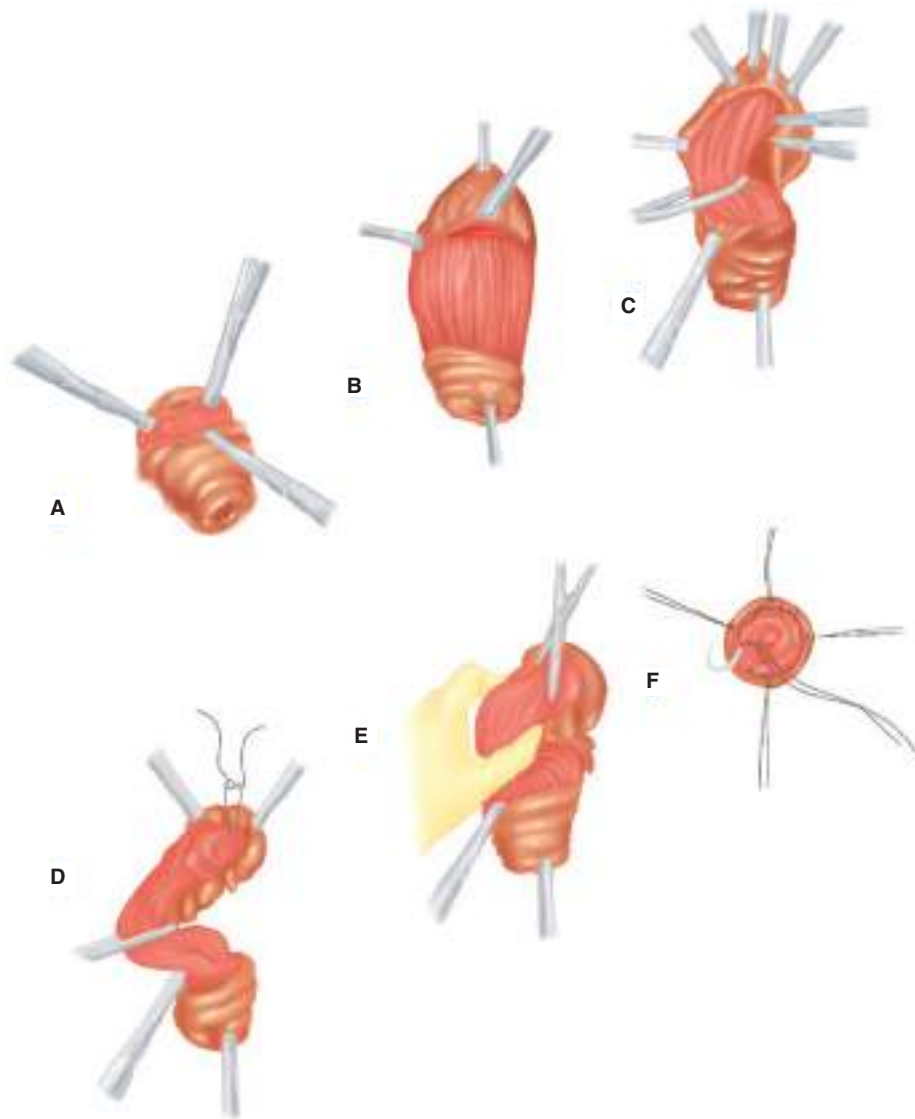

Figure 29-29. Perineal rectosigmoidectomy shown in lithotomy position. **A.** A circular incision is made 2 cm proximal to the dentate line. **B.** The anterior peritoneal reflection is opened. **C.** The mesentery is divided and ligated. **D.** The peritoneum may be sutured to the bowel wall. **E.** The bowel is resected. **F.** A hand-sewn anastomosis is performed.

narrowing at the site of the volvulus and a pathognomonic *bird's beak* (Fig. 29-30).

Unless there are obvious signs of gangrene or peritonitis, the initial management of sigmoid volvulus is resuscitation followed by endoscopic detorsion. Detorsion is usually most easily accomplished by using a rigid proctoscope, but a flexible sigmoidoscope or colonoscope may also be effective. A rectal tube may be inserted to maintain decompression. Although these techniques are successful in reducing sigmoid volvulus in the majority of patients, the risk of recurrence is high (up to 40%). For this reason, an elective sigmoid colectomy should be performed after the patient has been stabilized and undergone an adequate bowel preparation.

Clinical evidence of gangrene or perforation mandates immediate surgical exploration without an attempt at endoscopic decompression. Similarly, the presence of necrotic mucosa, ulceration, or dark blood noted on endoscopy examination suggests strangulation and is an indication for operation. If dead bowel is present at laparotomy, a sigmoid colectomy with end colostomy (Hartmann's procedure) may be the safest operation to perform.

Cecal Volvulus. Cecal volvulus results from nonfixation of the right colon. In the majority of cases, rotation occurs around the ileocolic blood vessels and vascular impairment occurs early, although 10% to 30% of the cecum folds upon itself (cecal bascule). Plain X-rays of the abdomen show a characteristic kidney-shaped, air-filled structure in the left upper quadrant (opposite the site of obstruction), and a Gastrografin enema confirms obstruction at the level of the volvulus.

Unlike sigmoid volvulus, cecal volvulus can almost never be detorsed endoscopically. Moreover, because vascular compromise occurs early in the course of cecal volvulus, surgical exploration is necessary when the diagnosis is made. Right hemicolectomy with a primary ileocolic anastomosis can usually be performed safely and prevents recurrence. Simple detorsion or detorsion and cecopexy are associated with a high rate of recurrence.

Transverse Colon Volvulus. Transverse colon volvulus is extremely rare. Nonfixation of the colon and chronic constipation with megacolon may predispose to transverse colon

A

B

Figure 29-30. Sigmoid volvulus: (A) Illustration and (B) Gastrografin enema showing “bird-beak” sign (arrow). (B. Reproduced with permission from James EC, Corry RJ, Perry JCF: Basic Surgical Practice. Philadelphia, PA: Hanley & Belfus; 1987.)

volvulus. The radiographic appearance of transverse colon volvulus resembles sigmoid volvulus, but Gastrografin enema will reveal a more proximal obstruction. Although colonoscopic detorsion is occasionally successful in this setting, most patients require emergent exploration and resection.

Megacolon

Megacolon describes a chronically dilated, elongated, hypertrophied large bowel. Megacolon may be congenital or acquired and is usually related to chronic mechanical or functional obstruction. In general, the degree of megacolon is related to the duration of obstruction. Evaluation must always include examination of the colon and rectum (either endoscopically or radiographically) to exclude a surgically correctable mechanical obstruction.

Congenital megacolon caused by Hirschsprung’s disease results from the failure of migration of neural crest cells to the distal large intestine. The resulting absence of ganglion cells in the distal colon results in a failure of relaxation and causes a functional obstruction. The proximal, healthy bowel becomes progressively dilated. Surgical resection of the aganglionic segment is curative. Although Hirschsprung’s disease primarily is a disease of infants and children, it occasionally presents later in adulthood, especially if an extremely short segment of the bowel is affected (*ultrashort-segment Hirschsprung’s disease*).

Acquired megacolon may result from infection or chronic constipation. Infection with the protozoan *Trypanosoma cruzi* (*Chagas’ disease*) destroys ganglion cells and produces both megacolon and megaesophagus. Chronic constipation from slow transit or secondary to medications (especially anticholinergic

medications) or neurologic disorders (paraplegia, poliomyelitis, amyotrophic lateral sclerosis, multiple sclerosis) may produce progressive colonic dilatation. Diverting ileostomy or subtotal colectomy with an ileorectal anastomosis is occasionally necessary in these patients.

Colonic Pseudo-Obstruction (Ogilvie’s Syndrome)

Colonic pseudo-obstruction (Ogilvie’s syndrome) is a functional disorder in which the colon becomes massively dilated in the absence of mechanical obstruction. Pseudo-obstruction most commonly occurs in hospitalized patients and is associated with the use of narcotics, bed rest, and comorbid disease. Pseudo-obstruction is thought to result from autonomic dysfunction and severe adynamic ileus. The diagnosis is made based on the presence of massive dilatation of the colon (usually predominantly the *right* and *transverse* colon) in the absence of a mechanical obstruction. Initial treatment consists of cessation of narcotics, anticholinergics, or other medications that may contribute to ileus. Strict bowel rest and intravenous hydration are crucial. Most patients will respond to these measures. In patients who fail to improve, colonoscopic decompression often is effective. However, this procedure is technically challenging, and great care must be taken to avoid causing perforation. Up to 40% of patients recur. Intravenous neostigmine (an acetylcholinesterase inhibitor), administered as a single 2 mg dose, also is extremely effective in decompressing the dilated colon and is associated with a low rate of recurrence (20%).¹⁵⁵ However, neostigmine may produce transient but profound bradycardia and may be inappropriate in patients with cardiopulmonary

disease. Because the colonic dilatation is typically greatest in the proximal colon, placement of a rectal tube is rarely effective. It is crucial to exclude mechanical obstruction (usually with a Gastrografin enema) prior to medical or endoscopic treatment.

Ischemic Colitis

Intestinal ischemia occurs most commonly in the colon. Unlike small bowel ischemia, colonic ischemia rarely is associated with major arterial or venous occlusion. Instead, most colonic ischemia appears to result from low flow and/or small vessel occlusion. Risk factors include vascular disease, diabetes mellitus, vasculitis, hypotension, and tobacco use. In addition, ligation of the inferior mesenteric artery during aortic surgery predisposes to colonic ischemia. Occasionally, thrombosis or embolism may cause ischemia. Although the splenic flexure is the most common site of ischemic colitis, any segment of the colon may be affected. The rectum is relatively spared because of its rich collateral circulation.

Signs and symptoms of ischemic colitis reflect the extent of bowel ischemia. In mild cases, patients may have diarrhea (usually bloody) without abdominal pain. With more severe ischemia, intense abdominal pain (often out of proportion to the clinical examination), tenderness, fever, and leukocytosis are present. Peritonitis and/or systemic toxicity are signs of full-thickness necrosis and perforation.

The diagnosis of ischemic colitis is often based on the clinical history and physical examination. Plain films may reveal *thumb printing*, which results from mucosal edema and submucosal hemorrhage. CT often shows nonspecific colonic wall thickening and pericolic fat stranding. Angiography is usually not helpful because major arterial occlusion is rare. While sigmoidoscopy may reveal characteristic dark, hemorrhagic mucosa, the risk of precipitating perforation is high. For this reason, *sigmoidoscopy is relatively contraindicated* in any patient with significant abdominal tenderness. Contrast studies (Gastrografin or barium enema) are similarly contraindicated during the acute phase of ischemic colitis.

Treatment of ischemic colitis depends on clinical severity. Unlike ischemia of the small bowel, the majority of patients with ischemic colitis can be treated medically. Bowel rest and broad-spectrum antibiotics are the mainstay of therapy, and 80% of patients will recover with this regimen. Hemodynamic parameters should be optimized, especially if hypotension and low flow appear to be the inciting cause. Long-term sequelae include stricture (10–15%) and chronic segmental ischemia (15–20%). Colonoscopy should be performed after recovery to evaluate strictures and to rule out other diagnoses such as inflammatory bowel disease or malignancy. Failure to improve after 2 to 3 days of medical management, progression of symptoms, and deterioration in clinical condition are indications for surgical exploration. In this setting, all necrotic bowel should be resected. Primary anastomosis should be avoided. Occasionally, repeated exploration (a *second-look operation*) may be necessary.

Infectious Colitis

Pseudomembranous Colitis (*Clostridium difficile* Colitis). *Pseudomembranous colitis* is caused by *C difficile*, a gram-positive anaerobic bacillus. *Clostridium difficile colitis* is extremely common and is the leading cause of nosocomially acquired diarrhea. The spectrum of disease ranges from watery

diarrhea to fulminant, life-threatening colitis. *Clostridium difficile* is carried in the large intestine of many healthy adults. Colitis is thought to result from overgrowth of this organism after depletion of the normal commensal flora of the gut with the use of antibiotics. Although clindamycin was the first antimicrobial agent associated with *C difficile* colitis, almost any antibiotic may cause this disease. Moreover, although the risk of *C difficile* colitis increases with prolonged antibiotic use, even a single dose of an antibiotic may cause the disease. Immunosuppression, medical comorbidities, prolonged hospitalization or nursing home residence, and bowel surgery increase the risk.

The pathogenic changes associated with *C difficile* colitis result from production of two toxins: *toxin A* (an enterotoxin) and *toxin B* (a cytotoxin). Diagnosis of this disease was traditionally made by culturing the organism from the stool. Detection of one or both toxins (either by cytotoxic assays or by immunoassays) has proven to be more rapid, sensitive, and specific.¹⁵⁶ The diagnosis may also be made endoscopically by detection of characteristic ulcers, plaques, and pseudomembranes.¹⁵⁷

Management should include immediate cessation of the offending antimicrobial agent. Patients with mild disease (diarrhea but no fever or abdominal pain) may be treated as outpatients with a 10-day course of oral metronidazole. Oral vancomycin is a second-line agent used in patients allergic to metronidazole or in patients with recurrent disease. More severe diarrhea associated with dehydration and/or fever and abdominal pain is best treated with bowel rest, intravenous hydration, and oral metronidazole or vancomycin. Proctosigmoiditis may respond to vancomycin enemas. Recurrent colitis occurs in up to 20% of patients and may be treated by a longer course of oral vancomycin (up to 1 month) or rifaximin (a rapamycin derivative). Reintroduction of normal flora by ingestion of *probiotics* or *stool transplantation* has been suggested as a possible treatment for recurrent or refractory disease. Fulminant colitis, characterized by septicemia and/or evidence of perforation, requires emergent laparotomy. A total abdominal colectomy with end ileostomy may be lifesaving. Over the past decade, *C difficile* colitis has increased in prevalence, and new, more virulent strains have appeared, making this disease increasingly challenging to treat.^{157,158}

Other Infectious Colitides. A variety of other infections with bacteria, parasites, fungi, or viruses may cause colonic inflammation. Common bacterial infections include enterotoxigenic *E coli*, *C jejuni*, *Yersinia enterocolitica*, *S typhi*, *Shigella*, and *N gonorrhoeae*. Less commonly, *Mycobacterium tuberculosis*, *M bovis*, *Actinomyces israelii*, or *Treponema pallidum* (syphilis) may cause colitis or proctitis. Parasitic infections such as amebiasis, cryptosporidiosis, and giardiasis are also relatively common. Fungal infections (*Candida* species, histoplasmosis) are extremely rare in otherwise healthy individuals. The most common viral infections that produce colitic symptoms are HIV, herpes simplex viruses, and CMV.

Most symptoms are nonspecific and consist of diarrhea (with or without bleeding), crampy abdominal pain, and malaise. A thorough history may offer clues to the etiology (other medical conditions, especially immunosuppression; recent travel or exposures; and ingestions). Diagnosis is usually made by identification of a pathogen in the stool, either by microscopy or culture. Serum immunoassays may also be useful (amebiasis, HIV, CMV). Occasionally, endoscopy with biopsy may be required. Treatment is tailored to the infection.

Any patient with anal/perianal symptoms requires a careful history and physical, including a digital rectal examination. Other studies such as defecography, manometry, CT scan, MRI, contrast enema, endoscopy, endoanal ultrasound, or exam under anesthesia may be required to arrive at an accurate diagnosis.

Hemorrhoids

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fibers that are located in the anal canal (see Fig. 29-4). Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions. Hemorrhoids are thought to function as part of the continence mechanism and aid in complete closure of the anal canal at rest. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. Excessive straining, increased abdominal pressure, and hard stools increase venous engorgement of the hemorrhoidal plexus and cause prolapse of hemorrhoidal tissue. Bleeding, thrombosis, and symptomatic hemorrhoidal prolapse may result.

External hemorrhoids are located distal to the dentate line and are covered with anoderm. Because the anoderm is richly innervated, thrombosis of an external hemorrhoid may cause significant pain. It is for this reason that external hemorrhoids should not be ligated or excised without adequate local anesthetic. A *skin tag* is redundant fibrotic skin at the anal verge, often persisting as the residua of a thrombosed external hemorrhoid. Skin tags are often confused with symptomatic hemorrhoids. External hemorrhoids and skin tags may cause itching and difficulty with hygiene if they are large. Treatment of external hemorrhoids and skin tags is only indicated for symptomatic relief.

Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but they rarely become painful unless they develop thrombosis and necrosis (usually related to severe prolapse, incarceration, and/or strangulation). Internal hemorrhoids are graded according to the extent of prolapse. *First-degree hemorrhoids* bulge into the anal canal and may prolapse beyond the dentate line on straining. *Second-degree hemorrhoids* prolapse through the anus but reduce spontaneously. *Third-degree hemorrhoids* prolapse through the anal canal and require manual reduction. *Fourth-degree hemorrhoids* prolapse but cannot be reduced and are at risk for strangulation.

Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids. Hemorrhoidectomy is often required for large, symptomatic, combined hemorrhoids. *Postpartum hemorrhoids* result from straining during labor, which results in edema, thrombosis, and/or strangulation. Hemorrhoidectomy is often the treatment of choice, especially if the patient has had chronic hemorrhoidal symptoms. *Portal hypertension* was long thought to increase the risk of hemorrhoidal bleeding because of the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses). It is now understood that hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. *Rectal varices*, however, may occur and may cause hemorrhage in these patients. In general, rectal varices are best treated by lowering portal venous pressure. Rarely, suture ligation may be necessary if massive bleeding persists. Surgical hemorrhoidectomy should be avoided in

these patients because of the risk of massive, difficult-to-control variceal bleeding.

Treatment

Medical Therapy Bleeding from first- and second-degree hemorrhoids often improves with the addition of dietary fiber, stool softeners, increased fluid intake, and avoidance of straining. Associated pruritus often may improve with improved hygiene. Many over-the-counter topical medications are desiccants and are relatively ineffective for treating hemorrhoidal symptoms.

Rubber Band Ligation Persistent bleeding from first-, second-, and selected third-degree hemorrhoids may be treated by rubber band ligation.

Mucosa located 1 to 2 cm proximal to the dentate line is grasped and pulled into a rubber band applicator. After firing the ligator, the rubber band strangulates the underlying tissue, causing scarring and preventing further bleeding or prolapse (Fig. 29-31). In general, only one or two quadrants are banded per visit. Severe pain will occur if the rubber band is placed at or distal to the dentate line where sensory nerves are located. Other complications of rubber band ligation include *urinary retention, infection, and bleeding*. Urinary retention occurs in approximately 1% of patients and is more likely if the ligation has inadvertently included a portion of the internal sphincter. *Necrotizing infection* is an uncommon, but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the patient usually with an exam under anesthesia. Treatment includes debridement of necrotic tissue, drainage of associated abscesses, and broad-spectrum antibiotics. *Bleeding* may occur approximately 7 to 10 days after rubber band ligation, at the time when the ligated pedicle necroses and sloughs. Bleeding is usually self-limited, but persistent hemorrhage may require exam under anesthesia and suture ligation of the pedicle.

Infrared Photocoagulation Infrared photocoagulation is an effective office treatment for small first- and second-degree hemorrhoids. The instrument is applied to the apex of each hemorrhoid to coagulate the underlying plexus. All three quadrants may be treated during the same visit. Larger hemorrhoids and hemorrhoids with a significant amount of prolapse are not effectively treated with this technique.

Sclerotherapy The injection of bleeding internal hemorrhoids with sclerosing agents is another effective office technique for treatment of first-, second-, and some third-degree hemorrhoids. One to 3 mL of a sclerosing solution (phenol in olive oil, sodium morrhuate, or quinine urea) is injected into the submucosa of each hemorrhoid. Few complications are associated with sclerotherapy, but infection and fibrosis have been reported.

Excision of Thrombosed External Hemorrhoids Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24 to 72 hours after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is rarely effective. After 72 hours, the clot begins to resorb, and the pain resolves spontaneously. Excision is unnecessary, but sitz baths and analgesics are often helpful.

Operative Hemorrhoidectomy A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa.

Figure 29-31. Rubber band ligation of internal hemorrhoids. The mucosa just proximal to the internal hemorrhoids is banded.

Closed Submucosal Hemorrhoidectomy The Parks or Ferguson hemorrhoidectomy involves resection of hemorrhoidal tissue and closure of the wounds with absorbable suture. The procedure may be performed in the prone or lithotomy position under local, regional, or general anesthesia. The anal canal is examined and an anal speculum inserted. The hemorrhoid cushions and associated redundant mucosa are identified and excised using an elliptical incision starting just distal to the anal verge and extending proximally to the anorectal ring. It is crucial to identify the fibers of the internal sphincter and carefully brush these away from the dissection in order to avoid injury to the sphincter. The apex of the hemorrhoidal plexus is then ligated and the hemorrhoid excised. The wound is then closed with a running absorbable suture. All three hemorrhoidal cushions may be removed using this technique; however, care should be taken to avoid resecting a large area of perianal skin in order to avoid postoperative anal stenosis (Fig. 29-32).

Open Hemorrhoidectomy This technique, often called the Milligan and Morgan hemorrhoidectomy, follows the same principles of excision described earlier, but the wounds are left open and allowed to heal by secondary intention.

Whitehead's Hemorrhoidectomy Whitehead's hemorrhoidectomy involves circumferential excision of the hemorrhoidal cushions just proximal to the dentate line. After excision, the rectal mucosa is then advanced and sutured to the dentate line.

While some surgeons still use Whitehead's hemorrhoidectomy, most have abandoned this approach because of the risk of ectropion (*Whitehead's deformity*).

Procedure for Prolapse and Hemorrhoids/Stapled Hemorrhoidectomy Procedure for prolapse and hemorrhoids (PPH) is also referred to as a stapled hemorrhoidopexy. Best suited for patients with second- and third-degree hemorrhoids, this outpatient procedure uses a stapling device similar in appearance and mechanism of action to an end-to-end anastomotic (EEA) stapling device used for rectal surgery. Just as with an EEA stapler, proximal and distal tissue donuts, in this case consisting of mucosa and submucosa, are generated by the PPH stapler though the primary means by which this procedure provides relief for internal hemorrhoids is by pexing the redundant hemorrhoidal tissue, ligating the venules feeding the hemorrhoidal plexus and fixing redundant mucosa proximal to the dentate line. Several studies suggest that this procedure is safe and effective, that it is associated with less postoperative pain and disability, and that it has an equivalent risk of postoperative complications when compared to excisional hemorrhoidectomy. Complications associated with this procedure include chronic anal pain, bacteremia, rectovaginal fistula, formation of an obstructing rectal stricture and even rectal perforation. In at least one systematic review comparing outcomes between PPH and excisional hemorrhoidectomy, overall incidence of complications was similar,

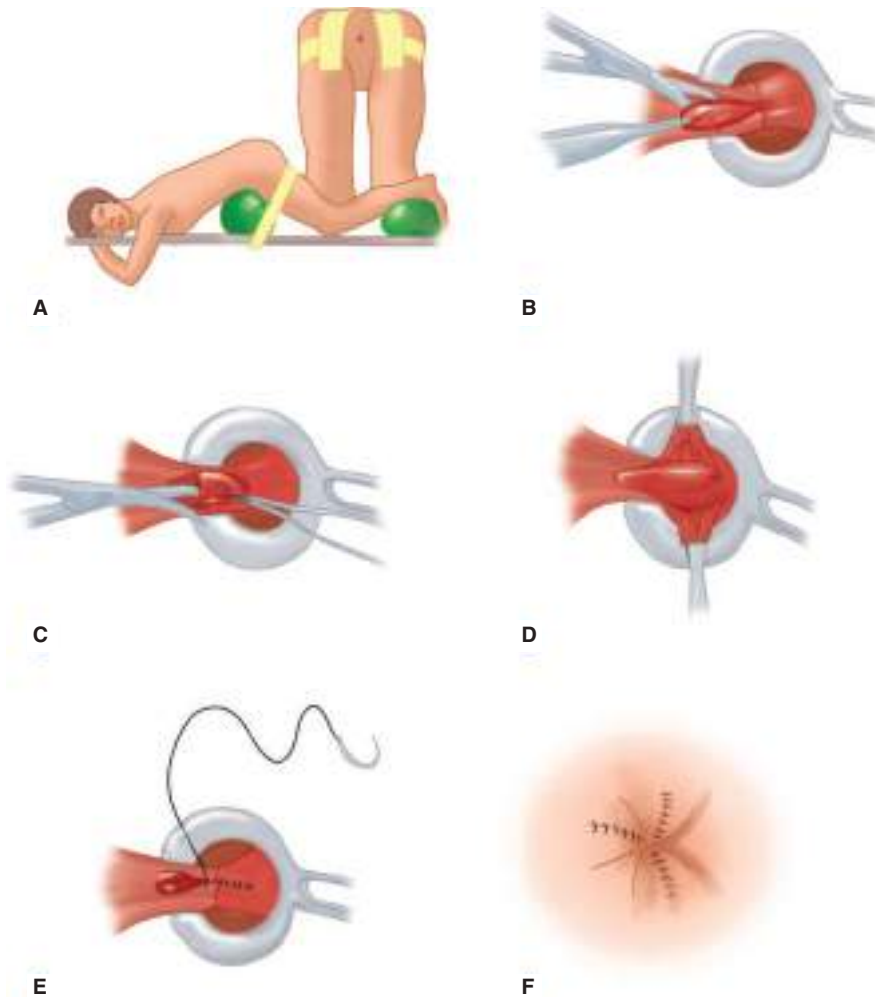

Figure 29-32. Technique of closed submucosal hemorrhoidectomy. **A.** The patient is in prone jackknife position. **B.** A Fansler anoscope is used for exposure. **C.** A narrow ellipse of anoderm is excised. **D.** A submucosal dissection of the hemorrhoidal plexus from the underlying anal sphincter is performed. **E.** Redundant mucosa is anchored to the proximal anal canal, and the wound is closed with a running absorbable suture. **F.** Additional quadrants are excised to complete the procedure.

though the incidence of recurrent hemorrhoids was lower following excisional hemorrhoidectomy.^{159,160}

Doppler-Guided Hemorrhoidal Artery Ligation Another recent approach to treating symptomatic hemorrhoids is Doppler-guided hemorrhoidal artery ligation (also called transanal hemorrhoidal dearterialization). In this procedure, a Doppler probe is used to identify the artery or arteries feeding the hemorrhoidal plexus. These vessels are then ligated. Early reports have shown promise, but long-term durability remains to be determined.¹⁶¹

Complications of Hemorrhoidectomy. Postoperative pain following excisional hemorrhoidectomy requires analgesia usually with oral narcotics. Nonsteroidal anti-inflammatory drugs, muscle relaxants, topical analgesics, and comfort measures, including sitz baths, are often useful as well. Urinary retention is a common complication following hemorrhoidectomy and has been reported to be as high as 10% to 50% in some series. The risk of urinary retention can be minimized by limiting intraoperative and perioperative intravenous fluids and by providing adequate analgesia. Pain can also lead to *fecal impaction*. Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation,

liberal use of laxatives postoperatively, and adequate pain control. While a small amount of *bleeding*, especially with bowel movements, is to be expected, massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle. This type of hemorrhage mandates an urgent return to the operating room where suture ligation of the bleeding vessel will often solve the problem. Bleeding may also occur 7 to 10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. While some of these patients may be safely observed, others will require an exam under anesthesia to ligate the bleeding vessel or to oversee the wounds if no specific site of bleeding is identified. *Infection* is uncommon after hemorrhoidectomy; however, necrotizing soft tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of infection. If infection is suspected, emergent examination under anesthesia, drainage of abscess, and/or debridement of all necrotic tissue are required.

Long-term sequelae of hemorrhoidectomy include *incontinence*, *anal stenosis*, and *ectropion* (*Whitehead's deformity*). Many patients experience transient incontinence to flatus, but these symptoms are usually short-lived, and few patients have

permanent fecal incontinence. Anal stenosis may result from scarring after extensive resection of perianal skin. Ectropion may occur after Whitehead's hemorrhoidectomy.

Anal Fissure

A fissure in ano is a tear in the anoderm distal to the dentate line. The pathophysiology of anal fissure is thought to be related to trauma from either the passage of hard stool or prolonged diarrhea. A tear in the anoderm causes spasm of the internal anal sphincter, which results in pain, increased tearing, and decreased blood supply to the anoderm. This cycle of pain, spasm, and ischemia contributes to development of a poorly healing wound that becomes a *chronic fissure*. The vast majority of anal fissures occur in the posterior midline. Ten percent to 15% occur in the anterior midline. Less than 1% of fissures occur off midline.

Symptoms and Findings. Anal fissure is extremely common. Characteristic symptoms include tearing pain with defecation and hematochezia (usually described as blood on the toilet paper). Patients may also complain of a sensation of intense and painful anal spasm lasting for several hours after a bowel movement. On physical examination, the fissure can often be seen in the anoderm by gently separating the buttocks. Patients are often too tender to tolerate digital rectal examination, anoscopy, or proctoscopy. An *acute fissure* is a superficial tear of the distal anoderm and almost always heals with medical management. *Chronic fissures* develop ulceration and heaped-up edges with the white fibers of the internal anal sphincter visible at the base of the ulcer. There often is an associated external skin tag and/or a hypertrophied anal papilla internally. These fissures are more challenging to treat and may require surgery. A lateral location of a chronic anal fissure may be evidence of an underlying disease such as Crohn's disease, HIV, syphilis, tuberculosis, or leukemia. If the diagnosis is in doubt or there is suspicion of another cause for the perianal pain such as abscess or fistula, an examination under anesthesia may be necessary.

Treatment. Therapy focuses on breaking the cycle of pain, spasm, and ischemia thought to be responsible for development of fissure in ano. First-line therapy to minimize anal trauma includes bulk agents, stool softeners, and warm sitz baths. The addition of 2% lidocaine jelly or other analgesic creams can provide additional symptomatic relief. Nitroglycerin ointment has been used locally to improve blood flow but often causes severe headaches. Both oral and topical calcium channel blockers (diltiazem and nifedipine) have also been used to heal fissures and may have fewer side effects than topical nitrates.¹⁶² Newer agents, such as arginine (a nitric oxide donor) and topical bethanechol (a muscarinic agonist), have also been used to treat fissures. Medical therapy is effective in most acute fissures, but it will heal only approximately 50% of chronic fissures.¹⁶²

Botulinum toxin (Botox) causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals. Injection of botulinum toxin is used in some centers as an alternative to surgical sphincterotomy for chronic fissure. Although there are few long-term complications from the use of botulinum toxin, healing appears to be equivalent to other medical therapies.^{163,164}

Surgical therapy has traditionally been recommended for chronic fissures that have failed medical therapy, and lateral internal sphincterotomy is the procedure of choice. The aim of this procedure is to decrease spasm of the internal sphincter by

Figure 29-33. A through D. Open lateral internal sphincterotomy for fissure in ano. m = muscle.

dividing a portion of the muscle. Approximately 30% of the internal sphincter fibers are divided laterally by using either an open (Fig. 29-33) or closed (Fig. 29-34) technique. Healing is achieved in more than 95% of patients using this technique, and most patients experience immediate pain relief. Recurrence occurs in less than 10% of patients, and the risk of incontinence (usually to flatus) ranges from 5% to 15%. Advancement flaps (VY) with or without sphincterotomy have also been reported to successfully treat chronic fissures.

Anorectal Sepsis and Cryptoglandular Abscess

Relevant Anatomy. The majority of anorectal suppurative disease results from infections of the anal glands (cryptoglandular infection) found in the intersphincteric plane. Their ducts traverse the internal sphincter and empty into the anal crypts at the level of the dentate line. Infection of an anal gland results in the formation of an abscess that enlarges and spreads along one of several planes in the perianal and perirectal spaces. The *perianal space* surrounds the anus and laterally becomes continuous with the fat of the buttocks. The *intersphincteric space* separates the internal and external anal sphincters. It is continuous with the perianal space distally and extends cephalad into the rectal wall. The *ischioanal space (ischioanal fossa)* is located lateral and posterior to the anus and is bounded medially by the levator ani, and inferiorly by the transverse septum. The ischioanal space contains the inferior rectal vessels and lymphatics. The two ischioanal spaces connect posteriorly above the anococcygeal ligament but below the levator ani muscle, forming the *deep postanal space*. The *supralelevator spaces* lie above the levator ani on either side of the rectum and communicate posteriorly. The anatomy of these spaces influences the location and spread of cryptoglandular infection (Fig. 29-35).

As an abscess enlarges, it spreads in one of several directions. A *perianal abscess* is the most common manifestation and appears as a painful swelling at the anal verge. Spread through the external sphincter below the level of the puborectalis produces an *ischioanal abscess*. These abscesses may become extremely large and may not be visible in the perianal region.

Figure 29-34. A through D. Closed lateral internal sphincterotomy for fissure in ano.

Digital rectal exam will reveal a painful swelling laterally in the ischioanal fossa. *Intersphincteric abscesses* occur in the intersphincteric space and are notoriously difficult to diagnose, often requiring an examination under anesthesia. *Pelvic* and *supralelevator abscesses* are uncommon and may result from extension of an intersphincteric or ischioanal abscess upward or extension of an intraperitoneal abscess downward (Fig. 29-36).

Diagnosis. Severe anal pain is the most common presenting complaint. A palpable mass is often detected by inspection of the perianal area or by digital rectal examination. Occasionally, patients will present with fever, urinary retention, or life-threatening sepsis. The diagnosis of a perianal or ischioanal abscess can usually be made with physical exam alone (either in the office or in the operating room). However, complex or atypical presentations may require imaging studies such as CT or MRI to fully delineate the anatomy of the abscess.

Treatment. Anorectal abscesses should be treated by drainage as soon as the diagnosis is established. If the diagnosis is in question, an examination and drainage under anesthesia are often the most expeditious ways both to confirm the diagnosis and to treat the problem. Delayed or inadequate treatment may occasionally cause extensive and life-threatening suppuration with massive tissue necrosis and septicemia. Antibiotics are only indicated if there is extensive overlying cellulitis or if the patient is immunocompromised, has diabetes mellitus, or has

valvular heart disease. Antibiotics alone are ineffective at treating perianal or perirectal infection.

Perianal Abscess

Most perianal abscesses can be drained under local anesthesia in the office, clinic, or emergency department. Larger, more complicated abscesses may require drainage in the operating room. A skin incision is created, and a disk of skin excised to prevent premature closure. No packing is necessary, and sitz baths are started the next day (Fig. 29-37).

Ischioanal Abscess

An ischioanal abscess causes diffuse swelling in the ischioanal fossa that may involve one or both sides, forming a “horseshoe” abscess. Simple ischioanal abscesses are drained through an incision in the overlying skin. Horseshoe abscesses require drainage of the deep postanal space and often require counterincisions over one or both ischioanal spaces (Fig. 29-38).

Intersphincteric Abscess

Intersphincteric abscesses are notoriously difficult to diagnose because they produce little swelling and few perianal signs of infection. Pain is typically described as being deep and “up inside” the anal area and is usually exacerbated by coughing or sneezing. The pain is so intense that it usually precludes a digital rectal examination. The diagnosis is made based on a high index of suspicion and usually requires an examination

Figure 29-35. Anatomy of perianorectal spaces. (A) Anterior view and (B) lateral view. m = muscle.

Figure 29-36. A and B. Pathways of anorectal infection in perianal spaces. m = muscle.

Figure 29-37. A through C. Technique of drainage of perianal abscess.

Figure 29-38. Drainage of horseshoe abscess. The deep postanal space is entered, incising the anococcygeal ligament. Counter-drainage incisions are made for each limb of the ischioanal space.

under anesthesia. Once identified, an intersphincteric abscess can be drained through a limited, usually posterior, internal sphincterotomy.

Supralelevator Abscess

This type of abscess is uncommon and can be difficult to diagnose. Because of its proximity to the peritoneal cavity, supralelevator abscesses can mimic intra-abdominal conditions. Digital rectal examination may reveal an indurated, bulging mass above the anorectal ring. It is essential to identify the origin of a supralelevator abscess prior to treatment. If the abscess is secondary to an upward extension of an intersphincteric abscess, it should be drained through the rectum. If it is drained through the ischioanal fossa, a complicated, suprasphincteric fistula may result. If a supralelevator abscess arises from the upward extension of an ischioanal abscess, it should be drained through the ischioanal fossa. Drainage of this type of abscess through the rectum may result in an extrasphincteric fistula. If the abscess is secondary to intra-abdominal disease, the primary process requires treatment and the abscess is drained via the most direct route (transabdominally, rectally, or through the ischioanal fossa).

Perianal Sepsis in the Immunocompromised Patient

The immunocompromised patient with perianal pain presents a diagnostic dilemma. Because of leukopenia, these patients may develop serious perianal infection without any of the cardinal signs of inflammation. While broad-spectrum antibiotics may cure some of these patients, an exam under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.¹⁶⁵

Necrotizing Soft Tissue Infection of the Perineum

Necrotizing soft tissue infection of the perineum is a rare, but lethal, condition. Most of these infections are polymicrobial and synergistic. The source of sepsis is commonly an undrained or inadequately drained cryptoglandular abscess or a urogenital infection. Occasionally, these infections may be encountered postoperatively (e.g., after hemorrhoidectomy). Immunocompromised patients and diabetic patients are at increased risk.

Physical examination may reveal necrotic skin, bullae, or crepitus. Patients often have signs of systemic toxicity and may be hemodynamically unstable. A high index of suspicion is necessary because perineal signs of severe infection may be minimal and prompt surgical intervention can be lifesaving.

Surgical debridement of all nonviable tissue is required to treat all necrotizing soft tissue infections. Multiple operations may be necessary to ensure that all necrotic tissue has been resected. Broad-spectrum antibiotics are frequently employed, but adequate surgical debridement remains the mainstay of therapy. Colostomy may be required if extensive resection of the sphincter is required or if stool contamination of the perineum makes wound management difficult. Despite early recognition and adequate surgical therapy, the mortality of necrotizing perineal soft tissue infections remains approximately 50%.

Fistula In Ano

Drainage of an anorectal abscess results in cure for about 50% of patients. The remaining 50% develop a persistent *fistula in ano*. The fistula usually originates in the infected crypt (*internal opening*) and tracks to the *external opening*, usually the site of prior drainage. The course of the fistula can often be predicted by the anatomy of the previous abscess.

While the majority of fistulas are cryptoglandular in origin, trauma, Crohn's disease, malignancy, radiation, or unusual infections (tuberculosis, actinomycosis, and chlamydia) may also produce fistulas. A complex, recurrent, or nonhealing fistula should raise the suspicion of one of these diagnoses.

Diagnosis. Patients present with persistent drainage from the internal and/or external openings. An indurated tract is often palpable. Although the external opening is often easily identifiable, identification of the internal opening may be more challenging. Goodsall's rule can be used as a guide in determining the location of the internal opening (Fig. 29-39). In general, fistulas with an external opening *anteriorly* connect to the internal opening by a *short, radial tract*. Fistulas with an external opening *posteriorly* track in a *curvilinear fashion to the posterior midline*. However, exceptions to this rule often occur if an anterior external opening is greater than 3 cm from the anal margin. Such fistulas usually track to the posterior midline.

Fistulas are categorized based on their relationship to the anal sphincter complex, and treatment options are based on these classifications. An *intersphincteric fistula* tracks through the distal internal sphincter and intersphincteric space to an external opening near the anal verge (Fig. 29-40A). A *transsphincteric fistula* often results from an ischiorectal abscess and extends through both the internal and external sphincters (Fig. 29-40B). A *suprasphincteric fistula* originates in the intersphincteric plane and tracks up and around the entire external sphincter (Fig. 29-40C). An *extrasphincteric fistula* originates in the rectal wall and tracks around both sphincters to exit laterally, usually in the ischiorectal fossa (Fig. 29-40D).

Treatment. The goal of treatment of fistula in ano is eradication of sepsis without sacrificing continence. Because fistulous tracts encircle variable amounts of the sphincter complex,

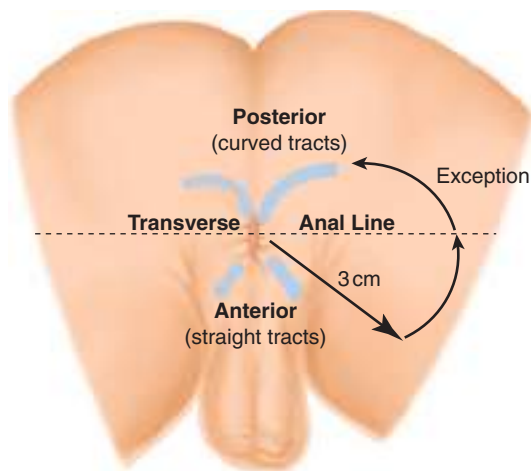

Figure 29-39. Goodsall's rule to identify the internal opening of fistulas in ano.

surgical treatment is dictated by the location of the internal and external openings and the course of the fistula. The external opening is usually visible as a red elevation of granulation tissue with or without concurrent drainage. The internal opening may be more difficult to identify. Injection of hydrogen peroxide or dilute methylene blue may be helpful. Care must be taken to avoid creating an artificial internal opening (thus often converting a simple fistula into a complex fistula).

Simple intersphincteric fistulas can often be treated by *fistulotomy* (opening the fistulous tract), curettage, and healing by secondary intention (see Fig. 29-40A). "*Horseshoe*" fistulas usually have an internal opening in the posterior midline and extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space. Treatment of a transsphincteric fistula depends on its location in the sphincter complex. Fistulas that include less than 30% of the sphincter muscles can often be treated by sphincterotomy without significant risk of major incontinence (see Fig. 29-40B). High transsphincteric fistulas, which encircle a greater amount of muscle, are more safely treated by initial placement of a *seton*. Similarly, suprasphincteric fistulas are usually treated with seton placement (see Fig. 29-40C). Extrasphincteric fistulas are rare, and treatment depends on both the anatomy of the fistula and its etiology. In general, the portion of the fistula outside the sphincter should be opened and drained. A primary tract at the level of the dentate line may also be opened if present. Complex fistulas with multiple tracts may require numerous procedures to control sepsis and facilitate healing. Liberal use of drains and setons is helpful. Failure to heal may ultimately require fecal diversion (see Fig. 29-40D). Complex and/or nonhealing fistulas may result from Crohn's disease, malignancy, radiation proctitis, or unusual infection. Proctoscopy should be performed in all cases of complex and/or nonhealing fistulas to assess the health of the rectal mucosa. Biopsies of the fistula tract should be taken to rule out malignancy.

A *seton* is a drain placed through a fistula to maintain drainage and/or induce fibrosis. *Cutting setons* consist of a suture or a rubber band that is placed through the fistula and intermittently tightened in the office. Tightening the seton results in fibrosis and gradual division of the sphincter, thus eliminating the fistula while maintaining continuity of the sphincter. A *noncutting seton* is a soft plastic drain (often a vessel loop) placed in the fistula to maintain drainage. The fistula tract may subsequently be laid open with less risk of incontinence because scarring prevents retraction of the sphincter. Alternatively, the seton may be left in place for chronic drainage. Higher fistulas may be treated by an *endorectal advancement flap*. *Fibrin glue* and a variety of collagen-based plugs also have been used to treat persistent fistulas with variable results. A more recent technique, *ligation of the intersphincteric fistula tract (LIFT)*, also shows promise. In this procedure, the fistula is identified in the intersphincteric plane (usually by placement of a lacrimal probe), divided, and the two ends ligated. Early reports have shown success with this technique, but long-term outcome is not yet known.¹⁶⁶⁻¹⁶⁸

Rectovaginal Fistula

A rectovaginal fistula is a connection between the vagina and the rectum or anal canal proximal to the dentate line. Rectovaginal fistulas are classified as *low* (rectal opening close to the dentate line and vaginal opening in the fourchette), *middle* (vaginal opening between the fourchette and cervix), or *high* (vaginal opening near the cervix). Low rectovaginal fistulas are

Figure 29-40. The four major categories of fistula in ano (*left side of drawings*) and the usual operative procedure to correct the fistula (*right side of drawings*). **A.** Intersphincteric fistula with simple low tract. **B.** Uncomplicated transsphincteric fistula. **C.** Uncomplicated suprasphincteric fistula. **D.** Extrasphincteric fistula secondary to anal fistula.

commonly caused by obstetric injuries or trauma from a foreign body. Mid-rectovaginal fistulas may result from more severe obstetric injury, but they also occur after surgical resection of a mid-rectal neoplasm, radiation injury, or extension of an undrained abscess. High rectovaginal fistulas result from operative or radiation injury. Complicated diverticulitis may cause a colovaginal fistula. Crohn's disease can cause rectovaginal fistulas at all levels, as well as colovaginal and enterovaginal fistulas.

Diagnosis. Patients describe symptoms varying from the sensation of passing flatus from the vagina to the passage of solid stool from the vagina. Most patients experience some degree of fecal incontinence. Contamination may result in *vaginitis*. Large fistulas may be obvious on anoscopic and/or vaginal speculum examination, but smaller fistulas may be difficult to locate. Occasionally, a barium enema or vaginogram may identify these fistulas. Endorectal ultrasound may also be useful. With

the patient in the prone position, installation of methylene blue into the rectum while a tampon is in the vagina may confirm the presence of a small fistula.

Treatment. The treatment of rectovaginal fistula depends on the size, location, etiology, and condition of surrounding tissues. Because up to 50% of fistulas caused by obstetric injury heal spontaneously, it is prudent to wait 3 to 6 months before embarking on surgical repair in these patients. If the fistula was caused by a cryptoglandular abscess, drainage of the abscess may allow spontaneous closure.

Low and mid-rectovaginal fistulas are usually best treated with an endorectal advancement flap. The principle of this procedure is based on the advancement of healthy mucosa, submucosa, and circular muscle over the rectal opening (the high-pressure side of the fistula) to promote healing (Fig. 29-41). If a sphincter injury is present, an overlapping sphincteroplasty

Figure 29-41. Endorectal advancement flap for rectovaginal fistula. (Reproduced with permission from Gordon PH, Nivatvongs S: Principles and Practice of Surgery for the Colon, Rectum, and Anus, 2nd ed. New York, NY: Marcel Dekker, Inc; 1999.)

should be performed concurrently. Fecal diversion is rarely required. High rectovaginal, colovaginal, and enterovaginal fistulas are usually best treated via a transabdominal approach. The diseased tissue, which caused the fistula (upper rectum, sigmoid colon, or small bowel), is resected and the hole in the vagina closed. Healthy tissue, such as omentum or muscle, frequently is interposed between the bowel anastomosis and the vagina to prevent recurrence.

Rectovaginal fistulas caused by Crohn's disease, radiation injury, or malignancy almost never heal spontaneously. In Crohn's disease, treatment is based on adequate drainage of perianal sepsis and nutritional support. An endorectal advancement flap may be performed if the rectum is spared from active Crohn's disease. Fistulas resulting from radiation damage are not amenable to local repair with an advancement flap because of damage to the surrounding rectal and vaginal tissues. Such mid- and high rectovaginal fistulas are occasionally repaired

successfully with a transabdominal approach in which healthy tissue (omentum, muscle, or nonradiated bowel) is interposed between the damaged rectum and vagina. Fistulas caused by malignancy should be treated with resection of the tumor. Because differentiating radiation damage from malignancy can be extremely difficult, all fistulas resulting from radiation should be biopsied to rule out the presence of cancer.

Perianal Dermatitis

Pruritus Ani. Pruritus ani (severe perianal itching) is a common problem with a multitude of etiologies. Surgically correctable (anatomic) causes include prolapsing hemorrhoids, ectropion, fissure, fistula, and neoplasms. Perianal infection may also present with pruritus ani. Infections may be caused by fungus (*Candida* species and *Epidermophyton* organisms), parasites (*Enterobius vermicularis* [pinworms], *Pediculus pubis* [a louse], and *Sarcoptes scabiei* [scabies]), bacteria

(*Corynebacterium minutissimum* [erythrasma] and *T pallidum* [syphilis]), or viruses (HPV [condyloma acuminata]). Antibiotic use may also cause itching, usually by precipitating fungal infection. Noninfectious dermatologic causes include seborrhea, psoriasis, and contact dermatitis. Contact dermatitis can be particularly troublesome because many over-the-counter topical agents used by patients to relieve itching may exacerbate the problem. Occasionally, systemic diseases such as jaundice and diabetes may present with pruritus ani.

Despite the myriad of causes, the majority of pruritus ani is idiopathic and probably related to local hygiene, neurogenic, or psychogenic causes. Treatment focuses on removal of irritants, improving perianal hygiene, dietary adjustments, and avoiding scratching. Biopsy and/or culture may be required to rule out an infectious or dermatologic cause. Hydrocortisone ointment 0.5% to 1.0% can provide symptomatic relief but should not be used for prolonged periods of time because of the risk of dermal atrophy. Skin barriers such as Calmoseptine can also provide relief. Systemic antihistamines or tricyclic antidepressants have also been used with some success.

Nonpruritic Lesions. Several perianal skin conditions may present with perianal skin changes. Leprosy, amebiasis, actinomycosis, and lymphogranuloma venereum produce characteristic perianal lesions. Neoplasms such as squamous intraepithelial lesions, Paget's disease, and invasive carcinomas may also appear first in the perianal skin. Biopsy can usually distinguish these diagnoses.

Sexually Transmitted Diseases

Bacterial Infections. Proctitis is a common symptom of anorectal bacterial infection. *Neisseria gonorrhoeae* is the most common bacterial cause of proctitis and causes pain, tenesmus, rectal bleeding, and mucus discharge. *Chlamydia trachomatis* infection may be asymptomatic or may produce similar symptoms. *Treponema pallidum*, the microbe causing syphilis, causes a chancre at the site of inoculation, which may be asymptomatic or may present as an atypical fissure (primary syphilis). Condyloma lata are characteristic of secondary syphilis. Chancroid, caused by *Haemophilus ducreyi*, is a disease manifested by multiple painful, bleeding lesions. Inguinal lymphadenopathy and fluctuant, draining lymph nodes are characteristic. *Donovania granulomatis* infection produces shiny, red masses on the perineum (granuloma inguinale). Diarrheal illnesses caused by organisms such as *Campylobacter* or *Shigella* may also be sexually transmitted. Treatment consists of antimicrobial agents directed against the infecting organism.

Parasitic Infections. *Entamoeba histolytica* is an increasingly common sexually transmitted disease. Amebas produce ulcerations in the gastrointestinal mucosa and can infect any part of the gut. Symptoms include diarrhea, abdominal pain, and tenesmus. *Giardia lamblia* is also common and produces diarrhea, abdominal pain, and malaise.

Viral Infections

Herpes Simplex Virus Herpes proctitis is extremely common. Proctitis is usually caused by type 2 herpes simplex virus and less commonly by type 1 herpes simplex virus. Patients complain of severe, intractable perianal pain and tenesmus. Pain often precedes the development of characteristic vesicles, and these patients may require an examination under anesthesia to exclude another diagnosis such as an intersphincteric abscess. Diagnosis is confirmed by viral culture of tissue or vesicular fluid.

Human Papillomavirus HPV causes condyloma acuminata (anogenital warts) and is associated with squamous intraepithelial lesions and squamous cell carcinoma (see previous section, "Anal Canal and Perianal Tumors"). Condylomas occur in the perianal area or in the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum may be affected. There are approximately 30 serotypes of HPV. As previously mentioned, HPV types 16 and 18, in particular, appear to predispose to malignancy and often cause flat dysplasia in skin unaffected by warts. In contrast, HPV types 6 and 11 commonly cause warts, but do not appear to cause malignant degeneration.

Treatment of anal condyloma depends on the location and extent of disease. Small warts on the perianal skin and distal anal canal may be treated in the office with topical application of bichloroacetic acid or podophyllin. Although 60% to 80% of patients will respond to these agents, recurrence and reinfection are common. Imiquimod (Aldara) is an immunomodulator that was recently introduced for topical treatment of several viral infections, including anogenital condyloma.¹⁰⁰ Initial reports suggest that this agent is highly effective in treating condyloma located on the perianal skin and distal anal canal. Larger and/or more numerous warts require excision and/or fulguration in the operating room. Excised warts should be sent for pathologic examination to rule out dysplasia or malignancy. It is important to note that prior use of podophyllin may induce histologic changes that mimic dysplasia. The recent introduction of a vaccine against HPV holds promise for preventing anogenital condylomas.^{169,170}

Human Immunodeficiency Virus See later section, "The Immunocompromised Patient."

Pilonidal Disease

Pilonidal disease (cyst, infection) consists of a hair-containing sinus or abscess occurring in the intergluteal cleft. Although the etiology is unknown, it is speculated that the cleft creates a suction that draws hair into the midline pits when a patient sits. These ingrown hairs may then become infected and present acutely as an abscess in the sacrococcygeal region. Once an acute episode has resolved, recurrence is common.

An acute abscess should be incised and drained as soon as the diagnosis is made. Because these abscesses are usually very superficial, this procedure can often be performed in the office, clinic, or emergency department under local anesthetic. Because midline wounds in the region heal poorly, some surgeons recommend using an incision *lateral* to the intergluteal cleft. A number of procedures have been proposed to treat a chronic pilonidal sinus. The simplest method involves unroofing the tract, curetting the base, and marsupializing the wound. The wound must then be kept clean and free of hair until healing is complete (often requiring weekly office visits for wound care). Alternatively, a small lateral incision can be created and the pit excised. This method is effective for most primary pilonidal sinuses. In general, extensive resection should be avoided. Complex and/or recurrent sinus tracts may require more extensive resection and closure with a Z-plasty, advancement flap, or rotational flap.

Hidradenitis Suppurativa

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. Infected glands rupture and form subcutaneous sinus tracts. The infection may mimic complex anal fistula disease, but stops at the anal verge because there are no apocrine

glands in the anal canal. Treatment involves incision and drainage of acute abscesses and unroofing of all chronically inflamed fistulas and debridement of granulation tissue. Radical excision and skin grafting are almost never necessary.

TRAUMA

Penetrating Colorectal Injury

Colorectal injury is common following penetrating trauma to the abdomen and has historically been associated with high mortality. In the first half of the 20th century, the mortality rate from colorectal injury was as high as 90%. The introduction of exteriorization of colonic injuries and fecal diversion during World War II dramatically decreased mortality, and this principle has governed the management of large bowel injury for over 50 years. Recently, however, this practice was challenged, and trauma surgeons are increasingly performing primary repairs in selected patients.

Management of colonic injury depends on the mechanism of injury, the delay between the injury and surgery, the overall condition and stability of the patient, the degree of peritoneal contamination, and the condition of the injured colon. A primary repair may be considered in hemodynamically stable patients with few additional injuries and minimal contamination if the colon appears otherwise healthy. Contraindications to primary repair include shock, injury to more than two other organs, mesenteric vascular damage, and extensive fecal contamination. A delay of greater than 6 hours between the injury and the operation also is associated with increased morbidity and mortality and is a relative contraindication to primary repair. Injuries caused by high-velocity gunshot wounds or blast injuries are often associated with multiple intra-abdominal injuries and tissue loss and therefore are usually treated by fecal diversion after debridement of all nonviable tissue. Patient factors, such as medical comorbidities, advanced age, and the presence of tumor or radiation injury, must also be considered (Table 29-4).

Like injuries to the intraperitoneal colon, penetrating trauma to the rectum traditionally has been associated with high morbidity and mortality. Primary repair of the rectum is more difficult than primary repair of the colon, however, and most rectal injuries are associated with significant contamination. For that reason, the majority of penetrating rectal injuries should be treated with proximal fecal diversion. Distal washout (copious irrigation of the rectum) and presacral drains are not routinely recommended.¹⁵⁸ Small, clean rectal injuries may be closed primarily without fecal diversion in an otherwise stable patient. Intractable rectal bleeding may require angiographic embolization. Very rarely, hemorrhage or extensive tissue loss (especially if the anal sphincter is severely damaged) may require an emergent APR. However, this operation should be avoided, if at all possible, because of the morbidity associated with an extensive pelvic dissection in a severely injured patient.¹⁷¹

Blunt Colorectal Injury

Blunt injury to the colon and rectum is considerably less common than penetrating injury. Nevertheless, blunt trauma can cause colon perforation, and shear injury to the mesentery can devascularize the intestine. Management of these injuries should follow the same principles outlined for management of penetrating injuries. Small perforations with little contamination in a stable patient may be closed primarily; more extensive injury requires fecal diversion. A serosal hematoma alone does not

mandate resection, but the bowel should be carefully inspected to ensure that there is not an associated perforation or significant bowel ischemia.

Blunt injury to the rectum may result from significant trauma, such as a pelvic crush injury, or may result from local trauma caused by an enema or foreign body. Crush injuries, especially with an associated pelvic fracture, are often associated with significant rectal damage and contamination. These patients require debridement of all nonviable tissue, proximal fecal diversion, and a distal rectal washout, with or without drain placement. Blunt trauma from an enema or foreign body may produce a mucosal hematoma, which requires no surgical treatment if the mucosa is intact. Small mucosal tears may be closed primarily if the bowel is relatively clean and there is little contamination.

Iatrogenic Injury

Intraoperative Injury. The colon and rectum are at risk for inadvertent injury during other procedures, especially during pelvic operations. The key to managing these injuries is *early recognition*. The vast majority of iatrogenic colorectal injuries may be closed primarily if there is little contamination and if the patient is otherwise stable. Delayed recognition of colorectal injuries may result in significant peritonitis and life-threatening sepsis. In these cases, fecal diversion is almost always required, and the patient may need repeated exploration for drainage of abscesses.

Injury From Barium Enema. Colorectal injury from a barium enema is an extremely rare complication associated with a high rate of morbidity and mortality. Perforation with spillage

of barium, especially above the peritoneal reflection, may result in profound peritonitis, sepsis, and a systemic inflammatory response. If the perforation is recognized early, it may be closed primarily and the abdomen irrigated to remove stool and barium. However, if the patient has developed sepsis, fecal diversion (with or without bowel resection) is almost always required. Rarely, a small mucosal injury to the extraperitoneal rectum may be managed with bowel rest, broad-spectrum antibiotics, and close observation.

Colonoscopic Perforation. Perforation is the most common major complication after either diagnostic or therapeutic colonoscopy. Fortunately, this complication is rare and occurs in less than 1% of procedures. Perforation may result from trauma from the tip of the instrument, from shear forces related to the formation of a “loop” in the colonoscope, or from barotrauma from insufflation. Biopsy or fulguration can also cause perforation. Polypectomy using electrocautery may produce a full-thickness burn, resulting in *postpolypectomy syndrome* in which a patient develops abdominal pain, fever, and leukocytosis without evidence of diffuse peritonitis.

Management of colonoscopic perforation depends on the *size of the perforation*, the *duration of time* since the injury, the *overall condition of the patient*, and the *underlying diagnosis*. A large perforation recognized during the procedure requires surgical exploration. Because the bowel has almost always been prepared prior to the colonoscopy, there is usually little contamination associated with these injuries, and most can be repaired primarily. If there is significant contamination, if there has been a delay in diagnosis with resulting peritonitis, or if the patient is hemodynamically unstable, proximal diversion with or without resection is the safest approach. It is also important to know the indication for and findings at the time of colonoscopy. If the patient has an underlying neoplasm and is stable, definitive resection is best. Occasionally, a patient will develop abdominal pain and localized signs of perforation after what was thought to be an uneventful colonoscopy. Many of these patients will have a “microperforation,” which will resolve with bowel rest, broad-spectrum antibiotics, and close observation. Evidence of peritonitis or any deterioration in clinical condition mandates exploration. Similarly, free retroperitoneal or intraperitoneal air may be discovered incidentally after colonoscopy. In a completely asymptomatic patient, this finding is thought to result from barotrauma and dissection of air through tissue planes without a free perforation. Many of these patients can be successfully treated with bowel rest and broad-spectrum antibiotics. Surgical exploration is indicated if any clinical deterioration occurs.

Anal Sphincter Injury and Incontinence

The most common cause of anal sphincter injury is obstetric trauma during vaginal delivery. The risk of sphincter injury is increased by a laceration that extends into the rectum (fourth-degree tear), infection of an episiotomy or laceration repair, prolonged labor, and possibly by use of a midline episiotomy. Sphincter damage may also result from hemorrhoidectomy, sphincterotomy, abscess drainage, or fistulotomy. Patients with incontinence and a suspected sphincter injury can be evaluated with anal manometry, EMG, pudendal nerve motor latency, and endoanal ultrasound. Mild incontinence, even in the presence of a sphincter defect, may respond to dietary changes and/or biofeedback. More severe incontinence may require surgical repair.

The anal sphincter can also be injured by penetrating or blunt mechanisms (impalement, blast injury, crush injuries of the pelvis). Because damage to the anal sphincter is not life-threatening, definitive repair of the sphincter is often deferred until other injuries have been repaired and the patient’s clinical condition is stable. Isolated sphincter injuries that do not involve the rectum may be repaired primarily. Rectal injury accompanied by sphincter injury should be treated with fecal diversion and distal rectal washout, with or without drain placement. Significant perineal tissue loss may require extensive debridement and a diverting colostomy.

Surgical Repairs. The most common method of repair of the anal sphincter is a *wrap-around sphincteroplasty* (Fig. 29-42).¹⁷² The procedure involves mobilization of the divided sphincter muscle and reapproximation without tension. The internal and external sphincters may be overlapped together or separately. *Postanal intersphincteric levatorplasty* is less commonly used to repair sphincter defects but may be useful for incontinence caused by prolapse and/or loss of the anorectal angle (see “Continence”). The approach is via the intersphincteric plane posteriorly. It may be performed concomitantly with a perineal repair of rectal prolapse. The levator ani muscle is approximated to restore the anorectal angle, and the puborectalis and external sphincter muscles are tightened with sutures. These elective procedures usually do not require a diverting colostomy.

In cases where there has been significant loss of sphincter muscle or in which prior repairs have failed, more complex techniques, such as *gracilis muscle transposition* with or without

Figure 29-42. Overlapping sphincteroplasty for incontinence from sphincter disruption. **A.** The external sphincter muscle with scar at site of injury is mobilized. **B.** The muscle edges are aligned in an overlapping fashion. **C.** Mattress sutures are used to approximate the muscle. **D.** The completed operation.

chronic, low-frequency electrostimulation, have been used with some success.¹⁷³ In this procedure, the gracilis muscle is mobilized from the thigh, detached from its insertion on the tibial tuberosity, tunneled through the perineum, and wrapped around the anal canal. Another alternative in patients who have failed other repairs is the *artificial anal sphincter*. This device consists of an inflatable silastic cuff, a pressure-regulating balloon, and a control pump. Patients deflate the cuff manually to open the anal canal; the cuff then reinflates spontaneously to maintain closure of the anal canal. Frequent infections and erosion can lead to device loss.^{173,174} *Sacral nerve stimulation* via an implanted pulse generator is a technique used for neurogenic incontinence when the sphincter is intact.¹²⁻¹⁴ In some patients, an end stoma provides the best relief for intractable incontinence.¹⁷⁶

Foreign Body

Foreign body entrapment in the rectum is not uncommon. Depending on the level of entrapment, a foreign body may cause damage to the rectum, rectosigmoid, or descending colon. Generalized abdominal pain suggests intraperitoneal perforation. Evaluation of the patient includes inspection of the perineum and a careful abdominal examination to detect any evidence of perforation. Plain films of the abdomen are mandatory to detect free intra-abdominal air.

Foreign bodies lodged low in the rectum may often be removed under conscious sedation with or without a local anesthetic block. Objects impacted higher in the rectum may require regional or general anesthesia for removal. Only rarely will a laparotomy be required to remove the object, either through manual manipulation of the object to expel from the anus, or via colotomy. After removal of the foreign body, it is crucial to evaluate the rectum and sigmoid colon for injury. Proctoscopy and/or flexible sigmoidoscopy should be performed. A hematoma without evidence of perforation requires no surgical treatment. Perforation of the rectum or sigmoid colon should be managed as described in the preceding sections.

THE IMMUNOCOMPROMISED PATIENT

Human Immunodeficiency Virus

Patients infected with HIV may present with a myriad of gastrointestinal symptoms. Diarrhea, in particular, is extremely common. The severity of gastrointestinal disease depends in part on the degree of immunosuppression; however, both ordinary and opportunistic pathogens may affect patients at any stage of the disease. Opportunistic infections with bacteria (*Salmonella*, *Shigella*, *Campylobacter*, *Chlamydia*, and *Mycobacterium* species), fungi (histoplasmosis, coccidiosis, *Cryptococcus*), protozoa (toxoplasmosis, cryptosporidiosis, isosporiasis), and viruses (CMV, herpes simplex virus) can cause diarrhea, abdominal pain, and weight loss. CMV in particular may cause severe enterocolitis and is the most common infectious cause of emergency laparotomy in acquired immunodeficiency syndrome (AIDS) patients. *Clostridium difficile colitis* is a major concern in these patients, especially because many patients are maintained on suppressive antibiotic therapy. The incidence of gastrointestinal malignancy is also increased in patients with HIV infection.¹⁷⁷ Kaposi's sarcoma is the most common malignancy in AIDS patients and can affect any part of the gastrointestinal tract. Patients may be asymptomatic or may develop bleeding or obstruction. Gastrointestinal lymphoma (usually non-Hodgkin's lymphoma) is also common. The incidence of colorectal

carcinoma may also be increased in this population, although definitive data are lacking.

Perianal disease is extremely common in patients with HIV infection. Because HIV is sexually transmitted, it is common to find concomitant infection with other sexually transmitted diseases such as *Chlamydia*, *herpes simplex virus*, and *HPV* (anal condyloma). *Anal condyloma* in particular are very common, and the incidence of dysplasia (HGAIN) is high in the HIV-infected population.¹⁰⁵ Abscesses and fistulas may be more difficult to diagnose in these patients and may be complex. Many patients require an examination under anesthesia with biopsy and cultures to determine the etiology of many of these perianal problems. The introduction of highly active antiretroviral therapy (HAART) has changed the natural history of HIV infection, but it remains to be seen how these medications will affect the incidence and outcome of colorectal disease in this patient population.¹⁷⁷

IMMUNOSUPPRESSION FOR TRANSPLANTATION

The gastrointestinal tract is a common site for posttransplantation complications that are responsible for significant morbidity and mortality. In these patients, infection and medication are the most common causes of diarrhea. Immunosuppressant medications, in particular, may cause diarrhea. CMV infection is common and may be severe. *Clostridium difficile* colitis also occurs commonly. Diverticulitis appears to be more common in some populations of transplant patients and may be more likely to present with abscess or free perforation. Elective resection after recovery from one episode of confirmed diverticulitis may be indicated in the transplant population.¹⁷⁸ Graft-versus-host disease is unique to transplant patients and often requires endoscopy and biopsy to diagnose gastrointestinal involvement. Patients are subject to the same opportunistic infections outlined earlier; however, sexually transmitted infections and Kaposi's sarcoma are somewhat less prevalent. Perianal disease is somewhat less common in the transplant population than in patients infected with HIV; however, similar infections may occur, and immunosuppression often makes diagnosis and treatment challenging.

With increasing long-term survival among transplant recipients, the development of posttransplant malignancy has become a major concern. Posttransplant lymphoproliferative disease is increasingly common and may occur anywhere in the gastrointestinal tract. The risk of colorectal carcinoma is increased in patients with predisposing conditions such as ulcerative colitis. However, immunosuppression alone does not appear to increase the incidence of colorectal cancer, and current screening recommendations are similar to those for the average risk population. In contrast, the incidence of anal squamous cell carcinoma is dramatically increased in transplant patients, and patients with known HPV infection should undergo more vigorous screening.

THE NEUTROPENIC PATIENT

Neutropenic enterocolitis (*typhlitis*) is a life-threatening problem with a mortality rate of greater than 50%. This syndrome is characterized by abdominal pain and distention, fever, diarrhea (often bloody), nausea, and vomiting in a patient with fewer than 1000 neutrophils/ μ L blood from any cause (bone marrow transplantation, solid-organ transplantation, or chemotherapy). Its etiology is poorly understood. Histologic features can be

seen on biopsy or surgical resection and include a paucity of inflammatory and leukemic infiltrates but with mucosal and submucosal edema, villous sloughing, stromal hemorrhage, and patchy-to-complete epithelial necrosis. CT scan of the abdomen often shows a dilated cecum with pericolic stranding. However, a normal-appearing CT scan does not exclude the diagnosis. Some patients will respond to bowel rest, broad-spectrum antibiotics, parenteral nutrition, and granulocyte infusion or colony-stimulating factors.¹⁷⁹ Evidence of perforation, generalized peritonitis, and deterioration in clinical condition are indications for operation.

Neutropenic patients often develop perianal pain, and diagnosis may be difficult because of a lack of inflammatory response to infection. While broad-spectrum antibiotics may cure some of these patients, an examination under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

 81. Lefevre JH, Rodrigue CM, Mourra N, et al. **Implication of MYH in colorectal polyposis.** *Ann Surg.* 2006;244:874-879. *MYH* is a base excision repair gene that removes adenines from DNA that have been mispaired with a nucleotide product of oxidative reaction (8oxoG). Without *MYH*, mispaired adenines will lead to somatic transversions G:C→T:A in genes such as *APC* or *K-ras*. The authors reviewed 433 patients who underwent prophylactic surgery for colorectal polyposis over a 25-year time frame and evaluated 31 patients who did not have *APC*, finding biallelic *MYH* mutations in 6 patients. They conclude that *MYH* is a new gene responsible for approximately 1.4% of all adenomatous polyposis and 20% of polyposis without an *APC* mutation identified.

 85. **Rex DK, Ahnen DJ, Baron JA, et al. Serrated lesions of the colorectum: review and recommendations from an expert panel.** *Am J Gastroenterol.* 2012;107:1315-1329. An expert panel provide their recommendation after a thorough literature review and 2-day conference. Hyperplastic polyps, sessile serrated adenomas/polyps, and traditional serrated adenomas are all included in the category of serrated lesions of the colon. This review outlines the histologic features of these lesions. Sessile serrated adenomas are predominantly flat, often with indistinct borders, right sided. They are associated with interval colon adenocarcinomas and are thought to progress to cancer, possibly through a promoter CpG island hypermethylation pathway. The panel recommends that these lesions are completely excised and points to the variability in detection rates between endoscopists, hypothesizing that difficulty in endoscopic detection is related to the high rate of subsequent cancer diagnosis in these patients.

The German Rectal Cancer Study Group randomized patients with clinical stage II and III rectal cancer to preoperative or postoperative long-course chemoradiation. The study occurred between 1994 and 2002 and, of note, the approach to staging did not include MRI. Among the 799 patients who were analyzed, fewer local recurrences were seen in patients assigned to preoperative chemoradiation compared with patients assigned to postoperative chemoradiation (6% vs. 13%; P = 0.006) at 5 years. The authors also found that in the long term, 72% of local recurrences were associated with distant metastases. A subgroup analysis showed that the strongest difference in hazard ratios between preoperative and postoperative chemoradiation were in the patients who had intersphincteric or abdominoperineal resections (hazard ratio 2.24; P = 0.03).

Five-year follow-up of the Medical Research Council CLASICC trial of laparoscopically assisted versus open surgery for colorectal cancer. *Br J Surg*. 2010;97(11):1638-1645. doi: 10.1002/bjs.7160. This study presents 5-year follow-up from the UK Medical Research Council CLASSIC Trial comparing the safety and efficacy of laparoscopic vs. open surgery for colorectal cancer. Outcomes included overall and disease free survival and local, distant, and port site recurrences. The investigators found no differences between the two groups. They conclude, therefore, that long-term outcomes are not compromised by a laparoscopic approach.

 166. Jacob TJ, Perakath B, Keighley MR. **Surgical intervention for anorectal fistula.** *Cochrane Database Syst Rev*. 2010;5:CD006319. This meta-analysis evaluated 10 randomized trials on outcomes after anorectal fistula procedures, with the ideal procedure stated to be associated with low recurrence rates, minimal incontinence, and good quality of life. Evaluated surgical interventions included: fistulotomy, fistulectomy, myo-mucosal advancement flap, fibrin glue, and cutting or loose setons. There were no differences in the procedures compared, except that fibrin glue had more recurrences. Trial sample sizes were noted to be small, and more recently discussed procedures such as the anal fistula plug and Ligation of Intersphincteric Fistula Tract (LIFT) were not evaluated in this review.

HISTORY

Although anatomists such as Vesalius and Leonardo Da Vinci had written about the appendix, Claudius Amyand in the early 18th century was the first surgeon to describe a successful appendectomy.¹ In subsequent centuries, significant progress was made in the diagnosis and management of appendicitis, especially after Chester McBurney advocated for early appendectomy in his 1889 publication.² Famously, the magician Harry Houdini died of a ruptured appendix after suffering a blow to his abdomen. Following the introduction and widespread use of antibiotics in the 1940s, mortality rates improved further. In 1982, Kurt Semm, a gynecologist, reported on the first laparoscopic appendectomy, which is now the most widely adopted technique.

EMBRYOLOGY, ANATOMY, AND HISTOLOGY

Previously considered a vestigial organ, the appendix is now linked to the development and preservation of gut-associated lymphoid tissue (GALT) and to the maintenance of intestinal flora. It has been suggested that appendectomy is associated with increased *Clostridium difficile* infections and increased subsequent cancer (colon, esophageal) as a result of microbial alteration, although this is currently unproven.³ The protective effect of an early appendectomy against development of ulcerative colitis has been proposed to be mechanistically linked to the release of dimeric forms of IgA from plasma B cells and the Th2 response mediated by IL-13–producing natural killer T cells.⁴

The appendix, along with the ileum and the colon, develops from the midgut and first appears at 8 weeks of gestation. As the gut rotates medially, the cecum becomes fixed in the right lower quadrant, thus determining the final position of the

appendix. The appendix is a true diverticulum of the cecum as it contains all the histological layers of the colon, although certain differences in the irregularity of crypts remain. The average appendix measures 6 to 9 cm and derives its blood supply from the appendicular branch of the ileocolic artery. Visceral innervation occurs along the superior mesenteric plexus (T10-L1) and the vagus nerves. The appendix is intraperitoneal and retrocecal in location, but it can be pelvic (30%) and retroperitoneal (7%).⁵ Grossly, the appendiceal base can be identified by tracing the convergence of the cecal taenia.

ACUTE APPENDICITIS

Inflammation of the appendix is a significant public health problem with a lifetime incidence of 8.6% in men and 6.7% in women, with the highest incidence occurring in the second and third decade of life.⁶ While the rate of appendectomy in developed countries has decreased over the last several decades, it remains one of the most frequent emergent abdominal operations.⁷

The etiology of appendicitis is perhaps due to luminal obstruction that occurs as a result of lymphoid hyperplasia in pediatric populations; in adults, it may be due to fecaliths, fibrosis, foreign bodies (food, parasites, calculi), or neoplasia.^{5,8-10} Early obstruction leads to bacterial overgrowth of aerobic organisms in the early period, and subsequently, it leads to mixed flora. Obstruction generally leads to increased intraluminal pressure and referred visceral pain to the periumbilical region.¹⁰ It is postulated that this leads to impaired venous drainage, mucosal ischemia leading to bacterial translocation, and subsequent gangrene and intraperitoneal infection. *Escherichia coli* and *Bacteroides fragilis* are the most common aerobic and anaerobic bacteria isolated in perforated appendicitis.^{11,12}

Key Points

- 1▶ Inflammation of the appendix is a significant public health problem with a lifetime incidence of 8.6% in men and 6.7% in women, with the highest incidence in the second and third decade of life.⁶ While the rate of appendectomy in developed countries has decreased over the last several decades, it remains one of the most frequent emergent abdominal operations.
- 2▶ The natural history of appendicitis is unclear, but it appears that progression to perforation is not predictable and that spontaneous resolution is common, suggesting that nonperforated and perforated appendicitis may, in fact, be different diseases.
- 3▶ C-reactive protein, bilirubin, IL-6, and procalcitonin have all been suggested to be helpful in the diagnosis of appendicitis, specifically in predicting perforated appendicitis.
- 4▶ Perforated appendicitis can be managed either operatively or nonoperatively. Immediate surgery is necessary in patients that appear septic, but this is usually associated with higher complications, including abscesses and enterocutaneous fistulae, due to dense adhesions and inflammation.
- 5▶ Single incision appendectomy has not been shown to improve outcomes, including cosmetic outcomes, in prospective randomized studies and has been suggested to have a higher incisional hernia rate.
- 6▶ While there is no evidence clearly evaluating long-term outcomes of patients undergoing incidental appendectomy with an asymptomatic appendix, the risk of adhesions and future complications after an appendectomy has been suggested to be higher than the risk of future appendicitis and increased economic costs. An incidental appendectomy is currently not advocated.
- 7▶ Older adult patients are at a higher risk for complications due to their premorbid conditions, and it is prudent to obtain definitive diagnostic imaging prior to taking patients to the operating room.
- 8▶ Patients with uncomplicated appendicitis do not require further antibiotics after an appendectomy, while patients with perforated appendicitis are treated with 3 to 7 days of antibiotics.
- 9▶ The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients also may present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause.

This sequence is not inevitable, however, and some episodes of acute appendicitis may resolve spontaneously. Due to differences in epidemiology, nonperforated and perforated appendicitis are considered different diseases.¹³ Additionally, since not all nonperforated appendicitis progresses to perforations, it is suggested that the pathogenesis of the two conditions may be different.

CLINICAL DIAGNOSIS

History

It is important to elicit an accurate history from the patient and/or family, in the case of pediatric patients. Inflammation of the visceral peritoneum usually progresses to the parietal peritoneum, presenting with migratory pain, which is a classic sign of appendicitis (likelihood ratio+, 2.06 [1.63–2.60]).¹⁴ Inflammation can often result in anorexia, nausea, vomiting, and fever (Table 30-1). Regional inflammation can also present with an ileus, diarrhea, small bowel obstruction, and hematuria. Pertinent negative history (including menstrual) must be obtained to rule out other etiologies of abdominal pain.

Physical Examination

Most patients lay quite still due to parietal peritonitis. Patients are generally warm to the touch (with a low-grade fever, ~38.0°C [100.4°F]) and demonstrate focal tenderness with guarding. McBurney's point, which is found one-third of the distance between the anterior superior iliac spine and the umbilicus, is often the point of maximal tenderness in a patient with an anatomically normal appendix. Certain physical signs with their respective eponyms can be helpful in discerning the location of the appendix: *Rovsing's sign*, pain in the right lower quadrant after release of gentle pressure on left lower quadrant (normal position); *Dunphy's sign*, pain with coughing (retrocecal

appendix); *obturator sign*, pain with internal rotation of the hip (pelvic appendix); *iliopsoas sign*, pain with flexion of the hip (retrocecal appendix). In addition, pain with rectal or cervical examinations is also suggestive of pelvic appendicitis.

Laboratory Findings

Patients with appendicitis usually have leukocytosis of 10,000 cells/mm³, with a higher leukocytosis associated with gangrenous and perforated appendicitis (~17,000 cells/mm³). C-reactive protein, bilirubin, IL-6, and procalcitonin have all been suggested to help in the diagnosis of appendicitis, specifically in predicting perforated appendicitis.^{14,15} The authors believe that a white blood cell (WBC) count and a C-reactive protein are two appropriate lab tests to obtain in the initial work up of appendicitis; a pregnancy test is also essential in women of childbearing age. Lastly, a urinalysis can be valuable in ruling out nephrolithiasis or pyelonephritis.

Imaging

Imaging is often utilized to confirm a diagnosis of appendicitis because a negative operation rate is acceptable in <10% of male patients and <20% of female patients. Routine use of cross-sectional imaging somewhat reduces the rate of negative laparotomies. Imaging studies are most appropriate for patients in whom a diagnosis of appendicitis is unclear or who are at high risk from operative intervention and general anesthesia, such as pregnant patients or patients with multiple comorbidities. Commonly utilized imaging modalities include computerized tomography (CT), ultrasound (US), and magnetic resonance imaging (MRI).

CT Scan. A contrast-enhanced CT scan has a sensitivity of 0.96 (95% confidence interval [CI] 0.95–0.97) and specificity of 0.96 (95% CI 0.93–0.97) in diagnosing acute appendicitis.^{16,17} Features on a CT scan that suggest appendicitis include enlarged lumen and double wall thickness (greater than 6 mm),

Conclusions: Individually, disease history, clinical findings, and laboratory tests are weak. But when combined, they yield high discriminatory power. Data from Andersson RE: Meta-analysis of the clinical and laboratory diagnosis of appendicitis, *Br J Surg*. 2004 Jan;91(1):28-37.

wall thickening (greater than 2 mm), periappendiceal fat stranding, appendiceal wall thickening, and/or an appendicolith (Fig. 30-1). While there remains a concern of ionizing radiation exposure with a CT scan, typical low-dose CT scans result

Figure 30-1. McBurney's point. 1 = anterior superior iliac spine; 2 = umbilicus; x = McBurney's point.

in exposure of 2 to 4 mSv, which is not significantly higher than background radiation (3.1 mSv).¹⁸ Recent trials have also suggested that although low-dose CT scans of 2 mSv do not generate high-resolution images, using these lower resolution images does not affect clinical outcomes.¹⁹ Intravenous contrast is generally preferred in these studies, but it can be avoided in patients with allergies or low estimated glomerular filtration rate (less than 30 mL/minute for 1.73 m²). Several meta-analyses have suggested that CT scan is more sensitive and specific than ultrasound in diagnosing appendicitis.

Ultrasound. Ultrasonography has a sensitivity of 0.85 (95% CI 0.79–0.90) and a specificity of 0.90 (95% CI 0.83–0.95).²⁰ Graded compression ultrasonography is used to identify the anteroposterior diameter of the appendix. An easily compressible appendix <5 mm in diameter generally rules out appendicitis. Features on an ultrasound that suggest appendicitis include a diameter of greater than 6 mm, pain with compression, presence of an appendicolith, increased echogenicity of the fat, and periappendiceal fluid.²¹ Ultrasound is cheaper and more readily available than CT scan, and it does not expose patients to ionizing radiation, but it is user-dependent and has limited utility in obese patients. In addition, graded compression is usually

painful for patients with peritonitis. A comparison of the efficacy of ultrasound v. CT scan is found in Table 30-2.

MRI. MRI of the abdomen has a sensitivity of 0.95 (95% CI 0.88–0.98) and specificity of 0.92 (95% CI 0.87–0.95) for identification of acute appendicitis.²² MRI is an expensive test that requires significant expertise to perform and interpret and is usually recommended in patients for whom the risk of ionizing radiation outweighs the relative ease of obtaining a contrast CT scan, i.e., pregnant or pediatric patients.

Differential Diagnosis

Causes of acute abdominal pain that are often confused with acute appendicitis include acute mesenteric adenitis, cecal diverticulitis, Meckel's diverticulitis, acute ileitis, Crohn's disease, acute pelvic inflammatory disease, torsion of ovarian cyst or graafian follicle, and acute gastroenteritis. Frequently, no organic pathology is identified. Obtaining an antecedent history of a viral infection (mesenteric adenitis or gastroenteritis) and a cervical exam in women (exquisite tenderness with motion in pelvic inflammatory disease) are essential before planning any intervention. Detailed menstrual history can distinguish *mittelschmerz* (no fever or leukocytosis, mid-menstrual cycle pain) and ectopic pregnancies.

MANAGEMENT OF APPENDICITIS

Uncomplicated Appendicitis

The preferred approach to manage patients with uncomplicated appendicitis is an appendectomy. Several recent randomized trials and cohort studies have examined the role of nonoperative management of adult patients with appendicitis.^{23,24,25} In each of these well-designed studies with noninferiority as the endpoint, patients were randomized to either receiving antibiotics or undergoing an appendectomy, which was frequently performed open. A majority of the patients in the nonoperative arm received intravenous antibiotics for a short course followed by a course of a fluoroquinolone and metronidazole, or oral amoxicillin/clavulanic acid.^{23,26,27} Meta-analysis of the published data found that 26.5% of patients in the nonoperative group required an appendectomy within 1 year. In addition, the rate of adverse events following antibiotics therapy was higher (relative risk [RR] 3.18, 95% CI 1.63–6.21, $P = 0.0007$), and patients who recurred presented more frequently with complicated appendicitis (RR 2.52, 95% CI 1.17–5.43, $P = 0.02$).^{28,29} Currently, conservative management can be offered to informed patients using techniques of shared decision-making, but it is not the standard modality of management of appendicitis, except in patients with significant phobia of surgery.³⁰ Societal costs and long-term implications of the conservative strategy have not yet been completely evaluated.

Timing of Surgery. Emergent surgery is often performed in patients with appendicitis, but studies have evaluated the performance of urgent surgery (waiting less than 12 hours) in a semi-elective setting after administering antibiotics upon admission. The studies did not reveal any significant difference in outcomes, except for a slightly longer hospital stay in those undergoing urgent surgery.^{31–33} Currently, delaying surgery less than 12 hours is acceptable in patients with short duration of symptoms (less than 48 hours) and in nonperforated, nongangrenous appendicitis.

Approach of Surgery. Numerous meta-analyses comparing laparoscopic to open appendectomy have demonstrated relative

equivalence of the techniques, with laparoscopic appendectomy resulting in a shorter length of stay (LOS), faster return to work, and lower superficial wound infection rates, especially in obese patients.^{34,35} Open appendectomy results in shorter operative times and lower intra-abdominal infection rates.³⁶ Costs of the two techniques are relatively similar because of the offset of costs in laparoscopic techniques by shorter LOS. In the United States, laparoscopic appendectomies are increasingly utilized.³⁷

Complicated Appendicitis

Perforated and gangrenous appendicitis and appendicitis with abscess or phlegmon formation are considered complicated conditions. Patients with perforated appendicitis usually present after 24 hours of onset, although 20% of patients present within 24 hours. Such patients are often acutely ill and dehydrated and require resuscitation. Usually, the perforated abscess is walled off in the right lower quadrant, although retroperitoneal abscesses including psoas abscess, liver abscesses, fistulas, and pylephlebitis (portal vein inflammation) can also occur when left untreated.

Perforated appendicitis can be managed either operatively or nonoperatively. Immediate surgery is necessary in patients that appear septic, but this is usually associated with higher complications, including abscesses and enterocutaneous fistulae due to dense adhesions and inflammation.

The management of long-duration, complicated appendicitis is often staged.^{38,39} Patients are resuscitated and treated with IV antibiotics.^{40,41} Patients with longstanding perforation are better treated with adequate percutaneous image-guided drainage.⁴² This strategy is successful in 79% of patients who achieve complete resolution, which occurs more often in lower-grade abscesses, transgluteal drainage, and with CT- (vs. ultrasound-) guided drainage.⁴³ Operative intervention is performed in patients who fail conservative management and in patients with free intraperitoneal perforation.

Interval Appendectomy. The majority of patients with perforated appendicitis (80%) have resolution of their symptoms with drainage and antibiotics. There remains debate about the value of performing an interval appendectomy 6 to 8 weeks after the original inflammatory episode.^{44–46} Proponents of this approach cite the incidence of recurrent appendicitis (7.4%–8.8%) and the presence of appendiceal neoplasms detected on the appendectomy (relevant benign lesions 0.7%, malignant lesions 1.3%).⁴⁷ Opponents cite the high incidence of no future events after a median follow-up of 34 months in 91% of patients. Currently, shared decision-making is necessary before proceeding with an interval appendectomy.³⁹

OPERATIVE INTERVENTION

Preoperative Preparation

Once the decision to proceed with surgical intervention is made, patients can be taken to the operating room rather expeditiously. While resuscitative efforts are important in patients who present with significant dehydration or in a compromised host, the majority of patients can be taken to the operating room within a short interval. Placement of a Foley catheter is optional but not necessary while performing an appendectomy. Preoperative antibiotics must be administered at least 30 to 60 minutes prior to skin incision. The choice of antibiotics include cefoxitin, ampicillin/sulbactam, and cefazolin plus metronidazole for

uncomplicated appendicitis. Patients with β -lactam allergies can be given clindamycin in combination with a fluoroquinolone, gentamicin, or aztreonam. Postoperative antibiotics are usually not necessary.

In patients with perforated appendicitis undergoing operative intervention, preoperative antibiotics are necessary to cover gram-negative bacteria and anaerobes. Monotherapy with piperacillin/tazobactam or combination of cephalosporin with metronidazole are reasonable choices. The duration of postoperative antibiotics is generally less than 4 days once complete source control has been achieved (STOP-IT trial).⁴⁸ Patients with incomplete drainage, persistent catheters, complications from surgery, and uncertain resolution of inflammation might need a longer duration of antibiotics.⁴⁹

Operative Technique

Open Appendectomy. An open appendectomy is usually performed under general anesthesia, although regional anesthesia can be used. After wide prep and drape, an incision is usually made on McBurney's point either in an oblique fashion (McBurney's incision) or transverse incision (Rocky-Davis incision). A lower midline laparotomy incision is more appropriate for perforated appendicitis with a phlegmon. A muscle-splitting approach can be utilized to access the peritoneum in patients that are well paralyzed. The bed is positioned in Trendelenburg's with the left side down. The appendix is usually readily identified, but if necessary, it can be found by tracing the anterior taenia (taenia Liberia) of the cecum distally. We generally ligate the mesentery early to allow better exposure. If the base of the appendix is viable, ligating the appendix is acceptable. This can be imbricated with a Z-stitch or purse string configuration, or alternatively the mucosa can be fulgurated. In the event of retraction of the appendiceal artery or unexpected bleeding, the incision can be extended medially (Fowler extension). Skin closure is usually performed in a layered fashion, but in cases with significant abscess or contamination, closure by secondary intention or delayed primary closure has been considered. Recent trials have suggested no difference in surgical site infection rates between primary and delayed primary closure.⁵⁰ Placement of surgical drains has not been proven to be beneficial in multiple clinical trials for either complicated or uncomplicated appendicitis.^{51,52}

Laparoscopic Appendectomy. Patients undergoing laparoscopic appendectomy are positioned supine with the left arm tucked for better access. Monitors and assistants are positioned appropriately. Access to the peritoneum can be obtained using either the Hasson technique in a periumbilical fashion or with a Verees or optical trocar in the left upper quadrant 3 cm below the costal margin in the midclavicular line. Five-mm ports are usually placed in the suprapubic and left lower quadrant areas. It is also technically feasible to place the third port in the right upper quadrant. The bed is positioned in Trendelenburg, with the left side down to sweep the bowel away. The appendix is grasped and elevated upwards to identify the window between the mesoappendix and the cecum (Fig. 30-2). Occasionally, it is essential to release the mesenteric attachments of the cecum to mobilize a retrocecal or pelvic appendix to obtain this view. Using a Maryland grasper, the window is created, and the mesoappendix is divided with cautery, clip, or a bipolar energy source. The base of the appendix is divided either with an endoscopic stapler or after placing an endoloop. In the case

of a nonviable appendix base, a staple line through the cecum that avoids the ileocecal valve might be sufficient, unless significant inflammation is present. The appendix is retrieved through the midline port in a specimen bag, especially if an appendiceal lesion is suspected. If a periappendiceal phlegmon is encountered or if the operation is being performed for perforated appendicitis, careful sweeping of the bowel with a blunt dissector can release the appendix. It is important to carefully separate adjacent bowel, which can be friable in such settings. Conversion to open surgery should be considered for failure to progress. Typically, once the base of the appendix is identified, it is generally more helpful to divide the stump first. An endoscopic stapler or endoloop can be used for the base, provided the base is viable. Occasionally, an ileocectomy is necessary when resection of the base of the appendix or cecum is likely to impinge on the ileocecal valve. The mesoappendix is similarly divided with either a stapler with thin leg length staples, a clip, cautery, or energy device.

Novel Techniques

Three novel techniques have been investigated in the performance of an appendectomy: single incision appendectomy, natural orifice transluminal endoscopic surgery (NOTES), and robotic appendectomy. Single incision appendectomy has not been shown to improve outcomes, including cosmetic outcomes, in prospective randomized studies and has been suggested to have a higher incisional hernia rate.⁵³ NOTES surgery has been shown to have better cosmetic outcome and less postoperative pain in a meta-analysis of NOTES procedures including appendectomies, although only 40 patients were included in the analysis.⁵⁴ The risk of luminal contamination and closure of enteral or vaginal mucosa remain suboptimal; for this reason, there has not been widespread dissemination of this technique.⁵⁵ Robotic appendectomy allows flexible motions of intraperitoneal instruments and is therefore superior in ergonomics for the surgeon.⁵⁶ However, it is extremely expensive and requires larger ports based on most of the current platforms; thus, this technique is also not utilized widely.

Negative Exploration

Upon performing a laparoscopy or laparotomy for suspected appendicitis, if one finds no evidence of appendicitis, a thorough exploration of the peritoneum must be performed to rule out contributing pathology. A normal appendix is often removed to reduce future diagnostic dilemma.⁵⁷ Management of incidentally found common conditions is summarized in Table 30-3.

Incidental Appendectomy

The practice of prophylactic appendectomy has been considered during other operations to prevent the future risk of appendicitis.^{6,58} It is routinely performed in children undergoing chemotherapy, compromised hosts with an unclear physical exam, patients with Crohn's disease with a normal cecum, patients traveling to remote places with no urgent care, and in patients undergoing cytoreductive operations for ovarian malignancies.⁵⁹ While there is no evidence clearly evaluating long-term out-

comes of patients undergoing incidental appendectomy with an asymptomatic appendix, the risk of adhesions and future complications after an appendectomy has been suggested to be higher than the risk of future appendicitis and increased economic costs. For these reasons, an incidental appendectomy is currently not advocated.

Figure 30-2. Operating room setup.

SPECIAL CIRCUMSTANCES

Appendicitis in Children

Almost 1 in 8 children undergo a workup for the diagnosis of appendicitis.^{60,61} Of these, infants and young children are most likely to present with perforated disease (51%–100%), while school-age children have lower rates of perforation.^{62,63,64} While most age groups demonstrate the same symptoms previously described in adults, neonates can also present with abdominal distension and lethargy or irritability. The Pediatric Appendicitis Score has components similar to the Alvarado Score and is scored of 10 points, with maximum weight (2 points each) for right lower quadrant tenderness and pain with cough, percussion or hopping. A score of 7 or greater indicates that the patient has a high chance of having appendicitis (78%–96% percent).⁶⁵

In the pediatric population, special considerations must be made to exclude relevant differential diagnoses such as intussusception (currant jelly stools, abdominal mass), gastroenteritis (often no leukocytosis), malrotation (pain out of proportion), pregnancy (ectopic), mesenteric adenitis, torsion of the omentum, and ovarian or testicular torsion.

Table 30-3

Management of Intraoperative Findings Mimicking Appendicitis

Ovarian Torsion	Conservative management with detorsion and oophoropexy
Crohn's terminal ileitis	Appendectomy if base uninflamed
Meckel's diverticulitis	Segmental small bowel resection and primary anastomosis
Appendiceal Mass	Laparoscopic appendectomy/ ileocecectomy without capsular disruption or spillage and retrieval in a bag

With regard to the management of children with appendicitis, early appendicitis is treated preferably with a laparoscopic appendectomy, which has better outcomes than open appendectomies in children.^{66,67} For patients with complicated appendicitis, urgent appendectomy is advocated in the setting of no abscess or mass. Laparoscopic appendectomy appears to retain its benefits in this setting as well.^{68,69} In the setting of a perforation, antibiotics are continued after surgery for at least 3 days, and preferably 5 days (APSA guidelines).^{70,71} Management of perforated appendicitis with abscess is similar to adults, although no adverse effects of an early laparoscopic appendectomy have been seen even in this setting.^{39,72,73,74}

Nonoperative management of appendicitis has also been studied in children.⁷⁵⁻⁷⁷ It may be safe for children with early presentation (less than 48 hours), limited inflammation (WBC less than 18,000/cu.ml), appendicoliths, and no evidence of rupture on imaging.⁷⁸ Patients are usually administered IV antibiotics until inflammation reduces and then transitioned to oral antibiotics.⁷⁹ This is usually effective in reducing inflammation (88%–92%), but has a recurrence rate of 22% at 1 year and increased resource utilization.⁸⁰

Appendicitis in Older Adults

Older adult patients can have diminished inflammation and thus present with perforation or abscess more frequently.^{81,82} Such patients are at a higher risk for complications because of their premorbid conditions, and it is more prudent to obtain definitive diagnostic imaging prior to taking patients to the operating room. Laparoscopic appendectomy is safe and might allow patients to reduce pain and their hospital stay.⁸³

Appendicitis in Pregnancy

Appendicitis occurs in 1 in 800 to 1 in 1000 pregnancies, mostly in the first and second trimesters. Its incidence is rare in the antepartum state, and it can occur in the postpartum state in geriatric pregnancies (maternal age greater than 35 years).⁸⁴ While the majority of the clinical features are similar, patients can also present with heartburn, bowel irregularity, flatulence, or a change in bowel habits. The point of maximum tenderness is usually displaced on physical exam. Ultrasonography is the preferred imaging modality, although nonvisualization can occur. Sensitivity can vary from 67% to 100%, and specificity varies from 93% to 96%.³⁹ An alternative imaging modality is MRI, with a sensitivity of 94% and specificity of 97%.⁸⁵ While CT can be performed in pregnancy, the risk of fetal irradiation leads many practitioners to avoid it unless other modalities are inconclusive.⁸⁶ When discussing options with the patient and the patient's family, it is important to note that the risk of fetal loss is up to 36% if appendiceal perforation occurs.⁸⁷ Therefore, there remains a lower threshold to operate on such patients, with an acceptable negative exploration rate of as high as 30%. Laparoscopic appendectomies can be safely performed in pregnant patients, although studies suggest a variable but reproducible higher rate of fetal loss (around 7% vs. 3%) than open techniques. Lower intra-abdominal pressures (10–12 mmHg) during insufflation have been suggested to reduce early labor. Nonoperative management has also been proposed for pregnant patients, but treatment failure rates have been reported as high as 25%.

Chronic or Recurrent Appendicitis

Patients with recurrent right lower quadrant abdominal pain not associated with a febrile illness with imaging findings suggestive of an appendicolith or dilated appendix are classified as

having chronic appendicitis.⁸⁸ Patients often report resolution of symptoms with an appendectomy. In the absence of imaging abnormalities, prophylactic appendectomy is not encouraged.⁴⁵

OUTCOMES AND POSTOPERATIVE COURSE

Appendectomy is a relatively safe procedure with an extremely low mortality rate (less than 1%). The commonest adverse events include soft tissue infections, either superficial or deep (including abscesses). Patients with uncomplicated appendicitis do not require further antibiotics after an appendectomy, while patients with perforated appendicitis are treated with 3 to 7 days of antibiotics (4 days from the STOP-IT trial).⁸⁹ Patients with wound infections can be managed with simple wound opening and packing, and delayed primary closure has not been shown to be beneficial.⁹⁰ In laparoscopic cases, these are usually the periumbilical ports.⁹¹ Patients with deep space abscesses are managed with percutaneous drainage and antibiotics. Fistulas (appendicocutaneous or appendicovesicular) are managed conservatively as the first step. Bowel obstructions and infertility are infrequent but reported.

Stump Appendicitis

An uncommon complication after surgery is the development of appendicitis in an incompletely excised appendiceal stump (greater than 0.5 cm stump length). Optimal management requires reexcision of the appendiceal base, but diagnosis can be difficult and requires careful assessment of the patient's history, physical exam, and imaging studies.⁹² Use of the "appendiceal critical view" (appendix placed at 10 o'clock, taenia coli/libera at 3 o'clock, and terminal ileum at 6 o'clock) and identification of where the taenia coli merge and disappear is paramount to identifying and ligating the base of the appendix during the initial operation (Fig. 30-3). In patients who have had prior appendectomy, a low index of suspicion is important to prevent delay in diagnosis and complications. Prior appendectomy should not be an absolute criterion in ruling out acute appendicitis.

Appendiceal Neoplasms

The incidence of appendiceal neoplasms is estimated at around 1% of all appendectomy specimens, although the true incidence of appendiceal neoplasms is not known.⁹³ Neoplasms that occur in the appendix are predominantly gastroenteropancreatic neuroendocrine tumors (or GEP-NETs, previously called carcinoids), mucinous neoplasms, or adenocarcinomas.⁹⁴⁻⁹⁶ Almost one-third of the neoplasms of the appendix present with acute appendicitis, while the others are often incidentally detected or are detected after regional spread of disease.⁹⁷

Gastroenteropancreatic Neuroendocrine Tumors (GEP-NETs or Carcinoid)

Appendiceal carcinoid tumors are submucosal rubbery masses that are detected incidentally on the appendix.⁹⁸ Carcinoid tumors of the appendix are relatively indolent but can develop nodal or hepatic metastases.⁹⁹ Infrequently, these can be associated with a carcinoid syndrome if there are hepatic metastases (2.9%).¹⁰⁰ Upon incidental findings of a suspected carcinoid, the surgeon must evaluate the nodal basin along the ileocolic pedicle and also examine the liver for any signs of metastases. For lesions that are less than 1 cm (95% of all lesions), a negative margin appendectomy is adequate. For tumors 2 cm or larger, a right hemicolectomy is recommended. For lesions 1 to 2 cm in size, there is no consensus on a completion colectomy. A right colectomy is often performed for mesenteric invasion, enlarged

A

B

Figure 30-3. A and B. Appendiceal critical view.

nodes, or positive or unclear margins. Measurement of serum chromogranin A is recommended.

Goblet Cell Carcinomas

These lesions were mistakenly called goblet cell carcinoids, implying a rather indolent biology, while goblet cell carcinomas are adenocarcinoid with both adenocarcinoma and neuroendocrine features.^{101,102} Such lesions carry a worse prognosis than carcinoids but slightly better than adenocarcinomas. There is a high risk of peritoneal recurrence in such cases. For incidentally detected lesions, a systematic surveillance of the peritoneum must be performed, and a peritoneal cancer index score must be documented if disease is present.¹⁰³ In the absence of metastatic disease, a right hemicolectomy is generally appropriate, although some advocate for a right colectomy only for tumors 2 cm or larger.¹⁰⁴

Lymphomas

Appendiceal lymphomas are rare (1%–3% of lymphomas, usually non-Hodgkin's) and difficult to diagnose preoperatively (appendiceal diameter can be 2.5 cm or larger).^{105,106} Management includes an appendectomy in most cases.

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm with three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid. The most common mode of presentation for appendiceal carcinoma is acute appendicitis. Patients also may present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas have a propensity for early perforation, although they are not clearly associated with a worsened prognosis. Overall 5-year survival is 55% and varies with stage and grade. Patients with appendiceal adenocarcinoma are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the gastrointestinal tract.

Appendiceal Mucoceles and Mucinous Neoplasms of the Appendix

The term *appendiceal mucocele* broadly describes a mucus-filled appendix that could be secondary to neoplastic or nonneoplastic

pathologies (mucosal hyperplasia, simple or retention cysts, mucinous cystadenomas, mucinous cystadenocarcinoma). The most common form of presentation is incidental; however, presentation with appendicitis occurs in a third of cases.^{107,108} On cross-sectional imaging, a low attenuation, round, well encapsulated cystic mass in the right or quadrant is often encountered, and features such as wall irregularity and soft tissue thickening are suggestive of a neoplastic process. It is important to carefully assess for the presence of ascites, peritoneal disease, and scalloping of the liver surface on imaging upon initial evaluation. A reliable diagnosis cannot be established using imaging alone, and it is recommended that surgical excision without capsular disruption is undertaken.¹⁰⁹ The importance of careful handling of a mucocele and the avoidance of rupture cannot be overemphasized because the intraperitoneal spread of neoplastic cells at subsequent development of pseudomyxoma peritonei are nearly certain in cases of adenocarcinoma.^{110,111} When suspecting a mucinous neoplasm of the appendix, it is imperative to systematically examine the peritoneum and document a peritoneal cancer index score if mucin is present. Biopsies to examine the content of epithelial cell, neoplastic cells, and mucin can be helpful.

In cases where a homogeneous cyst without nodularity or signs of dissemination is encountered, laparoscopic excision is acceptable, provided that a stapler is fired across the base of the cecum to avoid a positive margin. The specimen should be placed in a plastic bag and carefully removed through a small incision. In the absence of mesenteric or peritoneal involvement, an appendectomy with concurrent appendiceal lymphadenectomy is sufficient, as the chances of lymph node involvement are quite low. If peritoneal spread is evident upon exploration, it is important to obtain biopsies and document the peritoneal disease burden. An appendectomy is acceptable if the patient has acute appendicitis, but suboptimal debulking is discouraged. In addition, colorectal, ovarian, and endometrial cancers can coexist in the setting of appendiceal mucoceles, and careful examination of intra-abdominal structures is important.

When there is discordance between the primary lesion histology and the peritoneum, the peritoneal histology is usually given priority. For instance, if patients had a neoplasm in the appendix but adenocarcinoma in the peritoneum, the patient would be considered as having adenocarcinoma (AJCC M1b) disease. The recent AJCC 8th edition and the PSOGI 2016

Table 30-4

AJCC 8th edition and the PSOGI 2016 classification consensus of mucinous neoplasia of the appendix

LESION	PERITONEAL DISEASE AT DIAGNOSIS	PROGNOSIS	TREATMENT
Low-grade appendiceal mucinous neoplasm (LAMN)	Confined to the appendix	Excellent-curative	Negative margin appendectomy, rarely need ileocecectomy
LAMN	Peri-appendiceal Acellular mucin dissecting through the wall (t4a) or adjacent organs (t4b)	Excellent-low risk of recurrence	Negative margin appendectomy, resection of acellular mucin
LAMN	Peri-appendiceal Epithelial cells dissecting through the wall (t4a) or adjacent organs (t4b)	Excellent-high risk of recurrence	Negative margin appendectomy, peritoneal surveillance with second look laparoscopy vs. HIPEC
LAMN	Distant epithelial cells or acellular mucin (M1a) Low grade mucinous carcinoma peritonei	Excellent-high risk of recurrence	Negative margin appendectomy, omentectomy, HIPEC
High-grade appendiceal mucinous neoplasm (HAMN-rare)	Management is identical to a LAMN with risk stratification as shown above but slightly worse prognosis.		
Mucinous adenocarcinoma	Confined to the appendix	Very Good	Right hemicolectomy
Mucinous adenocarcinoma	Peritoneal Dissemination High grade mucinous carcinoma peritonei with or without signet ring cells	Well Differentiated-Very good Moderately differentiated –Good Poorly differentiated/signet ring cell histology: 10 year survival of 10-20%	Cytoreductive surgery and HIPEC, with systemic chemotherapy for high grade histologies
Adenocarcinoma (non-mucinous, including goblet cell histology)	Management identical to the mucinous histologies, with more extensive use of systemic chemotherapy		
Serrated Adenoma (rare)	Confined to appendix	Excellent-curative	Appendectomy
Adenoma (rare)	Confined to appendix	Excellent-curative	Appendectomy

Data from American College of Surgeons. Amin MB, Edge SB, Greene FL, et al. (Eds.) AJCC Cancer Staging Manual, 8th Ed. Springer New York, 2017 and Carr NJ, Cecil TD, Mohamed F, et al: A Consensus for Classification and Pathologic Reporting of Pseudomyxoma Peritonei and Associated Appendiceal Neoplasia: The Results of the Peritoneal Surface Oncology Group International (PSOGI) Modified Delphi Process, *Am J Surg Pathol.* 2016 Jan;40(1):14-26.

classification consensus has resulted in a therapy-directed classification of mucinous neoplasms of the appendix, summarized in Table 30-4.¹¹²

Pseudomyxoma Peritonei Syndrome

Patients with appendiceal mucinous neoplasms develop peritoneal dissemination leading to pseudomyxoma peritonei (PMP) syndrome. This can occur in gastric, ovarian, pancreatic, and colorectal primary tumors as well.¹¹¹ Patients with this syndrome can have varied prognosis ranging from curative to palliative. Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) are considered the standard of care for patients with PMP syndrome from appendiceal primaries.¹¹³⁻¹¹⁵

Early detection and management of limited peritoneal disease is favorable and preferred as opposed to extensive intra-peritoneal mucin development. The surgical technique involves parietal and visceral peritonectomies, and intraperitoneal administration of heated (42°C [108°F]) chemotherapy (usually mitomycin) in the abdomen. Previously considered a morbid surgery, high volume centers and standardized practices have

made the morbidity and mortality similar to any major open GI procedure. This technique can also be performed laparoscopically when the disease is detected early and is low volume.

Key Points

- ▶ When operating on the liver, gallbladder, pancreas, or adjacent organs, recognition of the normal or variant vascular and biliary anatomy is essential to avoiding surgical complications.
- ▶ The liver is the largest gland in the body and performs a diverse spectrum of functions.
- ▶ Computed tomography and magnetic resonance imaging with contrast enhancement constitute the mainstays for the radiologic evaluation of the liver.
- ▶ Acute liver failure rapidly progresses to hepatic coma and death even with maximal medical therapy. The only definitive treatment is orthotopic liver transplantation.
- ▶ Acute variceal bleeding should be managed with aggressive resuscitation and prompt endoscopic diagnosis with hemorrhage control. The transjugular intrahepatic portosystemic shunt procedure can be considered for cases refractory to medical treatment.
- ▶ Common benign lesions of the liver include cysts, hemangiomas, focal nodular hyperplasia, and hepatocellular adenomas. In most instances, these lesions can be reliably diagnosed by their characteristic features on imaging.
- ▶ Many options exist for the treatment of hepatocellular carcinomas, and these cases are best managed by a multidisciplinary liver transplant team.
- ▶ Surgical resection is the treatment of choice for hilar cholangiocarcinoma. Under a protocol with strict eligibility criteria, patients with unresectable tumors can be considered for liver transplantation following neoadjuvant chemoradiation, with survival rates that compare favorably with the rates for resection.
- ▶ The resectability of colorectal cancer metastases to the liver is primarily determined by the volume of the future liver remnant and the health of the background liver and not actual tumor number.
- ▶ Laparoscopic liver resections can be performed safely by experienced surgeons in selected patients and have been shown to produce short-term patient benefits with comparable long-term oncologic results compared to open hepatic resections.

HISTORY OF LIVER SURGERY

The ancient Greek myth of Prometheus reminds us that the liver is the only organ that regenerates. According to Greek mythology, Zeus was furious with the Titan Prometheus because he gave fire to mortals. In return, Zeus chained Prometheus to Mount Caucasus and sent his giant eagle to eat his liver during the day, only to have it regenerate at night. Although this is folklore, the principles are correct that after hepatic resection, the remnant liver will hypertrophy over weeks to months to regain most of its original liver mass. It is interesting to note that the ancient Greeks seem to have been aware of this fact, because the Greek word for the liver, *hēpar*, derives from the verb *hēpaomai*, which means “mend” or “repair.” Hence *hēpar* roughly translates as “repairable.”¹ The importance of the liver dates back to even biblical times, for the Babylonians (c. 2000 B.C.) considered the liver to be the seat of the soul. There are scattered reports of liver surgery for battlefield injuries, but the first recorded elective hepatic resection was done in 1888 in Germany by Langenbuch. There followed reports of liver resections in the United States (Tiffany, 1890) and Europe (Lucke, 1891), as well as the first large series of hepatic resections by Keen in 1899.^{2,3} In 1908, Pringle described in *Annals of Surgery* the “arrest of hepatic hemorrhage due to trauma” by compression of the porta hepatis, a maneuver that now bears his name.⁴ Possibly due to the potential for massive hemorrhage during liver surgery, very little progress in surgical techniques was recorded for the next half-century. Work by Rex, Cantlie, and others laid the groundwork for experimental and clinical reports in the 1950s by Couinaud, Hjortsjo, Healey, Lortat-Jacob, and Starzl.^{5,6} These seminal contributions paved the way for the modern era of hepatic resection surgery.

LIVER ANATOMY

The liver is the largest organ in the body, weighing approximately 1500 g. It resides in the right upper abdominal cavity

beneath the diaphragm and is protected by the rib cage. It is reddish brown and is surrounded by a fibrous sheath known as *Glisson's capsule*. The liver is held in place by several ligaments (Fig. 31-1). The round ligament is the remnant of the obliterated umbilical vein and enters the left liver hilum at the front edge of the falciform ligament. The falciform ligament separates the left lateral and left medial segments along the umbilical fissure and anchors the liver to the anterior abdominal wall. Deep in the plane between the caudate lobe and the left lateral segment is the fibrous ligamentum venosum (Arantius' ligament), which is the obliterated ductus venosus and is covered by the plate of Arantius. The left and right triangular ligaments secure the two sides of the liver to the diaphragm. Extending from the triangular ligaments anteriorly on the liver are the coronary ligaments. The right coronary ligament also extends from the right undersurface of the liver to the peritoneum overlying the right kidney, thereby anchoring the liver to the right retroperitoneum. These ligaments (round, falciform, triangular, and coronary) can be divided in a bloodless plane to fully mobilize the liver to facilitate hepatic resection. Centrally and just to the left of the gallbladder fossa, the liver attaches via the hepatoduodenal and the gastrohepatic ligaments (Fig. 31-2). The hepatoduodenal ligament is known as the *porta hepatis* and contains the common bile duct, the hepatic artery, and the portal vein. From the right side and deep (dorsal) to the porta hepatis is the foramen of Winslow, also known as the *epiploic foramen* (see Fig. 31-2). This passage connects directly to the lesser sac and allows complete vascular inflow control to the liver when the hepatoduodenal ligament is clamped using the Pringle maneuver.

Segmental Anatomy

The liver is grossly separated into the right and left lobes by the plane from the gallbladder fossa to the inferior vena cava (IVC), known as *Cantlie's line*.⁵ The right lobe typically accounts for 60% to 70% of the liver mass, with the left lobe (and caudate lobe) making up the remainder. The caudate lobe lies to the left and anterior of the IVC and contains three subsegments:

Figure 31-1. Hepatic ligaments suspending the liver to the diaphragm and anterior abdominal wall.

the Spiegel lobe, the paracaval portion, and the caudate process.⁷ The falciform ligament does not separate the right and left lobes, but rather it divides the left lateral segment from the left medial segment. The left lateral and left medial segments also are referred to as *sections* as defined in the Brisbane 2000 terminology, which is outlined later in the section titled “Hepatic Resection.” A significant advance in our understanding of liver anatomy came from the cast work studies of the French surgeon and anatomist Couinaud in the early 1950s. Couinaud divided the liver into eight segments, numbering them in a clockwise direction beginning with the caudate lobe as segment I.⁶ Segments II and III comprise the left lateral segment, and segment IV is the left medial segment (Fig. 31-3). Thus, the left lobe is made up of the left lateral segment (Couinaud’s segments II and III) and the left medial segment (segment IV). Segment IV can be subdivided into segment IVA and segment IVB. Segment IVA is cephalad and just below the diaphragm, spanning from segment VIII to the falciform ligament adjacent to segment II. Segment IVB is caudad and adjacent to the gallbladder fossa. Many anatomy textbooks also refer to segment IV as the quadrate lobe. Quadrate lobe is an outdated term, and the preferred term is segment IV or left medial segment. Most surgeons still refer to segment I as the

caudate lobe, rather than segment I. The right lobe is comprised of segments V, VI, VII, and VIII, with segments V and VIII making up the right anterior lobe and segments VI and VII making up the right posterior lobe.

Figure 31-2. In situ liver hilar anatomy with hepatoduodenal and gastrohepatic ligaments. Foramen of Winslow is depicted.

Figure 31-3. Couinaud’s liver segments (I through VIII) numbered in a clockwise manner. The left lobe includes segments II to IV, the right lobe includes segments V to VIII, and the caudate lobe is segment I. IVC = inferior vena cava.

Additional functional anatomy was highlighted by Bismuth based on the distribution of the hepatic veins. The three hepatic veins run in corresponding scissura (fissures) and divide the liver into four sectors.⁸ The right hepatic vein runs along the right scissura and separates the right posterolateral sector from the right anterolateral sector. The main scissura contains the middle hepatic vein and separates the right and left livers. The left scissura contains the course of the left hepatic vein and separates the left posterior and left anterior sectors.

Hepatic Artery

The liver has a dual blood supply consisting of the hepatic artery and the portal vein. The hepatic artery delivers approximately 25% of the blood supply, and the portal vein approximately 75%. The hepatic artery arises from the celiac axis (trunk), which gives off the left gastric, splenic, and common hepatic arteries (Fig. 31-4). The common hepatic artery then divides into the gastroduodenal artery and the hepatic artery proper. The right gastric artery typically originates off of the hepatic artery proper, but this is variable. The hepatic artery proper divides into the right and left hepatic arteries. This “classic” or standard arterial anatomy is present in only approximately 76% of cases, with the remaining 24% having variable anatomy. It is critical

to avoid surgical complications when operating on the liver, gallbladder, pancreas, or adjacent organs.

The most common hepatic arterial variants are shown in Fig. 31-5. Approximately 10% to 15% of the time there is a replaced or accessory right hepatic artery arising from the superior mesenteric artery (SMA). When there is a replacement or accessory right hepatic artery, it travels posterior to the portal vein and then takes up a right lateral position before diving into the liver parenchyma. This can be recognized visually on a preoperative computed tomography (CT) or magnetic resonance imaging (MRI) scan and confirmed by palpation in the hilum where a separate right posterior pulsation is felt distinct from that of the hepatic artery proper that lies anteriorly in the hepatoduodenal ligament to the left of the common bile duct. In approximately 3% to 10% of cases, there exists a replacement (or accessory) left hepatic artery coming off of the left gastric artery and running obliquely in the gastrohepatic ligament anterior to the caudate lobe before entering the hilar plate at the base of the umbilical fissure. Other less common variants

(approximately 1–2% each) are the presence of both replaced right and replaced left hepatic arteries, as well as a completely replaced common hepatic artery coming off the SMA (see Fig. 31-5). Although not well demonstrated in the illustration, the clue for a completely replaced common hepatic artery coming off the SMA is the presence of a strong arterial pulsation to the right of and posterior to the common bile duct, rather than the left side and anterior, in the porta hepatis. Another important point is that the right hepatic artery passes deep and posterior to the common bile duct approximately 88% of the time but crosses anterior to the common bile duct in approximately 12% of cases. The cystic artery feeding the gallbladder usually arises from the right hepatic artery in Calot’s triangle.

Portal Vein

The portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein usually drains into the splenic vein upstream from the confluence (Fig. 31-6). The main portal vein traverses the porta hepatis before dividing into the left and right portal vein branches. The left portal vein typically branches from the main portal vein outside of the liver with a sharp bend to the left and consists of the transverse portion followed by a 90° turn at the base of the umbilical fissure to become the umbilical portion before entering the liver parenchyma (Fig. 31-7). The left portal vein then divides to give off the segment II and III branches to the left lateral segment, as well as the segment IV branches that supply the left medial segment. The left portal vein also provides the dominant inflow branch to the caudate lobe (although branches can arise from the main and right portal veins also), usually close to the bend between the transverse and umbilical portions. The division of the right portal vein is usually higher in the hilum and may be close to (or inside) the liver parenchyma at the hilar plate. Twenty percent to 35% of individuals have aberrant portal venous anatomy, with portal vein trifurcation or an aberrant branch from the left portal vein supplying the right anterior lobe being the most frequent.

The portal vein drains the splanchnic blood from the stomach, pancreas, spleen, small intestine, and majority of the colon to the liver before returning to the systemic circulation. The portal vein pressure in an individual with normal physiology is low at 3 to 5 mmHg. The portal vein is valveless, however, and in the setting of portal hypertension, the pressure can be

Figure 31-4. Arterial anatomy of the upper abdomen and liver, including the celiac trunk and hepatic artery branches. a. = artery; LHA = left hepatic artery; RHA = right hepatic artery.

Figure 31-5. Common hepatic artery anatomic variants. SMA = superior mesenteric artery.

quite high (20 to 30 mmHg). This results in decompression of the systemic circulation through portocaval anastomoses, most commonly via the coronary (left gastric) vein, which produces esophageal and gastric varices with a propensity for major hemorrhage. Another branch of the main portal vein is the superior pancreaticoduodenal vein (which comes off low in an anterior lateral position and is divided during pancreaticoduodenectomy). Closer to the liver, the main portal vein typically gives

off a short branch (posterior lateral) to the caudate process on the right side. It is important to identify this branch and ligate it during hilar dissection for anatomic right hemihepatectomy to avoid avulsion.

Hepatic Veins and Inferior Vena Cava

There are three hepatic veins (right, middle, and left) that pass obliquely through the liver to drain the blood to the suprahepatic IVC and eventually the right atrium (Fig. 31-8). The right hepatic vein drains segments V through VIII; the middle hepatic vein drains segment IV as well as segments V and VIII; and the left hepatic vein drains segments II and III. The caudate lobe

Figure 31-6. Portal vein anatomy. The portal vein is formed by the confluence of the splenic and superior mesenteric veins. The inferior mesenteric vein drains into the splenic vein. The coronary (left gastric) vein drains into the portal vein in the vicinity of the confluence. v. = vein.

Figure 31-7. Anatomy of the left portal vein (LPV). Note the transverse and umbilical portions of the LPV.

Figure 31-8. Confluence of the three hepatic veins (HV) and the inferior vena cava (IVC). Note that the middle and left HVs drain into a common trunk before entering the IVC. a. = artery; v. = vein. (Adapted with permission from Cameron JL: Atlas of Surgery. Vol. I, Gallbladder and Biliary Tract, the Liver, Portosystemic Shunts, the Pancreas. Toronto: BC Decker; 1990.)

is unique because its venous drainage feeds directly into the IVC. In addition, the liver usually has a few small, variable short hepatic veins that directly enter the IVC from the undersurface of the liver. The left and middle hepatic veins form a common trunk approximately 95% of the time before entering the IVC, whereas the right hepatic vein inserts separately (in an oblique orientation) into the IVC. There is a large inferior accessory right hepatic vein in 15% to 20% of cases that runs in the hepatocaval ligament. This can be a source of torrential bleeding if control of it is lost during right hepatectomy. The hepatic vein branches bisect the portal branches inside the liver parenchyma (i.e., the right hepatic vein runs between the right anterior and posterior portal veins; the middle hepatic vein passes between the right anterior and left portal vein; and the left hepatic vein crosses between the segment II and III branches of the left portal vein).

Bile Duct and Hepatic Ducts

Within the hepatoduodenal ligament, the common bile duct lies anteriorly and to the right. It gives off the cystic duct to the gallbladder and becomes the common hepatic duct before dividing into the right and left hepatic ducts. In general, the hepatic ducts follow the arterial branching pattern inside the liver. The right anterior hepatic duct usually enters the liver above the hilar

plate, whereas the right posterior duct dives behind the right portal vein and can be found on the surface of the caudate process before entering the liver. The left hepatic duct typically has a longer extrahepatic course before giving off segmental branches behind the left portal vein at the base of the umbilical fissure. Considerable variation exists, and in 30% to 40% of cases, there is a nonstandard hepatic duct confluence with accessory or aberrant ducts (Fig. 31-9). The cystic duct itself also has a variable pattern of drainage into the common bile duct. This can lead to potential injury or postoperative bile leakage during cholecystectomy or hepatic resection, and the surgeon needs to expect these variants. The gallbladder sits adherent to hepatic segments IVB (left lobe) and V (right lobe).

Neural Innervation and Lymphatic Drainage

The parasympathetic innervation of the liver comes from the left vagus, which gives off the anterior hepatic branch, and the right vagus, which gives off the posterior hepatic branch. The sympathetic innervation involves the greater thoracic splanchnic nerves and the celiac ganglia, although the function of these nerves is poorly understood. The denervated liver after hepatic transplantation seems to function with normal capacity. A common source of referred pain to the right shoulder and scapula as well as the right side or back is the right phrenic

A: Normal bifurcation 57%

nerve, which is stimulated by tumors that stretch Glisson's capsule or by diaphragmatic irritation.

Lymph is produced within the liver and drains via the perisinusoidal space of Disse and periportal clefts of Mall to larger lymphatics that drain to the hilar cystic duct lymph node (Calot's triangle node), as well as the common bile duct, hepatic artery, and retropancreatic and celiac lymph nodes. This is particularly important for resection of hilar cholangiocarcinoma, which has a high incidence of lymph node metastases. The hepatic lymph also drains cephalad to the cardiophrenic lymph nodes, and the latter can be pathologically identified on a staging CT or MRI scan.

LIVER PHYSIOLOGY

The liver is the largest gland in the body and has an extraordinary spectrum of functions. These include processes such as

storage, metabolism, production, and secretion. One crucial role is the processing of absorbed nutrients through the metabolism of glucose, lipids, and proteins. The liver maintains glucose concentrations in a normal range over both short and long periods by performing several important roles in carbohydrate metabolism. In the fasting state, the liver ensures a sufficient supply of glucose to the central nervous system. The liver can produce glucose by breaking down glycogen through glycogenolysis and by de novo synthesis of glucose through gluconeogenesis from noncarbohydrate precursors such as lactate, amino acids, and glycerol. In the postprandial state, excess circulating glucose is removed by glycogen synthesis or glycolysis and lipogenesis. The liver also plays a central role in lipid metabolism through the formation of bile and the production of cholesterol and fatty acids. Protein metabolism occurs in the liver through amino acid deamination, resulting in the production of ammonia as well as the production of a variety of amino acids. In addition to

metabolism, the liver also is responsible for the synthesis of most circulating plasma proteins. Among these proteins are albumin, factors of the coagulation and fibrinolytic systems, and compounds of the complement cascade. Furthermore, the detoxification of many substances through drug metabolism occurs in the liver, as do immunologic responses through the many immune cells found in its reticuloendothelial system.⁹

Bilirubin Metabolism

Bilirubin is the breakdown product of normal heme catabolism. Bilirubin is bound to albumin in the circulation and sent to the liver. In the liver, it is conjugated to glucuronic acid to form bilirubin diglucuronide in a reaction catalyzed by the enzyme glucuronyl transferase, making it water soluble. This glucuronide is then excreted into the bile canaliculi. A small amount dissolves in the blood and is then excreted in the urine. The majority of conjugated bilirubin is excreted in the intestine as waste because the intestinal mucosa is relatively impermeable to conjugated bilirubin. However, it is permeable to unconjugated bilirubin and urobilinogens, a series of bilirubin derivatives formed by the action of bacteria. Thus, some of the bilirubin and urobilinogens are reabsorbed in the portal circulation; they are again excreted by the liver or enter the circulation and are excreted in the urine.¹⁰

Formation of Bile

Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver through the biliary system and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (e.g., lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins and to eliminate waste products (bilirubin and cholesterol) through secretion into bile and elimination in feces. Bile is produced by hepatocytes and secreted through the biliary system. In between meals, bile is stored in the gallbladder and concentrated through the absorption of water and electrolytes. Upon entry of food into the duodenum, bile is released from the gallbladder to aid in digestion. The human liver can produce about 1 L of bile daily.

Bile salts, in conjunction with phospholipids, are responsible for the digestion and absorption of lipids in the small intestine. Bile salts are sodium and potassium salts of bile acids conjugated to amino acids. The bile acids are derivatives of cholesterol synthesized in hepatocytes. Cholesterol, ingested from the diet or derived from hepatic synthesis, is converted into the bile acids cholic acid and chenodeoxycholic acid. These bile acids are conjugated to either glycine or taurine before secretion into the biliary system. Bacteria in the intestine can remove glycine and taurine from bile salts. They can also convert some of the primary bile acids into secondary bile acids by removing a hydroxyl group, producing deoxycholic acid from cholic acid and lithocholic acid from chenodeoxycholic acid.

Bile salts secreted into the intestine are efficiently reabsorbed and reused. Approximately 90% to 95% of the bile salts are absorbed from the small intestine at the terminal ileum. The remaining 5% to 10% enter the colon and are converted to the secondary salts, deoxycholic acid and lithocholic acid. The mixture of primary and secondary bile salts and bile acids is absorbed primarily by active transport in the terminal ileum. The absorbed bile salts are transported back to the liver in the

portal vein and reexcreted in the bile. Those lost in the stool are replaced by synthesis in the liver. The continuous process of secretion of bile salts in the bile, their passage through the intestine, and their subsequent return to the liver is termed the *enterohepatic circulation*.¹⁰

Drug Metabolism

The liver plays an important role in providing mechanisms for ridding the body of foreign molecules (xenobiotics) that are absorbed from the environment. In most cases, a drug is relatively lipophilic to ensure good absorption. The liver participates in the elimination of these lipid-soluble drugs by transforming them into more readily excreted hydrophilic products. There are two main reactions important for drug metabolism. Phase 1 reactions include oxidation, reduction, and hydrolysis of molecules. These result in metabolites that are more hydrophilic than the original chemicals. The cytochrome P450 system is a family of hemoproteins important for oxidative reactions involving drugs and toxic substances. Phase 2 reactions, also known as *conjugation reactions*, are synthetic reactions that involve addition of subgroups to the drug molecule. These subgroups include glucuronate, acetate, glutathione, glycine, sulfate, and methyl groups. These drug reactions occur mainly in the smooth endoplasmic reticulum of hepatocytes.

Many factors can affect drug metabolism in the liver. When the rate of metabolism of a drug is increased (i.e., enzyme induction), the duration of the drug action will decrease. However, when the metabolism of a drug is decreased (i.e., enzyme inhibition), then the drug will circulate for a longer period of time. It is important to note that some drugs may be converted to active products by metabolism in the liver. An example is acetaminophen when taken in larger doses. Normally, acetaminophen is conjugated by the liver to harmless glucuronide and sulfate metabolites that are water soluble and eliminated in the urine. During an overdose, the normal metabolic pathways are overwhelmed, and some of the drug is converted to a reactive and toxic intermediate by the cytochrome P450 system. Glutathione normally reacts with this intermediate, leading to the production and subsequent excretion of a harmless product. However, as glutathione stores are diminished, the reactive intermediate cannot be detoxified and it combines with lipid membranes of hepatocytes, which results in cellular necrosis. Thus, treatment of acetaminophen overdoses consists of replenishing glutathione stores by supplementing with sulfhydryl compounds such as acetylcysteine.

Liver Function Tests

Liver function tests is a term frequently used to refer to measurement of the levels of a group of serum markers for evaluation of liver dysfunction. Most commonly, levels of aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase (AP), γ -glutamyltranspeptidase (GGT), and bilirubin are included in this panel. This term is a misnomer, however, because most of these tests measure not liver function but rather cell damage. More accurate measurement of the liver's synthetic function is provided by serum albumin levels and prothrombin time (PT). Although measuring liver enzyme levels is important in the assessment of a patient's liver disease, these test results can be nonspecific. Thus, evaluation of patients with suspected liver disease should always involve careful interpretation of abnormalities in these liver test results in the context of a thorough history and physical examination. The approach to

evaluating abnormal laboratory values also can be simplified by categorizing the type of abnormality that predominates (hepatocellular damage, abnormal synthetic function, or cholestasis).

Hepatocellular Injury

Hepatocellular injury of the liver is usually indicated by abnormalities in levels of the liver aminotransferases AST and ALT. These enzymes participate in gluconeogenesis by catalyzing the transfer of amino groups from aspartic acid or alanine to ketoglutaric acid to produce oxaloacetic acid and pyruvic acid, respectively (these enzymes are also referred to as *serum glutamic-oxaloacetic transaminase [SGOT]* and *serum glutamic-pyruvic transaminase [SGPT]*). AST is found in liver, cardiac muscle, skeletal muscle, kidney, brain, pancreas, lungs, and red blood cells and thus is less specific for disorders of the liver. ALT is predominately found in the liver and thus is more specific for liver disease. Hepatocellular injury is the trigger for release of these enzymes into the circulation. Common causes of elevated aminotransferase levels include viral hepatitis, alcohol abuse, medications, genetic disorders (Wilson's disease, hemochromatosis, α_1 -antitrypsin deficiency), and autoimmune diseases.

The extent of serum aminotransferase elevations can suggest certain etiologies of the liver injury. However, the levels of the enzymes in these tests correlate poorly with the severity of hepatocellular necrosis because they may not be significantly elevated in conditions of hepatic fibrosis or cirrhosis. In alcoholic liver disease, an AST to ALT ratio of $>2:1$ is common. Mild elevations of transaminase levels can be found in nonalcoholic fatty liver disease, chronic viral infection, or medication-induced injury. Moderate increases in the levels of these enzymes are common in acute viral hepatitis. In conditions of ischemic insults, toxin ingestions (i.e., acetaminophen), and fulminant hepatitis, AST and ALT levels can be elevated to the thousands.

Abnormal Synthetic Function

Albumin synthesis is an important function of the liver and thus can be measured to evaluate the liver's synthetic function. The liver produces approximately 10 g of albumin per day. However, albumin levels are dependent on a number of factors such as nutritional status, renal dysfunction, protein-losing enteropathies, and hormonal disturbances. In addition, level of albumin is not a marker of acute hepatic dysfunction due to albumin's long half-life of 15 to 20 days.

Most clotting factors (except factor VIII) are synthesized exclusively in the liver, and thus their levels can also be used as a measure of hepatic synthetic function. Measurements of the prothrombin time (PT) and international normalized ratio (INR) are some of the best tests of hepatic synthetic function. PT measures the rate of conversion of prothrombin to thrombin. To standardize the reporting of PT and avoid interlaboratory variability, the INR was developed. The INR is the ratio of the patient's PT to the mean control PT. Because vitamin K is involved in the γ -carboxylation of factors used to measure PT (factors II, VII, IX, and X), values also may be prolonged in other conditions such as vitamin K deficiency and warfarin therapy.

Cholestasis

Cholestasis is a condition in which bile flow from the liver to the duodenum is impaired. Disturbances in bile flow may be due to intrahepatic causes (hepatocellular dysfunction) or extrahepatic causes (biliary tree obstruction). Cholestasis often results in the

release of certain enzymes and thus can be detected by measuring the serum levels of bilirubin, AP, and GGT. Bilirubin is a breakdown product of hemoglobin metabolism. Unconjugated bilirubin is insoluble and thus is transported to the liver bound to albumin. In the liver, it is conjugated to allow excretion in bile. Measured total bilirubin levels can be normal or high in patients with significant liver disease because of the liver's ability to conjugate significant amounts of bilirubin. Thus, to help aid in the diagnosis of hyperbilirubinemia, fractionation of total bilirubin is usually performed to distinguish between conjugated (direct) and unconjugated (indirect) bilirubin. *Indirect bilirubin* is a term frequently used to refer to unconjugated bilirubin in the circulation because the addition of another chemical is necessary to differentiate this fraction from the whole. Normally, $>90\%$ of serum bilirubin is unconjugated. The testing process for conjugated bilirubin, in contrast, is direct without the addition of other agents. The direct bilirubin test measures the levels of conjugated bilirubin and δ bilirubin (conjugated bilirubin bound to albumin).

The patterns of elevation of the different fractions of bilirubin provide important diagnostic clues as to the cause of cholestasis. In general, an elevated indirect bilirubin level suggests intrahepatic cholestasis, and an elevated direct bilirubin level suggests extrahepatic obstruction. Mechanisms that can result in increases in unconjugated bilirubin levels include increased bilirubin production (hemolytic disorders and resorption of hematomas) or defects (inherited or acquired) in hepatic uptake or conjugation. The rate-limiting step in bilirubin metabolism is the excretion of bilirubin from hepatocytes, so conjugated hyperbilirubinemia can be seen in inherited or acquired disorders of intrahepatic excretion or extrahepatic obstruction. Conjugated bilirubin that cannot be excreted accumulates in hepatocytes, which results in its secretion into the circulation. Because conjugated bilirubin is water soluble, it can be found in the urine of patients with jaundice.

AP is an enzyme with a wide tissue distribution but is found primarily in the liver and bones. In the liver, it is expressed by the bile duct epithelium. In conditions of biliary obstruction, levels rise as a result of increased synthesis and release into the serum. Because the half-life of serum AP is approximately 7 days, it may take several days for levels to normalize even after resolution of the biliary obstruction.

GGT is another enzyme found in hepatocytes and released from the bile duct epithelium. Elevation of GGT is an early marker and also a sensitive test for hepatobiliary disease. Like AP elevation, however, it is nonspecific and can be produced by a variety of disorders in the absence of liver disease. Increased levels of GGT can be induced by certain medications, alcohol abuse, pancreatic disease, myocardial infarction, renal failure, and obstructive pulmonary disease. For this reason, elevated GGT levels are often interpreted in conjunction with other enzyme abnormalities. For example, a raised GGT level with increased AP level supports a liver source.

Jaundice

Jaundice refers to the yellowish staining of the skin, sclera, and mucous membranes with the pigment bilirubin. Hyperbilirubinemia usually is detectable as jaundice when blood levels rise above 2.5 to 3 mg/dL. Jaundice can be caused by a wide range of benign and malignant disorders. However, when present, it may indicate a serious condition, and thus knowledge of the differential diagnosis of jaundice and a systematic approach to

the workup of the patient is necessary. Workup of a patient with jaundice is simplified by organizing the possible causes of the disorder into groups based on the location of bilirubin metabolism. As mentioned previously, bilirubin metabolism can take place in three phases: prehepatic, intrahepatic, and posthepatic. The prehepatic phase includes the production of bilirubin from the breakdown of heme products and its transport to the liver. The majority of the heme results from red blood cell metabolism and the rest from other heme-containing organic compounds such as myoglobin and cytochromes. In the liver, the insoluble unconjugated bilirubin is then conjugated to glucuronic acid to allow for solubility in bile and excretion. The posthepatic phase of bilirubin metabolism consists of excretion of soluble bilirubin through the biliary system into the duodenum. Dysfunction in any of these phases can lead to jaundice.¹⁰

Prehepatic. Jaundice as a result of elevated levels of unconjugated bilirubin occurs from faulty prehepatic metabolism and usually arises from conditions that interfere with proper conjugation of bilirubin in the hepatocyte. Insufficient conjugation is often seen in processes that result in excessive heme metabolism. Subsequently, the conjugation system is overwhelmed, which results in unconjugated hyperbilirubinemia. Causes of hemolysis include inherited and acquired hemolytic anemias. Inherited hemolytic anemias include genetic disorders of the red blood cell membrane (hereditary spherocytosis and elliptocytosis), enzyme defects (glucose-6-phosphate dehydrogenase deficiency), and defects in hemoglobin structure (sickle cell anemia and thalassemias). Hemolytic anemias can also be acquired, and these can be further divided into those with immune-mediated and those with non-immune-mediated causes. Immune-mediated hemolytic anemias result in a positive finding on a direct Coombs test and have a variety of autoimmune and drug-induced causes. In contrast, direct Coombs test results are negative in nonimmune hemolytic anemias. The causes in this latter category are varied and include drugs and toxins that directly damage red blood cells, mechanical trauma (heart valves), microangiopathy, and infections. Prehepatic dysfunction of bilirubin metabolism also can result from failure in the transport of unconjugated bilirubin to the liver by albumin in any condition that leads to plasma protein loss. A poor nutritional state or excess protein loss as seen in burn patients can lead to elevated levels of unconjugated bilirubin in the circulation and jaundice.

Intrahepatic. Intrahepatic causes of jaundice involve the intracellular mechanisms for conjugation and excretion of bile from the hepatocyte. The enzymatic processes in hepatocytes can be affected by any condition that impairs hepatic blood flow and subsequent function of the liver (ischemic or hypoxic events). Furthermore, there are multiple inherited disorders of enzyme metabolism that can result in either unconjugated or conjugated hyperbilirubinemia. Gilbert's syndrome is a genetic variant characterized by diminished activity of the enzyme glucuronyltransferase, which results in decreased conjugation of bilirubin to glucuronide. It is a benign condition that affects approximately 4% to 7% of the population. Typically, the disease results in transient mild increases in unconjugated bilirubin levels and jaundice during episodes of fasting, stress, or illness. These episodes are self-limited and usually do not require further treatment. Another inherited disorder of bilirubin conjugation is Crigler-Najjar syndrome. It is a rare disease found in neonates and can result in neurotoxic sequelae from bilirubin encephalopathy.

In addition to defects in conjugation, disorders in bilirubin excretion in hepatocytes can also lead to jaundice. Rotor's syndrome and Dubin-Johnson syndrome are two uncommon genetic disorders that disrupt secretion of conjugated bilirubin from the hepatocyte into the bile and result in conjugated hyperbilirubinemia. There are also multiple acquired conditions that result in inflammation and intrahepatic cholestasis by affecting hepatocyte mechanisms for conjugation and excretion of bile. Viruses, alcohol abuse, sepsis, and autoimmune disorders all can result in inflammation in the liver with subsequent disruption of bilirubin transport in the liver. In addition, jaundice can also occur from the cytotoxic effects of many medications, including acetaminophen, oral contraceptives, and anabolic steroids.

Posthepatic. Posthepatic causes of jaundice are usually the result of intrinsic or extrinsic obstruction of the biliary duct system that prevents the flow of bile into the duodenum. There is a wide spectrum of pathologies that may present with obstructive jaundice. Intrinsic obstruction can occur from biliary diseases, including cholelithiasis, choledocholithiasis, benign and malignant biliary strictures, cholangiocarcinoma, cholangitis, and disorders of the papilla of Vater. Extrinsic compression of the biliary tree is commonly due to pancreatic disorders. Patients with pancreatitis, pseudocysts, and malignancies can present with jaundice due to external compression of the biliary system. Finally, with the growing armamentarium of endoscopic tools and minimally invasive surgical approaches, surgical complications are becoming more frequent causes of extrahepatic cholestasis. Misadventures with surgical clips, retained stones, and inadvertent ischemic insults to the biliary system can result in obstructive jaundice recognized at any time from immediately postoperatively to many years later.

MOLECULAR SIGNALING PATHWAYS IN THE LIVER

Acute Phase Reaction

The liver is the site of synthesis of acute phase proteins that consists of a group of plasma proteins that are rapidly released in response to inflammatory conditions elsewhere in the body. The synthesis of these proteins in the liver is mediated by a number of inflammatory mediators. Cytokines such as tumor necrosis factor alpha (TNF- α), interferon- γ (IFN- γ), interleukin-1 (IL-1), interleukin-6 (IL-6), and interleukin-8 (IL-8) are released by inflammatory cells into the circulation at sites of injury and modulate the acute phase response. In response to these cytokines, the liver increases synthesis and release of a wide variety of proteins including ceruloplasmin, complement factors, C-reactive protein (CRP), D-dimer protein, alpha 1-antitrypsin, and serum amyloid A. There are proteins, such as serum albumin and transferrin, that also decrease (negative acute phase proteins) in response to inflammation.

The acute phase response of the liver can be initiated in response to infection, trauma, or malignancy. The purpose of the release of these proteins from the liver is to contain infectious processes, prevent further tissue damage and to begin reparative and regeneration processes to restore body homeostasis. For example, products of the complement pathways can attach to microbes to allow for phagocytosis and act as chemoattractants to the areas of inflammation. CRP is an important acute phase protein that is also involved in the clearance of microorganisms by binding to their membranes and functioning as an opsonin to

facilitate phagocytosis. Other proteins such as α 1-antitrypsin are protease inhibitors and restrict the protease activity of enzymes of inflammatory cells. Thus, the secretion of acute phase proteins from the liver during the acute phase response is an early defense measure against harmful stimuli prior to the full activation of the immune response.¹¹

LPS Signaling

The liver is a complex organ with an important function in immune surveillance and clearance of bacteria and their products. This function is facilitated by the fact that the liver receives all the drainage of the gastrointestinal tract via the portal blood flow, making it the last barrier preventing bacteria and their toxins from reaching the systemic circulation. The importance of preventing bacteria and their products from reaching the systemic blood stream is evident in patients who are infected with gram-negative bacteria. Gram-negative bacteria infection produces an acute inflammatory reaction that can lead to septic shock and multiple organ failure. The complications of gram-negative sepsis are initiated by endotoxin (lipopolysaccharide [LPS]). LPS is a glycolipid constituent of gram-negative bacteria outer membranes composed of a hydrophilic polysaccharide portion and a hydrophobic domain called lipid A. The lipid A structure is the LPS component responsible for the biological effects of LPS. Mere nanogram amounts of LPS injected into humans are needed to result in the manifestations of septic shock. The profound effects of LPS are caused not only by the direct effect of LPS itself but also by the activation of LPS-sensitive cells, resulting in the excessive release of cytokines and other inflammatory mediators.

Since sepsis from gram-negative bacterial infection continues to be a major cause of morbidity and mortality, significant efforts have been made to identify the molecules involved in LPS-binding and signaling. Lipopolysaccharide binding protein (LBP), CD14, MD2, and Toll-like receptors have all been identified as important mediators in the pathway of LPS stimulation. LBP is an acute-phase protein synthesized by hepatocytes that binds the lipid A moiety of LPS and forms a soluble LBP-LPS complex. This LBP-LPS complex then interacts with CD14, a receptor identified as important in LPS recognition, resulting in the release of inflammatory cytokines and mediators. Studies have shown that although LBP is important, it is not required for LPS to interact with CD14; however, its presence markedly decreases the concentration of LPS necessary for cellular activation. This may be important especially at the low concentrations of LPS found under physiological conditions. CD14 exists in two forms, membrane (mCD14) and soluble (sCD14) form. The interaction of LPS with membrane CD14 or soluble CD14 is important in host clearance of LPS. This interaction is also responsible for the toxic effects of LPS seen in the liver and systemic circulation after the release of inflammatory cytokines and mediators. While membrane CD14 is a membrane protein found on the surface of myeloid lineage and mediates the activation of these cells by LPS, soluble CD14 is found in the serum and enables responses to LPS by cells that do not express CD14. In addition to its important role in the release of LBP as an acute phase reactant during LPS-mediated inflammatory insults, the liver is also one of the major sources of soluble CD14 into the circulation.

The binding of the LBP-LPS complex to CD14 is not enough to transduce an intracellular LPS signal. Membrane CD14 is a glycosyl phosphatidylinositol-anchored protein

without a membrane-spanning domain. Thus, signaling further downstream of LPS requires additional elements. In studies using chemically modified, radiiodinated LPS capable of cross-linking to nearby proteins, LPS has been shown to cross-link specifically to two other molecules, TLR4 and MD-2. TLR4 is a member of the family of proteins called Toll-like receptors and has been identified as the transmembrane coreceptor to CD14. TLR4 was originally identified as the molecular sensor for bacterial LPS when studies demonstrated that mutations in the *tlr4* gene were responsible for defective LPS signaling in mutant mice. Thus, initiation of LPS signal cascade requires the interaction of LPS directly with the heteromeric receptor complex of CD14, TLR4, and MD-2. Activation of this complex senses the presence of bacterial LPS at the cell surface and then transmits a signal into the cytoplasm through two distinct pathways. One pathway is dependent upon an adaptor known as myeloid differentiation factor 88 (MyD88). The other pathway is MyD88-independent and relies on an adaptor known as Toll/IL-1 receptor domain-containing adaptor-inducing IFN β (TRIF).

The liver is the main organ involved in the clearance of LPS from the bloodstream and so plays a critical role in the identification and processing of LPS. Kupffer cells are the resident macrophages of the liver and have been shown to participate in LPS clearance. Studies have demonstrated that the majority of radiolabelled LPS injected intravenously is quickly cleared from the circulation and found in the liver, primarily localized to the Kupffer cells. Kupffer cells also contribute to the inflammatory cascade by producing cytokines in response to LPS. Interestingly, hepatocytes, the parenchymal cells of the liver, also have all the components required for LPS recognition and signaling and can participate in the response to LPS and process LPS for clearance.

Although the liver is essential in the host response to gram-negative bacteria infection by contributing to LPS clearance and to the LPS-induced inflammatory reaction, evidence reveals that LPS may actually have a reciprocal role in the pathogenesis of liver disorders. The relationship between LPS and liver disease is not a novel concept. Early studies have shown the correlation between the presence or absence of gut-derived LPS and the development of liver injury. Attempts to eliminate gut-derived LPS have had protective effects in various animal models of liver injury, including alcohol-induced liver disease. Other studies have shown the synergism between LPS and hepatotoxins in worsening liver injury.

In summary, the liver is essential in the clearance of LPS, but it can also contribute to the negative systemic effects seen in gram-negative bacterial sepsis by excessive activation of the LPS signaling pathway. In addition, there is evidence that this signaling pathway may participate in the pathogenesis of a variety of liver disease. An understanding and characterization of the LPS pathway within the liver is an important step to understanding the molecular basis for the lethal effect of LPS during sepsis and liver disorders.^{12,13}

Nitric Oxide

Nitric oxide (NO) is a diffusible, free radical gas that was first identified in 1980 as endothelium-derived relaxing factor. Its physiologic and pathophysiologic importance was first discovered in the cardiovascular system with its vital role as a vasodilator. However, its mediation in a variety of other diverse biological activities has since been discovered. In the liver, the

influence of NO on normal physiology as well as in states of disease has been extensively studied. The activation of inflammatory cascades in the liver almost universally includes the upregulation of the inducible or inflammatory isoform of nitric oxide synthase (iNOS) and subsequent NO production. The functions of iNOS and NO in the liver is complex, and a clear dichotomy of their roles in liver dysfunction, whether being protective or detrimental, has been demonstrated.

Nitric oxide can be produced by one of three NO synthases: (NOS)-neuronal NOS (nNOS), inducible or inflammatory NOS (iNOS), and endothelial NOS (eNOS). These enzymes catalyze the conversion of L-arginine to NO and L-citrulline. Neuronal and endothelial NOS are constitutively expressed in a wide range of tissues. The activity of iNOS and eNOS are primarily controlled by calcium-mediated signaling that results in transient activation of these enzymes to produce small amounts of NO. Inducible NOS, as the name implies, is not normally expressed in resting states in most tissues but is upregulated by gene transcription under conditions of stress. In contrast to nNOS and eNOS, the amount of NO produced by iNOS is large and sustained. Although first identified in macrophages, the expression of iNOS has been shown in most cell types if appropriately stimulated. Interestingly, studies on the liver with hepatocytes provided the first evidence that parenchymal cells could express iNOS. It is now known that iNOS can be expressed in all cell types of the liver, but hepatocyte expression appears to be the most prominent. Studies have shown that many inflammatory mediators, including cytokines, microbial products, and oxidative stress, are all capable of stimulating iNOS expression in the liver.

The chemical action of NO in biological systems has been difficult to study due to its short-lived nature. NO is highly reactive with other molecules due to its one unpaired electron. These interactions can either result in nitrosation or oxidation with subsequent varied effects on cellular processes. Nitric oxide can also signal through cyclic nucleotides by activating the soluble isoform of guanylyl cyclase, increasing levels of cGMP. The functions of cGMP include acting as second messengers that transmit signals by activating downstream kinases or through the activation of cyclic nucleotide-gated channels. In addition to cGMP signaling, NO has also been found to modulate the expression of many genes.

The role of NO in inflammatory states of the liver is complex and is at times conflicting. Under physiologic conditions, NO is important in maintaining hepatic perfusion. However, in inflammatory conditions, such as ischemia/reperfusion (I/R), nitric oxide can play either a protective or harmful role depending on the enzymatic source (inducible versus endothelial nitric oxide synthase) and the type of ischemia reperfusion (cold vs. warm). It appears that the low level of constitutively expressed eNOS-derived NO is primarily beneficial in models of I/R injury with vasodilation and subsequent improvement in hepatic microcirculation as the proposed mechanism of protection. Interestingly, activation of iNOS in similar models suggests a potentially harmful role for iNOS. Nitric oxide, through its reaction with reactive nitrogen and oxygen intermediates generated in the course of reperfusion injury, can contribute to much of the hepatocellular damage depending on the intracellular ratio of these intermediates to nitric oxide. The production of iNOS and NO are also closely tied to multiple other inflammatory mediators in the liver, and activation of these downstream signals may explain some of the detrimental effects of NO in I/R injury of the liver. Thus, given its diverse biological effects as a

signaling molecule, it is not surprising that NO plays both protective and potentially harmful role in the setting of hepatic I/R injury. The final effect of NO varies in different liver diseases and depends on the overall hepatic environment. The potential use of NO pharmacologic manipulation to treat hepatic disease will require careful balance of the risks and benefits of this simple, yet extremely complicated, molecule.^{14,15}

Heme Oxygenase System

The heme oxygenase (HO) is the rate-limiting enzyme in the degradation of heme to yield biliverdin, carbon monoxide (CO), and free iron. The HO system, which is activated in response to multiple cellular stresses, has been shown to be an endogenous cytoprotectant in a variety of inflammatory conditions. There are currently three heme oxygenase isozymes identified. HO-1 is the inducible form of heme oxygenase, while HO-2 and HO-3 are constitutively expressed. The function of HO in heme degradation is essential due to the potentially toxic effects of heme. An excess of heme can cause cellular damage from oxidative stress due to its production of reactive oxygen species. Thus, the HO system is an important defense mechanism against free heme-mediated oxidative stress.

HO-1 has been shown to be induced in a variety of organs during diverse conditions such as hypoxia, endotoxemia, ischemia/reperfusion (I/R), hyperthermia, and radiation. It is thought that HO-1 is involved in maintaining redox homeostasis during cellular stress. In the liver, HO-1 is thought to normally modulate hepatic microvasculature tone through its generation of CO and, like nitric oxide, its activation of guanylyl cyclase. This important role is demonstrated in animal models of portal hypertension where inhibition of HO-1 exacerbates hypertension. Since HO-1 is induced as a protective mechanism in response to various stimuli, targeted induction of HO-1 has been studied as a therapeutic strategy for protection against inflammatory processes. HO-1 overexpression exerts hepatoprotective effects in models of I/R injury, hemorrhagic shock and resuscitation, acetaminophen-induced hepatonecrosis, and sepsis-mediated liver injury.

Although HO-1 has been shown to provide protective effects in a variety of inflammatory states, the specific mechanisms by which HO-1 mediates its protective effects are remains to be fully elucidated. Originally thought to be only potentially toxic waste, the byproducts generated during heme catabolism now appear to play important roles against cellular stress. The well-known hazardous effects of high doses of CO are attributable to its ability to bind hemoglobin and myoglobin, preventing the release of oxygen to tissues. However, only recently have the physiological and beneficial roles of CO been identified. CO is produced in injured tissues via induction of HO-1 and contributes to the attenuation of proinflammatory processes. Similar to NO, CO plays an important role in maintaining the microcirculation through its activation of soluble guanylyl cyclase and subsequent elevation of intracellular cyclic 3'5'-guanosine monophosphate (cGMP). The signaling activities of cGMP lead to smooth muscle relaxation and inhibition and platelet aggregation. In addition, CO has also been shown to inhibit proinflammatory cytokines (TNF- α , IL-1) and chemokines while simultaneously inducing anti-inflammatory cytokines (IL-10). Exogenous low-dose CO has been shown to protect the liver from I/R injury and endotoxemia.

Biliverdin and bilirubin are other metabolites of heme that are also recognized as possible mediators of HO-1's protective

function. The cytosolic enzyme biliverdin reductase catalyzes the reduction of biliverdin to bilirubin. Both biliverdin and bilirubin have important endogenous antioxidant properties. Free iron, the third byproduct of heme oxidation is known to be cytotoxic by catalyzing the production of hydroxyl radicals. However, HO-1 induction is associated with increased levels of ferritin, the free iron sequestering protein. Thus, the increase in ferritin with the subsequent decrease in intracellular concentrations of free iron results in a net antioxidant effect. Importantly, both bilirubin and ferritin have been shown to protect against liver injury in a variety of I/R models.

In summary, HO-1 is upregulated and protective in multiple conditions of hepatic stress. Until recently, the degradation products of the HO system were thought to only be potentially toxic waste. It now appears that CO, biliverdin/bilirubin, ferritin are important in the maintenance of cellular redox homeostasis and may play a role in the mechanism of hepatoprotection in disease. Studies involving induction of HO-1 expression and use of its metabolic products hold therapeutic promises for novel protective agents against disorders of hepatic inflammation.^{16,17}

Toll-Like Receptors

The liver is a central regulator of the systemic immune response following acute insults to the body. Not only does it play a crucial role in modulating the systemic inflammatory response to infection or injury, it is also subject to injury and dysfunction from these same processes. Recent advances in the study of mechanisms for the activation of the innate immune system have pointed to the Toll-like receptors (TLRs) as a common pathway for immune recognition of microbial invasion and tissue injury. By recognizing either microbial products or endogenous molecules released from damaged sites, the TLR system is capable of alerting the host of danger by activating the innate immune system. Initially, this is manifested by the production of inflammatory mediators and the rapid uptake of invading microbes and their products. When excessive, this inflammatory response can contribute to organ damage and dysfunction.

To date, 13 TLRs have been described in mice, and 11 in humans. TLRs are a family of proteins that are mammalian homologues to the *Drosophila* Toll, a protein that functions in development and immunity. The cytoplasmic portion of Toll-like receptors is similar to that of the IL-1 receptor (IL-1R) family and is called the Toll/IL-1 receptor (TIR) domain. Unlike the IL-1 receptor extracellular portion that consists of an immunoglobulin-like domain, the Toll-like receptors have leucine-rich repeats in their extracellular portion. The TLR receptors have many structural similarities both extracellularly and intracellularly, but they differ from each other in ligand specificities, expression patterns, and with some variability in the signaling pathways they activate.

The TLR receptors were initially identified as components of the innate immune system that acted as a front-line defense mechanism against infections. Their recognition of patterns on pathogens, such as microbial peptides, lipopolysaccharide, lipoteichoic acids, bacterial DNA, and single-stranded RNA, resulted in the activation of an inflammatory response meant for controlling the invading organisms. In situations of noninfectious inflammation such as seen in trauma, clinicians have long recognized similar activation of the same inflammatory pathways and systemic manifestations. This observation, among others, led to the hypothesis that the immune system is designed to recognize any threats, whether from pathogens

or tissue damage, that may lead to disruption of homeostasis. In conditions of sterile inflammation, the activation of immune cells is through the release of endogenous danger molecules, normal cell constituents released by damage or dying cells or components of the extracellular matrix, released by the action of proteases at the site of tissue damage. Recent observations show that both microbial products and endogenous danger molecules can be recognized through the TLR system.

Perhaps more than any of the other TLR family members, TLR4 sits at the interface of microbial and sterile inflammation. Whereas the role of TLR4 in the recognition of lipopolysaccharide (LPS) is well established, only recently has it become apparent that TLR4 also participates in the recognition of endogenous danger molecules. In vivo evidence for TLR4-mediated danger signaling comes from studies of acute tissue injury in hemorrhagic shock, trauma, and I/R models. In each case, TLR4-mutant animals exhibited reduced injury or inflammation compared to wild-type controls. In efforts to identify the ligands responsible for TLR4-dependent signaling in noninfectious insults, multiple molecules have been suggested. These include heat shock proteins, fibrinogen, hyaluronic acid, heparan sulfate, and high mobility group box-1. Although a central role for TLR4 in recognizing tissue injury is building, studies are beginning to suggest that other TLR family members may also participate in the recognition of endogenous molecules released by tissue injury. The very recent realization that certain TLR family members also respond to endogenous molecules released from stressed or damaged tissues points to a molecular basis for a shared mechanism of innate immune activation by infection and injury.¹⁸⁻²⁰

RADIOLOGIC EVALUATION OF THE LIVER

Ultrasound

Abdominal ultrasound is a commonly applied imaging modality used to evaluate abdominal symptoms. Ultrasound technology is based on the pulse-echo principle. The ultrasound transducer converts electrical energy to high-frequency sound energy that is transmitted into tissue. Although some of the ultrasound waves are transmitted through the tissue, some are reflected back, and the ultrasound image is produced when the ultrasound receiver detects those reflected waves. This real-time gray-scale (B-mode) imaging is augmented by Doppler flow imaging. Doppler ultrasound not only can detect the presence of blood vessels but also can determine the direction and velocity of blood flow. Ultrasonography is a useful initial imaging test of the liver because it is inexpensive, widely available, involves no radiation exposure, and is well tolerated by patients. It is excellent for diagnosing biliary pathology and focal liver lesions. In addition, liver injury can be evaluated in trauma patients using the focused abdominal sonography for trauma examination. Limitations of ultrasound include incomplete imaging of the liver, most often at the dome or beneath ribs on the surface, and incomplete visualization of lesion boundaries. Moreover, obesity and overlying bowel gas also can interfere with image quality. Thus, ultrasonographically detected masses usually require further evaluation by other imaging modalities due to the lower sensitivity and specificity of ultrasound compared with CT and MRI.

The advent of contrast-enhanced ultrasound has improved the ability of this modality to differentiate among benign and malignant lesions. The injection of gas microbubble agents can

increase the sensitivity and specificity of ultrasound in detecting and diagnosing liver lesions. Microbubbles are $<10\ \mu\text{m}$ and, when given intravenously, allow for more effective echo enhancement. Contrast-enhanced ultrasound imaging of the liver improves delineation of liver lesions through identification of dynamic enhancement patterns and the vascular morphology of the lesion. In addition, some agents exhibit a late liver-specific phase in which the bubbles are taken up by cells in the reticuloendothelial system and accumulate in normal liver parenchyma after the vascular enhancement has faded.

The use of intraoperative ultrasound of the liver has rapidly expanded over the years with the increasing number and complexity of hepatic resections being performed.²¹ It has the ability to provide the surgeon with real-time accurate information useful for surgical planning. Intraoperative ultrasound is considered the gold standard for detecting liver lesions, and studies have shown that it can identify 20% to 30% more lesions than other preoperative imaging modalities. Importantly, it has been shown to influence surgical management in almost 50% of planned liver resections for malignancies. Applications for intraoperative ultrasound of the liver include tumor staging, visualization of intrahepatic vascular structures (Fig. 31-10), and guidance of resection plane by assessment of the relationship of a mass to the vessels. In addition, biopsy of lesions and ablation of tumors can be guided by intraoperative ultrasound.

Ultrasound elastography, also referred to as transient elastography, can be used to assess the degree of fibrosis or cirrhosis in the liver. Low-frequency vibrations transmitted through the liver induce an elastic shear wave that is detected by pulse-echo ultrasonography as the wave propagates through the liver. The velocity of the wave correlates with the stiffness of the organ—the wave travels faster through fibrotic or cirrhotic tissues. Ultrasound elastography has been found in large cohorts of individuals to have a sensitivity of 87% and a specificity of 91% for the diagnosis of cirrhosis when compared with liver biopsy.²² Unlike liver biopsy, ultrasound elastography is non-invasive and can be repeated often without additional risk to the patient. Furthermore, this rapid test can acquire information from a larger area of the tissue relative to needle biopsy, providing a better understanding of the entire hepatic parenchyma and reducing sampling error.

Computed Tomography

CT produces a digitally processed cross-sectional image of the body from a large series of X-ray images. The introduction of helical (spiral) CT has improved the imaging capabilities of this technique compared to earlier conventional axial CT by combining a continuous patient-table motion with continuous rotation of the CT gantry and allowing rapid acquisition of a volume of data within a single breath hold. With the recent advent of multidetector row CT scanners, high-resolution images can be obtained in submillimeter section thickness within a short scan time, with virtually no penalty in increased radiation dose. Together, these technologic advances have led to reduced motion artifacts due to variations in inspiration, facilitated optimal contrast delivery, and allowed for the capability to generate high-resolution reformations in any desired plane. In a single examination, modern-day CT scans provide detailed morphologic information on the number, size, distribution, and vascularity of liver lesions, all of which are vital in guiding the clinical management and therapeutic plan.

Figure 31-10. Intraoperative liver ultrasound images of the portal veins, hepatic veins, and inferior vena cava (IVC). *Upper panel* shows the portal vein bifurcation with echogenic Glissonian sheath. The confluence of the three hepatic veins (right hepatic vein [RHV], middle hepatic vein [MHV], and left hepatic vein [LHV]) and the IVC is shown in the *middle panel*. An accessory LHV is present in this patient. *Lower panel* is a color Doppler image showing flow.

Contrast medium is routinely used in CT evaluation of the liver because of the similar densities of most pathologic liver masses and normal hepatic parenchyma. A CT scan with a dual- or triple-phase bolus of intravenous contrast agent is performed to achieve the greatest enhancement of contrast between normal and pathologic tissues.²³ Ideally, contrast media should be selectively delivered to either the tumor or the liver, but not both. Radiologists use the dual blood supply of the liver and the hemodynamics of hepatic tumors to achieve this goal. The liver is unique in that it has a dual blood supply. As previously noted, the portal vein supplies approximately 75% of the blood

flow and the hepatic artery the remaining 25%. However, many liver tumors receive the majority of their blood supply from the hepatic artery. After injection of the contrast agent, the rapid scan time of helical CT allows for CT sections through the liver in both the arterial dominant phase (20 to 30 seconds after the beginning of contrast delivery) and venous or portal dominant phase (60 to 70 seconds after contrast injection) (Fig. 31-11). Thus, many hepatic tumors that derive the majority of their blood supply from the hepatic artery as well as other hypervascular lesions are well delineated in the arterial phase. On the other hand, the portal phase provides optimal enhancement of the normal liver parenchyma because the majority of its blood supply is derived from the portal vein. This allows

Figure 31-11. Computed tomographic (CT) images of hepatic veins and Couinaud's liver segments. The images show the three hepatic veins and inferior vena cava (IVC) (*upper panel*), as well as Couinaud's liver segments (*lower panels*). LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

for detection of hypovascular lesions because they will appear hypoattenuated in relation to the brighter normal liver parenchyma. Furthermore, the arterial and portal phase images allow for noninvasive mapping of the hepatic arterial and venous anatomy, information that is crucial in the preoperative planning for patients undergoing liver surgery.

CT cholangiography has emerged as a new imaging modality for biliary disease. This technique usually involves the use of contrast agents, which are excreted by hepatocytes into the bile ducts. CT cholangiography, therefore, provides information on hepatocyte function and bile flow, in addition to high-resolution depiction of the biliary tree. It has compared well to endoscopic retrograde cholangiopancreatography (ERCP) in identifying obstructive biliary disease.²⁴ One of the major advantages of CT cholangiography over other imaging modalities is the ability to depict small nondilated peripheral biliary radicals. This technique may be useful in the context of live liver donation or complex biliary surgery to aid in the preoperative depiction of biliary anatomy. It also may be applicable in the postoperative setting for the detection of biliary leakage or obstruction. A limitation of CT cholangiography is that the biliary tree may not be well visualized in patients with excessively dilated bile ducts or in those with hyperbilirubinemia, as bilirubin excretion is impaired in these cases.

Magnetic Resonance Imaging

MRI is a technique that produces images based on magnetic fields and radio waves. The MRI scanner creates a powerful magnetic field that aligns the hydrogen atoms in the body, and radio waves are used to alter the alignment of this magnetization. Different tissues absorb and release radio wave energy at different rates, and this information is used to construct an image of the body. Most tissues can be differentiated by differences in their characteristic T1 and T2 relaxation times. T1 is a measure of how quickly a tissue can become magnetized, and T2 measures how quickly it loses its magnetization. As with CT technology, advances in MRI now provide the opportunity to perform single-breath T1-weighted imaging and respiration-triggered T2-weighted imaging. The development of breath-hold imaging techniques has eliminated many of the motion artifacts that previously limited the sensitivity and application of MRI for imaging of the liver. Compared with CT scanning, the major advantages of MRI pertain to higher soft tissue contrast resolution and excellent depiction of fluid-containing structures, while obviating the need for ionizing radiation.

As with the iodinated contrast media use in CT scanning, multiple contrast agents have been developed for MRI to increase the difference in signal intensity between normal liver and pathologic lesions. Various gadolinium-based compounds have been used as MRI contrast agents that behave in a manner very similar to iodine in CT. Liver-specific MRI contrast agents also have been developed that rely either on excretion by Kupffer cells, such as ferumoxide (Feridex, Advanced Magnetics, Cambridge, MA), or on secretion in bile by hepatocytes, including gadoxetate (Eovist or Primovist, Bayer-Schering,

3▶ Berlin, Germany). These agents combine the information obtained during a standard MRI with additional functional data, which in turn yields improved detection and characterization of lesions within the liver.²⁵

Just as ultrasound elastography is useful in the diagnosis of hepatic fibrosis and cirrhosis, magnetic resonance (MR) elastography appears promising as an imaging modality in

reducing the need for liver biopsy. In this technique, a vibration device is used to induce a shear wave in the liver. A modified MRI machine detects the shear wave, then generates a color-coded image that depicts the wave velocity, and hence stiffness, throughout the organ. Although preliminary studies have shown that MR elastography can detect cirrhosis with a high degree of accuracy, the clinical utility of this modality, especially given its relatively high cost, remains to be determined.

Magnetic resonance cholangiopancreatography (MRCP) enables rapid, noninvasive depiction of both the biliary tree and the pancreatic duct without the use of ionizing radiation or intravenous contrast media. One of the most common clinical indications for MRCP is biliary obstruction. MRCP provides visualization of dilated bile ducts, and the high spatial and contrast resolution often enables accurate assessment of the level of occlusion in the biliary tree. MRCP also can be enhanced with liver-specific MRI contrast agents that are actively secreted into the bile, but the clinical indications for such studies are still a matter of intensive investigation.²⁶

Positron Emission Tomography

Positron emission tomography (PET) is a nuclear medicine test that produces images of metabolic activity in tissues by detecting gamma rays emitted by a radioisotope incorporated into a metabolically active molecule. Fluorodeoxyglucose (FDG) is the most common metabolic molecule used in PET imaging. Although traditional imaging such as CT, ultrasound, and MRI provide anatomic information, PET offers functional imaging of tissues with high metabolic activity, including most types of metastatic tumors. PET imaging increasingly is used as a tool in the diagnostic evaluation of a patient with potentially resectable hepatic disease. In nonrandomized trials, PET demonstrated better sensitivity and specificity than CT scanning for the detection of both intrahepatic and extrahepatic disease.²⁷ Integrated PET/CT improves diagnostic accuracy over standard PET or CT alone and has been shown to be sensitive in the detection of liver metastases derived from a wide range of cancers, including colorectal (Fig. 31-12), breast, or lung primaries.²⁷

More than 20% of patients with colorectal cancer initially present with hepatic metastasis, and a large percentage of patients undergoing resection for their primary colorectal cancer eventually experience disease recurrence in the liver.

The role of FDG-PET/CT in colorectal cancers lies predominantly in tumor staging and follow-up, particularly in the detection of occult intrahepatic metastases or extrahepatic disease. Although hepatic resection of colorectal metastases provides survival rates nearing 50%, the presence of extrahepatic disease is a poor prognosticator and usually precludes aggressive surgical intervention. Thus, accurate information regarding the extent of the disease is necessary for management of patients with colorectal metastases. PET/CT has also been shown to be more accurate than contrast-enhanced CT in tumor surveillance after radiofrequency ablation.²⁸ The sensitivity of FDG-PET, however, is lowered by neoadjuvant chemotherapy, most likely secondary to reduced metabolic activity within the tumor.

Although the role of PET/CT in the clinical management of liver metastases has been well-established, its utility in the diagnostic workup of primary liver tumors is still debated. In hepatocellular carcinoma (HCC), FDG uptake correlates with the degree of differentiation—high-grade HCC lesions have increased FDG uptake compared to low-grade HCCs. As a result, the overall sensitivity of FDG-PET/CT in the detection of HCCs is reported to be only 50% to 65%, rendering this modality insufficient when used alone in the diagnosis of primary HCCs. For this reason, dual-tracer PET has been introduced to improve sensitivity in detecting all HCC. This modality combines the use of FDG, which accumulates in poorly differentiated tumors, with ¹¹C-acetate, a tracer preferentially accumulated by well-differentiated HCC lesions. Although the clinical benefits of dual-tracer PET/CT have yet to be fully established, this combined modality has the potential to become a valuable tool in the diagnosis and staging of HCC. In cholangiocarcinoma tumors, FDG avidity depends on the morphologic characteristics and location of the lesion. Therefore, FDG-PET and FDG-PET/CT have not been shown to be highly beneficial in the diagnosis of primary cholangiocarcinoma, but they may be beneficial in the detection of regional and distal metastases, which can affect clinical decision making and patient management.

ACUTE LIVER FAILURE

Acute liver failure (ALF) occurs when the rate and extent of hepatocyte death exceeds the liver's regenerative capabilities. It was initially described as a specific disease entity in the 1950s.

Figure 31-12. Computed tomography (CT)–positron emission tomography (PET) scans before and after resection of liver metastasis from colorectal cancer in a 54-year-old patient. CT scan shows large 10-cm right lobe liver metastasis (*left panel*), and PET scan findings are strongly positive (*middle panel*). Two years after right hepatectomy, the patient has no evidence of recurrence and significant hypertrophy of the left lobe (*right panel*).

It also has been referred to as *fulminant hepatic failure*. ALF is a rare disorder affecting approximately 2000 patients annually in the United States. ALF is defined by the development of hepatic encephalopathy occurring within 26 weeks of severe liver injury in a patient without a history of previous liver disease or portal hypertension.²⁹ The manifestations of ALF may include cerebral edema, hemodynamic instability, increased susceptibility to bacterial and fungal infections, renal failure, coagulopathy, and metabolic disturbances. Even with current medical care, ALF can progress rapidly to hepatic coma and death. The most common cause of death is intracranial hypertension due to cerebral edema, followed by sepsis and multisystem organ failure. The causes of ALF, which are the most important variables in determining outcome, are numerous and can include viral infection as well as drug overdose, reaction, and toxicity. It has been determined that the etiologic factor leading to ALF varies according to geographic location.³⁰ Before the introduction of orthotopic liver transplantation (OLT), the chance for survival was <20%. Currently, most series report 5-year survival rates of >70% for affected patients.³¹

Etiology

Differences in etiology, management, and patient outcomes have been described for various regions of the globe. In the East and developing portions of the world, the most common causes of ALF are viral infections, primarily hepatitis B, A, and E.²⁰ In these areas, there are a relatively small number of drug-induced cases. In contrast, 65% of cases of ALF in the West are thought to be due to drugs and toxins, with acetaminophen (paracetamol) being the most common etiologic agent in the United States, Australia, United Kingdom, and most of Europe. In France and Spain, where acetaminophen sales are restricted, the rate of acetaminophen-induced ALF is quite low.³² Acetaminophen-induced ALF is also uncommon in South America. The U.S. Acute Liver Failure Study Group identified several other causes of ALF, including autoimmune hepatitis, hypoperfusion of the liver (in cardiomyopathy or cardiogenic shock), pregnancy-related conditions, and Wilson's disease.³³ Even with exhaustive efforts to identify a cause, approximately 20% of all cases of ALF remain indeterminate in origin.

Clinical Presentation

In a multicenter study involving 17 tertiary care centers and 308 patients in the United States, 73% of all patients with ALF were female, with a median age of 38 years.³⁴ The most common ethnic group affected was whites (74%), followed by Hispanics (9%) and African Americans (3%). Patients were ill for a median of 6 days before the onset of encephalopathy and had a median of 2 days between the onset of jaundice and the development of encephalopathy. Hepatic coma grade at presentation was approximately equally distributed across grades I to IV. Eighty-four percent of the patients in the study were referred from outside hospitals, 40% had a serum creatinine level exceeding 2.0 mg/dL, and 14% had an arterial pH of <7.30. In addition, 44% of the patients acquired a culture-proven infection.

Diagnosis and Clinical Management

When the medical history is obtained, it is important to address the possibility of exposure to viral infections, medications, and other possible toxins. The possibility of previous liver disease needs to be explored. The physical examination must assess and document the patient's mental status as well as attempt to identify findings of chronic liver disease. The initial laboratory

examination must evaluate the severity of the ALF as well as attempt to identify the cause (Table 31-1). A liver biopsy should be performed if certain disease entities such as autoimmune hepatitis or lymphoma are a possibility. Because of the associated coagulopathy, if a liver biopsy is needed, it is usually safest to obtain the tissue via a transjugular approach. Patients with ALF should be admitted to the hospital and monitored frequently. Due to the rapidity with which this disease process may progress, a liver transplant center should be contacted, and the affected patient should be transferred to the center early in the evaluation period.

If acetaminophen overdose is suspected to have occurred within a few hours of presentation, administration of activated charcoal may be useful to reduce the volume of acetaminophen present in the gastrointestinal (GI) tract. *N*-acetylcysteine (NAC), the clinically effective antidote for acetaminophen overdose, should be administered as early as possible to any patient with suspected acetaminophen-associated ALF.³⁵ NAC also should be administered to patients with ALF of unclear etiology because replenishing glutathione may be beneficial in this patient population as well.³⁶ NAC can be administered either orally (140 mg/kg initial dose, followed by 70 mg/kg every 4 hours \times 17 doses) or via the intravenous route (loading dose of 150 mg/kg, followed by a maintenance dose of 50 mg/kg every 4 hours \times 12 doses). For patients who are suspected of having drug-induced hepatotoxicity, it is important to obtain details regarding all prescription and nonprescription drugs, herbs, and dietary supplements that may have been taken in the previous year. Most instances of drug-induced hepatotoxicity occur in the first 6 months after drug initiation. Any suspected offending agent must be discontinued, and an attempt should be made to administer only essential medications.

The majority of patients with ALF need to be monitored in the intensive care unit (ICU) setting, and specific attention needs to be given to fluid management, ulcer prophylaxis, hemodynamic monitoring, electrolyte management, and surveillance for and treatment of infection. Surveillance cultures should be performed to identify bacterial and fungal infections as early as possible. Serum phosphorus levels need to be monitored.

Hypophosphatemia, a sign of hepatic regeneration, may indicate a higher likelihood of spontaneous recovery and needs to be corrected via intravenous (IV) administration of phosphate. Sedation should be avoided, and the head of the bed should be elevated at least 30°. Neurologic examinations should be performed frequently. Intracranial pressure monitoring is reserved for patients in whom a neurologic examination is no longer reliable. CT scans of the head should be performed to rule out mass lesion or hemorrhage, but they provide only limited information regarding increased intracranial pressure. The administration of blood products for thrombocytopenia and prolonged PT is recommended only in the setting of hemorrhage or before invasive procedures. Acute renal failure is a frequent complication in patients with ALF, and efforts should be made to protect renal function by maintaining sufficient perfusion and avoiding nephrotoxic medications. Should renal replacement therapy become necessary, continuous venovenous hemodialysis should be used rather than intermittent hemodialysis because continuous venovenous hemodialysis provides better hemodynamic and intracranial pressure stability. The most severely affected patients have a poor prognosis with medical management alone and require liver transplantation. Identifying these patients early in the clinical course is important both to maximize the time available to obtain a donor liver allograft for those in need and to avoid transplant in those who will recover without it.

Prognosis

Accurate identification of ALF patients who will recover spontaneously is important because of the severe shortage of donor liver allografts and the potential complications of lifelong non-specific immunosuppression. The most widely applied prognostic scoring system is the King's College Hospital ALF criteria.³⁷ This scoring system has separate criteria predicting a poor medical management outcome for acetaminophen-related and non-acetaminophen-related forms of ALF (Table 31-2). Many other prognostic models exist such as the Acute Physiology and Chronic Health Evaluation II (APACHE II) score, the Clichy criteria,³⁸ and actin-free Gc-globulin serum concentration.³⁹ Overall, prognostic scoring systems have proven to have acceptable specificity but low sensitivity in determining patient outcome and therefore should not replace the judgment of an experienced clinician.⁴⁰

Liver Transplantation

Despite advances in medical management, OLT remains the only definitive therapy for patients unable to regenerate sufficient hepatocyte mass in a timely manner. The advent of OLT has coincided with a rise in overall ALF survival rates from approximately 20% in the pretransplantation era to >70% at the present time. One-year posttransplantation survival for patients with ALF has been reported to be as high as 80% to 90%.³¹ Although these improvements in survival rates are impressive, it should be noted that 10% of patients still die while awaiting OLT, which confirms that the potential for improved patient outcome still has not been realized because of the ongoing liver allograft shortage.

Emerging Technologies

As mentioned earlier, patient survival could be improved if additional time could be gained for the patient while awaiting liver replacement or hepatocyte regeneration. The development of a support device to replace the acutely failing liver has been a highly sought after (and elusive) goal. Several systems have

Table 31-2

King's College selection criteria for liver transplantation in acute liver failure

CAUSE	SELECTION CRITERIA
Acetaminophen	Arterial pH <7.30 irrespective of hepatic coma grade <i>Or</i> Prothrombin time >100 s + serum creatinine level >3.4 mg/dL + grade III or IV hepatic coma
Not acetaminophen	Prothrombin time >100 s irrespective of hepatic coma grade <i>Or</i> Any three of the following, irrespective of hepatic coma grade: Cryptogenic or drug-induced hepatitis Jaundice to coma interval >7 d Prothrombin time >50 s Serum bilirubin level >17.5 mg/dL Age <10 y or >40 y

been tested without definitive evidence of efficacy. Transient improvement in hepatic encephalopathy has been observed in several trials, but improvement in hepatocyte function and long-term benefit have not been realized.⁴¹ Liver support trials are difficult to perform due to access to liver replacement, the rarity of affected patients, and the heterogeneous causes and varying levels of disease severity. Therefore, additional data are necessary, and liver support systems should be used only as part of an approved clinical trial. Focus has now shifted toward xenotransplantation,⁴² organ engineering, and cell transplantation.⁴³ In the meantime, living donation and auxiliary liver transplantation can help overcome the organ shortage.⁴⁴

CIRRHOSIS AND PORTAL HYPERTENSION

Cirrhosis, the final sequela of chronic hepatic insult, is characterized by the presence of fibrous septa throughout the liver subdividing the parenchyma into hepatocellular nodules (Fig. 31-13).⁴⁵ Cirrhosis is the consequence of sustained wound healing in response to chronic liver injury. Approximately 40% of cirrhotic patients are asymptomatic, but progressive deterioration leading to the need for liver transplantation or death is typical after the development of end-stage liver disease (ESLD). The complications of ESLD include progressive hyperbilirubinemia, malnutrition, decreased synthetic function of the liver, coagulopathy, portal hypertension (i.e., ascites and variceal bleeding), hepatic encephalopathy, and life-limiting fatigue. ESLD carries a 5-year mortality of 50%, with 70% of deaths due to liver failure.⁴⁶ In the United States, cirrhosis accounts for 30,000 deaths per year and is the most common nonneoplastic cause of death among patients with hepatobiliary and digestive diseases. An additional 10,000 to 12,000 deaths occur annually due to HCC, the most rapidly increasing neoplasm in the United States.⁴⁶

Morphologic Classification of Cirrhosis

Morphologically, cirrhosis can be described as micronodular, macronodular, or mixed. Micronodular cirrhosis is characterized

Figure 31-13. Histology of cirrhotic liver with regenerating macronodules. *Upper panel:* Grossly cirrhotic liver. *Lower panel:* Regenerative nodules and bridging fibrosis representative of cirrhosis seen on standard light microscopy (hematoxylin and eosin stain).

by thick regular septa, small uniform regenerative nodules, and involvement of virtually every hepatic lobule. Macronodular cirrhosis frequently has septa and regenerative nodules of varying sizes. The regenerative nodules consist of irregularly sized hepatocytes with large nuclei and cell plates of varying thickness. Mixed cirrhosis is present when regeneration is occurring in a micronodular liver and over time converts to a macronodular pattern. This morphologic categorization is limited, and cirrhosis is a dynamic process in which nodule size varies over time. The three patterns correlate poorly with etiology, and the same pattern can result from a variety of disease processes. Conversely, a single disease process can demonstrate several morphologic patterns. Irrespective of etiology and morphologic pattern, the cirrhotic liver frequently demonstrates right hepatic lobe atrophy, caudate lobe and left lateral segment hypertrophy, recanalization of the umbilical vein, a nodular surface contour, dilatation of the portal vein, gastroesophageal varices, and splenomegaly on radiographic evaluation.

Etiology of Cirrhosis

Cirrhosis can result from a wide range of disease processes, including viral, autoimmune, drug-induced, alcohol-induced,

Table 31-3

nonalcoholic fatty liver disease, and metabolic diseases (Table 31-3). In the diagnosis of alcoholic liver disease, documentation of chronic alcohol abuse is imperative. Liver biopsy will reveal the typical findings of alcoholic hepatitis, including hepatocyte necrosis, Mallory bodies, neutrophil infiltration, and perivenular inflammation.

Nonalcoholic fatty liver disease (NAFLD) covers a wide spectrum of disorders including simple fatty liver, nonalcoholic steatohepatitis (NASH), fibrosis/cirrhosis and NASH-associated hepatocellular carcinoma.⁴⁷ NAFLD is now the most common chronic liver disease worldwide⁴⁸ and NASH is a progressive form of NAFLD characterized by steatosis with hepatocellular injury and chronic inflammation.⁴⁹ NASH affects 3% to 5% of the population, and approximately 1 in 10 NASH patients will progress to cirrhosis, thereby placing them at risk for the well-described consequences of cirrhosis, including hepatocellular carcinoma.⁵⁰ Although hepatocellular carcinoma arises less frequently in patients with NASH compared to other liver diseases (e.g., hepatitis C viral infection), the overall higher prevalence and more rapidly increasing incidence of NASH relative to other chronic liver diseases mean that the majority of HCC will arise in the setting of NAFLD in the near future.^{51,52}

Patients with nonalcoholic steatohepatitis (NASH) often endorse a history of diabetes mellitus or metabolic syndrome. The diagnosis of NASH requires the demonstration of steatohepatitis on biopsy, the lack of a history of significant alcohol consumption, and exclusion of other causes of hepatic steatosis. Although cryptogenic cirrhosis, or cirrhosis without an apparent cause, accounted for a third of all cases in the past, this proportion has declined over time as it becomes increasingly apparent that many of such patients may actually have unrecognized NASH.

Due to the high prevalence of fatty liver disease, many patients considered for hepatic surgery will have background hepatic steatosis or steatohepatitis. In addition, chemotherapy treatment (e.g., irinotecan) for colorectal cancer liver metastases induces steatosis and steatohepatitis in the nontumor-bearing liver.⁵³ This has important implications as fatty liver disease can increase morbidity after liver resection.^{54,55} Thus, understanding the deleterious effects of steatosis and steatohepatitis

is crucial for the multidisciplinary care of patients undergoing liver surgery.

Chronic hepatitis C infection is the most common cause of chronic liver disease and the most frequent indication for liver transplantation in the United States. The identification of chronic hepatitis C infection is facilitated by serologic assays that detect antibody to hepatitis C and molecular assays that quantify hepatitis C viral RNA. Chronic hepatitis B, on the other hand, can be diagnosed based on the detection of hepatitis B surface antigen (HBsAg) more than 4 to 6 months after initial infection. Additional tests of hepatitis B viral replication, such as the hepatitis B e antigen (HBeAg) and hepatitis B viral DNA, can be used to confirm ongoing infection and to guide appropriate antiviral therapy.

Autoimmune causes of cirrhosis include primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis. Patients with primary biliary cirrhosis may be asymptomatic or may present with a history of fatigue, pruritus, and skin hyperpigmentation that is not related to jaundice. Anti-mitochondrial antibodies will test positive in the vast majority of cases. Affected patients also may have marked elevations in serum cholesterol, while hyperbilirubinemia is seen late in the course of the disease. Primary sclerosing cholangitis is a chronic cholestatic disease of the liver associated with ulcerative colitis and Crohn's disease. The clinical presentation can include pruritus, steatorrhea, fat-soluble vitamin deficiencies, and metabolic bone disease. The diagnosis is often established by imaging of the biliary tree, which reveals a characteristic picture of diffuse, multifocal strictures with focal dilation of the bile ducts resulting in a beaded appearance. Complications are common and can include biliary strictures, cholangitis, cholelithiasis, and cholangiocarcinoma. Autoimmune hepatitis is often accompanied by an elevation in serum globulins, particularly gamma globulins. Liver biopsy will show nonspecific changes such as a portal mononuclear cell infiltrate with the characteristic presence of plasma cells. Many patients with autoimmune hepatitis will respond to treatment with prednisone with or without azathioprine.

Hereditary hemochromatosis is the most common metabolic disorder causing cirrhosis. This entity should be suspected if the patient's clinical presentation includes skin hyperpigmentation, diabetes mellitus, pseudogout, cardiomyopathy, or a family history of cirrhosis. Elevated plasma ferritin and increased iron saturation levels suggest the presence of iron overload, but these findings also can be seen in other diseases of the liver. Confirmatory testing can be achieved by means of genetic testing, liver biopsy, or by assessing the response to phlebotomy. Other uncommon metabolic disorders leading to cirrhosis include Wilson's disease and α_1 -antitrypsin deficiency.

Clinical Manifestations of Cirrhosis

The clinical history associated with cirrhosis can include fatigue, anorexia, weight loss, jaundice, abdominal pain, peripheral edema, ascites, GI bleeding, and hepatic encephalopathy. On physical examination, a number of findings have been described in patients with cirrhosis. Spider angiomas and palmar erythema are believed to be caused by alterations in sex hormone metabolism. Finger clubbing may be a consequence of hypoalbuminemia, while the pathogenesis of white nail beds and Dupuytren's contractures are less well understood. Males may develop features of feminization such as gynecomastia, loss of chest and axillary hair, and testicular atrophy. Splenomegaly is

common, whereas the cirrhotic liver itself may be enlarged, normal sized, or small. Ascites and pleural effusion can be seen with fluid accumulation. Portal hypertension can manifest as caput medusae and/or the presence of the Cruveilhier-Baumgarten murmur, a venous hum that can be auscultated in the epigastrium resulting from collaterals between the portal system and the remnant of the umbilical vein. Jaundice usually does not appear until the bilirubin rises above 2 to 3 mg/dL. Asterixis can be detected in patients with hepatic encephalopathy. Other manifestations include fetor hepaticus, as well as features suggestive of malnutrition such as weakness, weight loss, and temporal muscle wasting.

Although fat stores and muscle mass are reduced, resting energy expenditure is increased. Muscle cramps occur frequently in the cirrhotic patient and are felt to correlate with ascites, low mean arterial pressure, and plasma renin activity. Abdominal hernias are common with ascites and should be electively repaired only in patients with well-compensated cirrhosis; otherwise, the hernia should be repaired at the time of or after hepatic transplantation. HCC can occur in all forms of cirrhosis, and every cirrhotic patient should undergo screening for the development of HCC every 6 months via imaging and measurement of a serum α -fetoprotein (AFP) level. Cirrhosis is associated with increased cardiac output and heart rate as well as decreased systemic vascular resistance and blood pressure. Patients with cirrhosis are more prone to infections due to impaired phagocytic activity of the reticuloendothelial system. Bacterial infections, often of intestinal origin, are common and must be suspected in a patient with unexplained pyrexia or clinical deterioration. Spontaneous bacterial peritonitis also is seen in cases of cirrhosis with ascites. Intrinsic drug metabolism is reduced in the cirrhotic liver, and this fact needs to be recognized when prescribing medications.

Laboratory Findings Associated With Cirrhosis

Laboratory findings vary in the cirrhotic patient depending on the degree of compensation; however, in general, a number of trends are seen. The cirrhotic patient usually has a mild normocytic normochromic anemia. The white blood cell and platelet counts are reduced, and the bone marrow is macronormoblastic. The PT is prolonged and does not respond to vitamin K therapy, and the serum albumin level is depressed. Urobilinogen is present and urinary sodium excretion is diminished in the presence of ascites. The serum levels of bilirubin, transaminases, and alkaline phosphatase may all be elevated. However, normal liver function test results do not eliminate the possibility of cirrhosis.

Liver Biopsy

The diagnosis of cirrhosis can be made in many cases from a constellation of clinical features, laboratory values, and radiographic findings. Histopathologic examination of liver tissue is occasionally needed to confirm the diagnosis of cirrhosis and in determining disease etiology, activity, and progression. Liver biopsy can be performed via a percutaneous, transjugular, or laparoscopic approach. If needed, ultrasound or CT guidance can be helpful in obtaining an adequate sample and avoiding other viscera.

Various serologic markers of hepatic fibrosis are currently being investigated to help predict the presence of cirrhosis without the need for liver biopsy. However, no currently available marker is sufficiently accurate for clinical use. Ultrasound elastography, which measures the stiffness of the liver by inducing

an elastic shear wave that propagates through the tissue, shows promise as a noninvasive test in identifying patients with advanced fibrosis and cirrhosis. (See earlier section, “Radio-logic Evaluation of the Liver.”)

Hepatic Reserve and Assessment of Surgical Risk in the Cirrhotic Patient

Assessing the hepatic reserve of the cirrhotic patient is important because cirrhosis and portal hypertension can have a negative impact on the outcome of nontransplant surgical procedures. Patients with liver disease undergoing surgery are at increased risk for surgical and anesthesia-related complications. The actual risk depends on the type of anesthetic used, the specific surgical procedure performed, and the severity of liver disease. Previous studies have demonstrated that emergency operations, cardiac surgery, hepatic resections, and abdominal surgery, particularly cholecystectomy, gastric resection, and colectomy, generate the highest operative risk among cirrhotic patients. Additionally, preoperative patient characteristics such as anemia, ascites, encephalopathy, malnutrition, hypoalbuminemia, hypoxemia, infection, jaundice, portal hypertension, and prolonged PT have also been associated with inferior outcomes after surgery. Nontransplant surgical procedures are contraindicated in patients with acute fulminant hepatitis and those with severe decompensated chronic hepatitis.

A number of laboratory tests have been used to assess hepatic reserve in patients with cirrhosis. Tests of indocyanine green, sorbitol, and galactose elimination capacity as well as the carbon-13 galactose breath test and carbon-13 aminopyrine breath test have all been disappointing clinically due to their dependence on flow to the liver as well as the unavailability and complexity of the tests. The monoethylglycylxylidide (MEGX) test, which measures MEGX formation after the administration of lidocaine, has been shown to be approximately 80% sensitive and specific in diagnosing cirrhosis. However, this test loses both sensitivity and specificity as the serum bilirubin level rises and interferes with the fluorescent readout system.

Child-Turcotte-Pugh Score

The Child-Turcotte-Pugh (CTP) score was originally developed to evaluate the risk of portocaval shunt procedures performed for portal hypertension and subsequently has been shown to be useful in predicting surgical risks of other intra-abdominal operations on cirrhotic patients (Table 31-4). Numerous studies have demonstrated overall surgical mortality rates of 10% for patients with class A cirrhosis, 30% for those with class B cirrhosis, and 75% to 80% for those with class C cirrhosis.⁵⁶ The CTP score is derived from five variables as shown in Table 31-4. The problems with the CTP score are the presence of subjective variables (encephalopathy and ascites), its narrow range (5 to 15 points), and the equal weighting given to each variable. Multiple retrospective studies have demonstrated that perioperative mortality and morbidity rates correlate well with the CTP score, and for over 30 years, this measure had been used as the principal predictor of operative risk.

Model for End-Stage Liver Disease Scoring System

The Model for End-Stage Liver Disease (MELD) is a linear regression model based on three objective laboratory values (INR, bilirubin level, and creatinine level). It was originally developed as a tool to predict mortality after transjugular

Table 31-4

Child-Turcotte-Pugh (CTP) score

VARIABLE	1 POINT	2 POINTS	3 POINTS
Bilirubin level	<2 mg/dL	2–3 mg/dL	>3 mg/dL
Albumin level	>3.5 g/dL	2.8–3.5 g/dL	<2.8 g/dL
International normalized ratio	<1.7	1.7–2.2	>2.2
Encephalopathy	None	Controlled	Uncontrolled
Ascites	None	Controlled	Uncontrolled

Child-Turcotte-Pugh class

Class A = 5–6 points

Class B = 7–9 points

Class C = 10–15 points

intrahepatic portosystemic shunt (TIPS) but has been validated and used as the sole method of liver transplant allocation in the United States since 2002. The MELD formula is as follows:

$$\text{MELD Score} = 9.57 \text{ Ln(SCR)} + 3.78 \text{ Ln(Tbil)} + 11.2 \text{ Ln(INR)} + 6.43$$

where Ln represents natural logarithm, SCr is serum creatinine level (in milligrams per deciliter), and Tbil is serum bilirubin level (in milligrams per deciliter).

A number of studies have examined the relative values of MELD and CTP scores in predicting postoperative mortality in cirrhotic patients undergoing nontransplant surgical procedures. Northup and colleagues demonstrated that MELD score was the only statistically significant predictor of 30-day mortality.⁵⁷ In this study, mortality increased by approximately 1% for each MELD point up to a score of 20 and by 2% for each MELD point above 20. A comparison of the MELD model with the CTP classification showed good correlation between the two measures in predicting mortality, especially in the setting of emergency surgery.⁵⁸ In these studies, the relative risk of mortality increased by 14% for each 1-point increase in MELD score. As a result, it has been proposed that patients with a MELD score below 10 can safely undergo elective surgery, those with MELD between 10 and 15 may undergo surgery with caution, while those with MELD scores in excess of 15 should not be subjected to elective surgical procedures.⁵⁹

Portal Hypertension

The portal venous system contributes approximately 75% of the blood and 72% of the oxygen supplied to the liver. In the average adult, 1000 to 1500 mL/min of portal venous blood is supplied to the liver. However, this amount can be significantly increased in the cirrhotic patient. The portal venous system is without valves and drains blood from the spleen, pancreas, gallbladder, and abdominal portion of the alimentary tract into the liver. Tributaries of the portal vein communicate with veins draining directly into the systemic circulation. These collateral communications occur at the gastroesophageal junction, anal canal, falciform ligament, splenic venous bed and left renal vein, and retroperitoneum (Fig. 31-14). The normal portal venous pressure is 5 to 10 mmHg, and at this pressure, very little blood is shunted from the portal venous system into the systemic circulation. As portal venous pressure increases, however, the

Figure 31-14. Intra-abdominal venous flow pathways leading to engorged veins (varices) from portal hypertension. 1, Coronary vein; 2, superior hemorrhoidal veins; 3, paraumbilical veins; 4, Retzius' veins; 5, veins of Sappey; A, portal vein; B, splenic vein; C, superior mesenteric vein; D, inferior mesenteric vein; E, inferior vena cava; F, superior vena cava; G, hepatic veins; a, esophageal veins; a', azygos system; b, vasa brevia; c, middle and inferior hemorrhoidal veins; d, intestinal; e, epigastric veins.

collateral communications with the systemic circulation dilate, and a large amount of blood may be shunted around the liver and into the systemic circulation.

Imaging of the Portal Venous System and Measurement of Portal Venous Pressure

The patency of the portal vein and the nature of the collateral circulation should be established. An understanding of portal vein patency and anatomy is crucial before undertaking porto-systemic shunts, hepatic resection, or hepatic transplantation. The simplest initial investigation is abdominal ultrasonography. A large portal vein suggests portal hypertension but is not diagnostic. Doppler ultrasound is capable of outlining the anatomy of the portal vein, excluding the presence of thrombosis, and identifying the direction of portal venous blood flow. Doppler ultrasound also is useful in evaluating blood flow through surgical shunts and TIPS. Abdominal CT and magnetic resonance angiography both are capable of revealing portal vein anatomy as well as patency. Visceral angiography and portal venography

are reserved for cases that cannot be evaluated satisfactorily by noninvasive methods and require further clarification of portal patency or anatomy.

The most accurate method of determining portal hypertension is hepatic venography. The most commonly used procedure involves placing a balloon catheter directly into the hepatic vein and measuring the free hepatic venous pressure (FHVP) with the balloon deflated and the wedged hepatic venous pressure (WHVP) with the balloon inflated to occlude the hepatic vein. The hepatic venous pressure gradient (HVPG) is then calculated by subtracting the free from the wedged venous pressure ($HVPG = WHVP - FHVP$). The HVPG represents the pressure in the hepatic sinusoids and portal vein and is a measure of portal venous pressure. Clinically significant portal hypertension is evident when HVPG exceeds 10 mmHg.

Etiology and Clinical Features of Portal Hypertension

The causes of portal hypertension can be divided into three major groups: presinusoidal, sinusoidal, and postsinusoidal.⁶⁰ Although multiple disease processes can result in portal hypertension (Table 31-5), in the United States, the most common cause of portal hypertension is usually an intrahepatic one, namely, cirrhosis. The most significant clinical finding associated with portal hypertension is the development of gastroesophageal varices, which are mainly supplied by the anterior branch of the left gastric (coronary) vein.

Table 31-5

Etiology of portal hypertension

Presinusoidal

Sinistral/extrahepatic

- Splenic vein thrombosis
- Splenomegaly
- Splenic arteriovenous fistula

Intrahepatic

- Schistosomiasis
- Congenital hepatic fibrosis
- Nodular regenerative hyperplasia
- Idiopathic portal fibrosis
- Myeloproliferative disorder
- Sarcoid
- Graft-versus-host disease

Sinusoidal

Intrahepatic

- Cirrhosis
- Viral infection
- Alcohol abuse
- Primary biliary cirrhosis
- Autoimmune hepatitis
- Primary sclerosing cholangitis
- Metabolic abnormality

Postsinusoidal

Intrahepatic

- Vascular occlusive disease

Posthepatic

- Budd-Chiari syndrome
- Congestive heart failure
- Inferior vena caval web
- Constrictive pericarditis

Portal hypertension also results in splenomegaly with enlarged, tortuous, and even aneurysmal splenic vessels. Splenomegaly is frequently associated with functional hypersplenism, causing leukopenia, thrombocytopenia, and anemia. Ascites occurs in the setting of severe portal hypertension in combination with hepatocyte dysfunction. The umbilical vein may recanalize and dilate, leading to visible collaterals on the abdominal wall. Anorectal varices are present in approximately 45% of cirrhotic patients and must be distinguished from hemorrhoids, which do not communicate with the portal system and are not present at increased incidence in patients with portal hypertension. Large spontaneous venous shunts may form between the portal venous system and the left renal vein or the IVC, but these shunts are ineffective in reducing portal venous pressures and preventing bleeding from gastroesophageal varices.

Management of Gastroesophageal Varices

The most significant manifestation and the leading cause of morbidity and mortality related to portal hypertension is variceal bleeding. Approximately 30% of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis have esophageal varices. One third of all patients with varices will experience variceal bleeding. Each episode of bleeding is associated with a 20% to 30% risk of mortality. If left untreated, 70% of patients who survive the initial bleed will experience recurrent variceal hemorrhage within 2 years of the index hemorrhage.

Prevention of Variceal Bleeding

Current measures aimed at preventing variceal bleeding include the administration of nonselective β -blockers and prophylactic endoscopic surveillance with variceal band ligation. Meta-analyses have demonstrated that nonselective β -blockers such as propranolol and nadolol reduce the index variceal bleed by approximately 45% and decrease bleeding mortality by 50%.⁶¹ However, approximately 20% of patients do not respond to β -blockade, and another 20% cannot tolerate β -blockade due to medication side effects. Endoscopic surveillance with prophylactic variceal band ligation has been associated with a lower incidence of a first variceal bleed.⁶² Variceal band ligation is recommended for patients with medium to large varices, performed every 1 to 2 weeks until obliteration, followed by esophagogastroduodenoscopy (EGD) 1 to 3 months later and surveillance EGD every 6 months to monitor for recurrence of varices.

Management of Acute Variceal Hemorrhage

Patients with acute variceal hemorrhage should be admitted to an ICU for resuscitation and management. Blood resuscitation should be performed carefully to reach a hemoglobin level of approximately 8 g/dL. Overzealous replacement of blood products and administration of saline can lead to both rebleeding and increased mortality. Administration of fresh frozen plasma and platelets can be considered in patients with severe coagulopathy. Use of recombinant factor VIIa has not been shown to be more beneficial than standard therapy and therefore is not recommended at this time. Cirrhotic patients with variceal bleeding have a high risk of developing bacterial infections, which are associated with increased risks of rebleeding and mortality. Spontaneous bacterial peritonitis accounts for approximately half of these infections, with urinary tract infections and pneumonias comprising the remainder. The use of short-term prophylactic antibiotics (e.g., ceftriaxone 1 g/d intravenously) has been shown both to decrease the rate of bacterial infections and to increase survival.

Vasoactive medications decrease blood flow to the gastroesophageal varices and can be initiated as soon as the diagnosis of

variceal bleeding is made. Although vasopressin is the most potent available vasoconstrictor, its use is limited by its systemic vasoconstrictive effects that can produce hypertension, myocardial ischemia, arrhythmias, ischemic abdominal pain, and limb gangrene. Octreotide, a somatostatin analog, has the advantage that it can be administered for 5 days or longer, and it is currently the preferred pharmacologic agent for initial management of acute variceal bleeding. In addition to pharmacologic therapy, endoscopy with variceal band ligation should be carried out as soon as possible. This combination of pharmacologic and endoscopic therapy has been shown both to improve the initial control of bleeding and to increase the 5-day hemostasis rate.⁶²

Luminal Tamponade

When medical and endoscopic measures fail to control variceal hemorrhage, balloon tamponade using a Sengstaken-Blakemore tube will control refractory bleeding in up to 90% of patients. However, its application is limited due to the potential for complications, which include aspiration, airway obstruction, and esophageal perforation due to overinflation or pressure necrosis. Therefore, the use of a Sengstaken-Blakemore tube should not exceed 36 hours to avoid tissue necrosis, and this treatment modality should only be considered a temporary bridge to more definitive measures of variceal hemorrhage control.

Transjugular Intrahepatic Portosystemic Shunt

The TIPS procedure involves implantation of a metallic stent between an intrahepatic branch of the portal vein and a hepatic vein radicle. The needle track is dilated until a portal pressure gradient of ≤ 12 mmHg is achieved. TIPS can be performed in 95% of patients by an experienced interventional radiologist, controls variceal bleeding in $>90\%$ of cases refractory to medical treatment, and should not affect subsequent hepatic transplantation. Possible complications include bleeding either intra-abdominally or via the biliary tree, infections, renal failure, decreased hepatic function, and hepatic encephalopathy, which occur in 25% to 30% of patients after the TIPS procedure. A high rate of thrombosis is seen and can be attributed to intimal hyperplasia of the metallic stent. Frequent follow-up with repeated interventions such as dilation or restenting often are needed to maintain TIPS patency.

Balloon-Occluded Retrograde Transvenous Obliteration

The balloon-occluded retrograde transvenous obliteration (BRTO) procedure has been used for the specific management of bleeding gastric varices in patients with spontaneous gastrorenal or splenorenal shunts shown on contrast-enhanced cross-sectional imaging. Using a transjugular or transfemoral approach, a balloon-occlusion catheter is directed through the left renal vein into the spontaneous shunt, which is then obliterated with the use of a sclerosing agent. BRTO effectively controls hemorrhage from gastric varices and preserves portal flow to the liver, thereby reducing the risk of hepatic encephalopathy relative to TIPS. The occlusion of spontaneous shunts, however, can theoretically exacerbate portal hypertension, precipitate hemorrhage from esophageal varices, and exacerbate the accumulation of ascites.

Surgical Shunting

The need for surgical shunts has been reduced since the introduction of the TIPS procedure and hepatic transplantation. At this time, the recommendation is that surgical shunts be considered only in patients who have MELD scores of <15 , who are

not candidates for hepatic transplantation, or who have limited access to TIPS therapy and the necessary follow-up. The aim of the surgical shunt is to reduce portal venous pressure, maintain total hepatic and portal blood flow, and avoid the high incidence of complicating hepatic encephalopathy. Patient survival is determined by hepatic reserve.

The portacaval shunt, as first described by Eck in 1877, either joins the portal vein to the IVC in an end-to-side fashion and completely disrupts portal vein flow to the liver, or joins it in a side-to-side fashion and thereby maintains partial portal venous flow to the liver. Currently this shunt is rarely performed due to the high incidence of hepatic encephalopathy and decreased liver function resulting from the reduction of portal perfusion. The Eck fistula also makes subsequent hepatic transplantation much more technically difficult.

The mesocaval shunt uses an 8- or 10-mm polytetrafluoroethylene (PTFE) graft to connect the superior mesenteric vein to the IVC. The mesocaval shunt is technically easier to perform and can be easily ligated during subsequent hepatic transplantation. The smaller caliber of the shunt avoids the deleterious effects of portal blood flow deprivation on hepatic function. Small-diameter portosystemic shunts have been reported to reduce the incidence of encephalopathy but at the expense of increased risks of shunt thrombosis and rebleeding.

The surgical shunt currently used most often is the distal splenorenal or Warren shunt (Fig. 31-15). This shunt is technically the most difficult to perform. It requires division of the gastroesophageal collaterals and allows venous drainage of the stomach and lower esophagus through the short gastrosplenic veins into the spleen, and ultimately decompresses the left upper quadrant by allowing the splenic vein to drain directly into the left renal vein via an end-to-side splenic to left renal vein anastomosis. This shunt has the advantages of being associated with a lower rate of hepatic encephalopathy and decompensation and not interfering with subsequent liver transplantation.

Nonshunt Surgical Management of Refractory Variceal Bleeding

In the patient with extrahepatic portal vein thrombosis and refractory variceal bleeding, the Sugiura procedure may be

considered. The Sugiura procedure consists of extensive devascularization of the stomach and distal esophagus along with transection of the esophagus, splenectomy, truncal vagotomy, and pyloroplasty. As with performance of surgical shunts, patient survival is dependent on hepatic reserve at the time of the surgical procedure. Experience in Western countries is somewhat limited, and a number of modifications have been made to the original Sugiura procedure over time.

Hepatic Transplantation

Patients with cirrhosis, portal hypertension, and variceal bleeding usually die as a result of hepatic failure and not acute blood loss. Therefore, hepatic transplantation must be considered in the patient with ESLD because it represents the patient's only chance for definitive therapy and long-term survival. Hepatic transplantation also can be considered for the patient with variceal bleeding refractory to all other forms of management. Survival after hepatic transplantation is not affected adversely by the previous performance of endoscopic variceal band ligation, TIPS, or splenorenal or mesocaval shunts. Previous creation of an Eck fistula, however, does make hepatic transplantation much more technically difficult, and therefore this procedure should be avoided in the transplant candidate. In addition to saving the patient's life, hepatic transplantation reverses most of the hemodynamic and humoral changes associated with cirrhosis.

Budd-Chiari Syndrome

Budd-Chiari syndrome (BCS) is an uncommon congestive hepatopathy characterized by the obstruction of hepatic venous outflow. The incidence of BCS is 1 in 100,000 of the general population worldwide.⁶³ Patients may present with acute signs and symptoms of abdominal pain, ascites, and hepatomegaly or more chronic symptoms related to long-standing portal hypertension. BCS is defined as primary when the obstructive process involves an endoluminal venous thrombosis. BCS is considered as a secondary process when the veins are compressed or invaded by a neighboring lesion originating outside the vein.

A thorough evaluation demonstrates one or more thrombotic risk factors in approximately 75% to 90% of patients with primary BCS.⁶³ Primary myeloproliferative disorders, such as

Figure 31-15. Surgical shunts for portal hypertension. Types of portacaval anastomoses. **A.** Normal anatomy. **B.** Side-to-side portacaval shunt. **C.** End-to-side portacaval shunt. **D.** Mesocaval shunt. **E.** Distal splenorenal (Warren) shunt. (Reproduced with permission from Doherty GM, Way LW: Current Surgical Diagnosis and Treatment, 12th ed. New York, NY: McGraw-Hill Education; 2006.)

essential thrombocythemia or polycythemia rubra, account for approximately 35% to 50% of the primary cases of BCS. All known inherited thrombophilias also have been implicated in the development of BCS. Activated protein C resistance, generally related to factor V Leiden mutation, is present in approximately 25% of patients. Anticardiolipin antibodies, hyperhomocysteinemia, and oral contraceptive use all have been shown to be risk factors for BCS.⁶³

Clinically significant BCS is usually the result of obstruction of two or more of the major hepatic veins. The obstruction results in hepatomegaly, liver congestion, and right upper quadrant pain. In addition, liver perfusion via the portal vein may be decreased, and 70% of affected patients have noninflammatory centrilobular necrosis on biopsy. Although ALF is rare, most patients will go on to develop chronic portal hypertension and ascites. Caudate lobe hypertrophy occurs in approximately 50% of cases and is due to the fact that the caudate lobe has direct venous drainage into the IVC. This caudate lobe hypertrophy, in turn, can result in further obstruction of the IVC.

Abdominal ultrasonography is the initial investigation of choice and can demonstrate the absence of hepatic vein flow, spider web hepatic veins, and collateral hepatic veins.⁶⁴ CT or MRI of the abdomen also is capable of demonstrating hepatic vein thrombosis and evaluating the IVC but is limited in that it cannot show direction of blood flow. The definitive radiographic study to evaluate BCS is hepatic venography to determine the presence and extent of hepatic vein thrombus as well as measure IVC pressures.

Initial treatment consists of diagnosing and medically managing the underlying disease process and preventing extension of the hepatic vein thrombosis through systemic anticoagulation. The BCS-associated portal hypertension and ascites can be medically managed in a manner similar to that in most cirrhotic patients. Radiologic and surgical intervention should be reserved for patients whose condition is nonresponsive to medical therapy. Percutaneous angioplasty and TIPS, in combination with thrombolytic therapy, are the preferred strategies to restore the outflow of blood from the liver. Thrombolytic therapy alone may be attempted for acute thrombosis. Surgical shunting, namely with the side-to-side portacaval shunt, essentially turns the portal vein into a hepatic outflow tract. Most patients with a portacaval shunt show improvement in hepatic function and fibrosis at 1 year without significant hepatic encephalopathy.⁶⁴ However, the enthusiasm for this procedure has been curbed due to the relatively high rate of operative mortality and shunt dysfunction. Patients with progressive BCS and manifestations of ESLD will ultimately require hepatic transplantation.

INFECTIONS OF THE LIVER

The liver contains the largest portion of the reticuloendothelial system in the human body and is therefore able to handle the continuous low-level exposure to enteric bacteria that it receives through the portal venous system. Due to the high level of reticuloendothelial cells in the liver, nonviral infections are unusual.

Pyogenic Liver Abscesses

Pyogenic liver abscesses are the most common liver abscesses seen in the United States. They may be single or multiple and are more frequently found in the right lobe of the liver.⁶⁵ The abscess cavities are variable in size and, when multiple, may coalesce to give a honeycomb appearance. Approximately 40% of abscesses are monomicrobial, an additional 40% are

polymicrobial, and 20% are culture-negative. The most common infecting agents are gram-negative bacteria. *Escherichia coli* is found in two thirds of cases, and other common organisms include *Streptococcus faecalis*, *Klebsiella*, and *Proteus vulgaris*. Anaerobic organisms such as *Bacteroides fragilis* also are seen frequently. In patients with endocarditis and infected indwelling catheters, *Staphylococcus* and *Streptococcus* species are more commonly found.

In the past, pyogenic liver abscesses often resulted from infections of the intestinal tract such as acute appendicitis and diverticulitis, which then spread to the liver via the portal circulation. With improved imaging modalities and earlier diagnosis of these intra-abdominal infections, this particular etiology of pyogenic liver abscesses has become less common. Pyogenic liver abscesses also occur as a result of impaired biliary drainage, subacute bacterial endocarditis, infected indwelling catheters, dental work, or the direct extension of infections such as diverticulitis or Crohn's disease into the liver. There appears to be an increasing incidence due to infection by opportunistic organisms among immunosuppressed patients, including transplant and chemotherapy recipients as well as patients with acquired immunodeficiency syndrome (AIDS).

Patients commonly present with right upper quadrant pain and fever. Jaundice occurs in up to one-third of affected patients. A thorough history and physical examination are usually helpful in identifying the underlying cause of the liver abscess. Leukocytosis, an elevated sedimentation rate, and an elevated AP level are the most common laboratory findings. Significant abnormalities in the results of the remaining liver function tests are unusual. Blood cultures will only reveal the causative organism in approximately 50% of cases. Ultrasound examination of the liver reveals pyogenic abscesses as round or oval hypoechoic lesions with well-defined borders and a variable number of internal echoes. CT scan is highly sensitive in the localization of pyogenic liver abscesses, which appear hypodense with peripheral enhancement and may contain air-fluid levels indicating a gas-producing infectious organism (Fig. 31-16). MRI of the abdomen can also detect pyogenic abscesses with a high level of sensitivity but plays a limited role because of its inability to be used for image-guided diagnosis and therapy.

The current cornerstones of treatment include correction of the underlying cause and IV antibiotic therapy. Empiric antibiotic therapy should cover gram-negative and anaerobic organisms; percutaneous needle aspiration and culture of the aspirate may be useful in guiding subsequent antibiotic therapy. IV antibiotic therapy should be continued for at least 8 weeks and can be expected to be effective in 80% to 90% of patients. Placement of a percutaneous drainage catheter is beneficial only for a minority of patients, as most pyogenic abscesses are quite viscous and catheter drainage is often ineffective.

Surgical drainage either via the laparoscopic or open approach may become necessary if initial therapies fail. Anatomic surgical resection can be performed in patients with recalcitrant abscesses. It must be kept in mind throughout the evaluation and treatment of the presumed pyogenic abscess that a necrotic hepatic malignancy must not be mistaken for a hepatic abscess. Therefore, early diagnosis and progression to surgical resection should be advocated for patients who do not respond to initial antibiotic therapy.

Amebic Abscesses

Entamoeba histolytica is a parasite that is endemic worldwide, infecting approximately 10% of the world's population.

Figure 31-16. Computed tomographic scan of pyogenic liver abscesses. Multiple hepatic abscesses are seen in a patient after an episode of diverticulitis. Note the loculated large central abscess as well as the left lateral segment abscess.

Amebiasis is most common in subtropical climates, especially in areas with poor sanitation. *E histolytica* exists as cysts in a vegetative form that are capable of surviving outside the human body. The cystic form passes through the stomach and small bowel unharmed and then transforms into a trophozoite in the colon. Here it invades the colonic mucosa forming typical flask-shaped ulcers, enters the portal venous system, and is carried to the liver. Occasionally, the trophozoite will pass through the hepatic sinusoid and into the systemic circulation, which results in lung and brain abscesses.

Amebae multiply and block small intrahepatic portal radicles with consequent focal infarction of hepatocytes. They contain a proteolytic enzyme that also destroys liver parenchyma. The abscesses formed are variable in size and can be single or multiple. The amebic abscess is most commonly located in the superior-anterior aspect of the right lobe of the liver near the diaphragm and has a necrotic central portion that contains a thick, reddish brown, pus-like material. This material has been likened to anchovy paste or chocolate sauce. Amebic abscesses are the most common type of liver abscesses worldwide.

Amebiasis should be considered in patients who have traveled to an endemic area and present with right upper quadrant pain, fever, hepatomegaly, and hepatic abscess.⁴⁶ Leukocytosis is common, whereas elevated transaminase levels and jaundice are unusual. The most common biochemical abnormality is a mildly elevated AP level. Even though this disease process is secondary to a colonic infection, the presence of diarrhea is unusual. Most patients have a positive fluorescent antibody test for *E histolytica*, and test results can remain positive for some time after a clinical cure. This serologic test has a high sensitivity, and therefore amebiasis is unlikely if the test results are negative.

Ultrasound and CT scanning of the abdomen are both very sensitive but nonspecific for the detection of amebic abscesses.⁶⁵ Amebic abscesses usually appear on CT as well-defined low-density round lesions that have enhancement of the wall, somewhat ragged in appearance with a peripheral zone of edema. The central cavity may have septations as well as fluid levels. CT scanning is also useful in the detection of extrahepatic involvement.

Metronidazole 750 mg three times a day for 7 to 10 days is the treatment of choice and is successful in 95% of cases. Defervescence usually occurs in 3 to 5 days, but the time necessary for the abscess to resolve depends on the initial size at presentation and varies from 30 to 300 days.⁶⁵ Both ultrasound and CT of the liver can be used as follow-up after the initiation of medical therapy. Aspiration of the abscess rarely is needed and should be reserved for patients with large abscesses, those who do not respond to medical therapy, or those who appear to be superinfected. Furthermore, abscesses of the left lobe of the liver at risk for rupture into the pericardium should be treated with aspiration and drainage.

Hydatid Disease

Hydatid disease is due to infection by the tapeworm *Echinococcus granulosus* in its larval or cyst stage.⁶⁶ The tapeworm lives in canids, which are infected by eating the viscera of sheep that contain hydatid cysts. Scolices, contained in the cysts, adhere to the small intestine of dogs and become adult taenia, which attach to the intestinal wall. Each worm sheds approximately 500 ova into the bowel. The infected ova-containing feces of dogs contaminate grass and farmland, and the ova are ingested by intermediate hosts such as sheep, cattle, pigs, and humans. The ova have chitinous envelopes that are dissolved by gastric juice. The liberated ovum then burrows through the intestinal mucosa and is carried by the portal vein to the liver, where it develops into an adult cyst. Most cysts are caught in the hepatic sinusoids, and therefore 70% of hydatid cysts form in the liver. A few ova pass through the liver and are held up in the pulmonary capillary bed or enter the systemic circulation, forming cysts in the lung, spleen, brain, or bones.

Hydatid disease is most common in sheep-raising areas, where dogs have access to infected offal. These include South Australia, New Zealand, Africa, Greece, Spain, and the Middle East. Hydatid cysts commonly involve the right lobe of the liver, usually the anterior-inferior or posterior-inferior segments. The uncomplicated cyst may be silent and found only incidentally or at autopsy. Occasionally, the affected patient presents with symptoms such as dull right upper quadrant pain or abdominal distention. Cysts may become secondarily infected, involve other organs, or even rupture, which leads to an allergic or anaphylactic reaction.

The diagnosis of hydatid disease is based on the findings of an enzyme-linked immunosorbent assay (ELISA) for echinococcal antigens, and results are positive in approximately 85% of infected patients.⁶⁶ The ELISA results may be negative in an infected patient if the cyst has not leaked or does not contain scolices or if the parasite is no longer viable. Eosinophilia is seen in approximately 30% of infected patients. Ultrasonography and CT scanning of the abdomen are both quite sensitive for detecting hydatid cysts. The appearance of the cysts on images depends on the stage of cyst development. Typically, hydatid cysts are well-defined hypodense lesions with a distinct wall. Ring-like calcifications of the pericysts are present in 20% to 30% of cases. As healing occurs, the entire cyst calcifies densely, and a lesion with this appearance is usually dead or inactive. Daughter cysts generally occur in a peripheral location within the main cyst and are typically slightly hypodense compared with the mother cyst. MRI of the abdomen may be useful to evaluate the pericyst, cyst matrix, and daughter cyst characteristics.

Unless the cysts are small or the patient is not a suitable candidate for surgical resection, the treatment of hydatid disease

is surgically based because of the high risk of secondary infection and rupture. Medical treatment with albendazole relies on drug diffusion through the cyst membrane. The concentration of drug achieved in the cyst is uncertain but is better than that of mebendazole, and albendazole can be used as initial treatment for small, asymptomatic cysts. For most cysts, surgical resection involving laparoscopic or open complete cyst removal with instillation of a scolicial agent is preferred and usually is curative. If complete cystectomy is not possible, then formal anatomic liver resection can be undertaken. During surgical resection, caution must be exercised to avoid rupture of the cyst with release of protoscolices into the peritoneal cavity. Peritoneal contamination can result in an acute anaphylactic reaction or peritoneal implantation of scolices with daughter cyst formation and inevitable recurrence.

Echinococcus multilocularis occurs in the Northern Hemisphere and can infect the liver in a fashion similar to that described earlier, although the cysts are multilocular. Infection of the lung also is common (alveolar echinococcosis). Canine species such as wolves, foxes, and dogs ingest infected viscera of an intermediate host (e.g., rodents, moose) and become infected; humans become infected incidentally by ingesting contaminated food or water. Treatment consists of albendazole; however, infection in the lung produces a more generalized granulomatous reaction, can present in a manner similar to that of a malignancy, and often requires resection.

Ascariasis

Ascaris infection is particularly common in the Far East, India, and South Africa. Ova of the roundworm *Ascaris lumbricoides* arrive in the liver by retrograde locomotion in the bile ducts from the GI tract. The adult worm is 10 to 20 cm long and may lodge in the common bile duct, causing partial bile duct obstruction and secondary cholangitic abscesses. The *Ascaris* may serve as a nidus for the development of intrahepatic gallstones. The clinical presentation in an affected patient may include biliary colic, acute cholecystitis, acute pancreatitis, or hepatic abscesses.⁶⁷ Plain abdominal radiographs, abdominal ultrasound, and ERCP can demonstrate the *Ascaris* as linear filling defects within the bile ducts. Occasionally, worms can be seen moving into and out of the biliary tree from the duodenum. Treatment consists of the administration of piperazine citrate, mebendazole, or albendazole in combination with endoscopic extraction of the worms. Surgical intervention may become necessary if the *Ascaris* cannot be removed via ERCP.

Schistosomiasis

Schistosomiasis affects >200 million people in 74 countries. Hepatic schistosomiasis occurs when emboli of the ova in the intestines reach the liver via the mesenteric venous system. Eggs excreted in the feces hatch in water to release free-swimming embryos, which enter snails and develop into fork-tailed cercariae. They then reenter human skin during contact with infected water. They burrow down to the capillary bed and enter the bloodstream, leading to widespread hematogenous dissemination. Those entering the intrahepatic portal system grow rapidly, resulting in a granulomatous reaction. The degree of consequent portal fibrosis is related to the adult worm load.

Schistosomiasis has three stages of clinical symptomatology: the first includes itching after the entry of cercariae through the skin; the second includes fever, urticaria, and eosinophilia; and the third involves hepatic fibrosis followed by presinusoidal portal hypertension. During this third phase, the liver shrinks,

the spleen enlarges, and the patient may develop complications of portal hypertension while hepatic function is maintained. Active infection is detected by stool examination. Serologic tests indicate past exposure but do not provide information regarding the timing of infection. A negative serologic test result excludes the presence of schistosomal infection. Serum levels of transaminases are usually normal, but the AP level may be mildly elevated. A decreased serum albumin level is usually the result of frequent GI bleeds and malnutrition.

Medical treatment of schistosomiasis includes education on hygiene and the avoidance of infected water. Treatment with praziquantel 40 to 75 mg/kg as a single dose is the treatment of choice for all forms of schistosomiasis and produces few side effects. GI bleeding usually is controlled by endoscopic variceal ligation. However, in a patient with refractory GI portal hypertensive bleeding, distal splenorenal shunt or gastric devascularization and splenectomy may be considered.

Viral Hepatitis

The role of the surgeon in the management of viral hepatitis is somewhat limited. However, the disease entities of hepatitis A, B, and C need to be kept in mind during any evaluation for liver disease. Hepatitis A usually results in an acute self-limited illness and only rarely leads to fulminant hepatic failure. Patients can present with fatigue, malaise, nausea, vomiting, anorexic fever, and right upper quadrant abdominal pain. The most common physical findings are jaundice and hepatomegaly. Because the disease is self-limited, the treatment is usually supportive. Patients who develop fulminant infection require aggressive therapy and should be transferred to a center capable of performing liver transplantation.

Hepatitis B and C, on the other hand, can both lead to chronic liver disease, cirrhosis, and HCC. The prevalence of chronic hepatitis B infection in the U.S. population is estimated to be 0.27%, but hepatitis B remains a major burden in resource-limited countries, accounting for 30% of cirrhosis and 53% of HCC cases. The ultimate goal of treatment for chronic hepatitis B is viral suppression, thereby preventing the development of clinical outcomes such as cirrhosis, liver failure, and HCC. The cornerstone of current antiviral therapy includes pegylated interferon and nucleoside analogs such as tenofovir or entecavir.⁶⁸ These agents have been proven to reduce complications of cirrhosis and HCC and perhaps reverse previous damage to the liver. Interferon therapy produces various side effects including fatigue, flu-like symptoms, mood changes, bone marrow suppression, and stimulation of autoimmunity. On the other hand, the nucleoside analogs are generally well-tolerated by patients. Compared with lamivudine, the nucleoside analogs are less likely to produce resistance and are more likely to be clinically effective. Despite its high rate of viral resistance, lamivudine may be the preferred treatment in some countries because of its relatively low cost.

Acute hepatitis C viral (HCV) infection typically develops 2 to 26 weeks after exposure to the virus, and presenting symptoms can include jaundice, nausea, dark urine, and right upper quadrant abdominal pain. Diagnosis is confirmed by testing for the presence of HCV RNA and anti-HCV antibodies in the serum; viral RNA is first detectable in the serum by polymerase chain reaction (PCR) within days to weeks following the exposure, whereas antibodies will not appear until 2 to 6 months after. If the diagnosis of acute hepatitis is established and the virus is not spontaneously cleared within 12 weeks, patients should generally be treated with pegylated interferon

monotherapy. High rates of sustained viral response, in excess of 80%, have been achieved with the early treatment of acute HCV infection.⁶⁹ Unfortunately, patients with acute HCV infection are typically asymptomatic, and the vast majority of cases go undetected. Untreated, most of these patients will eventually develop chronic infection.

Chronic HCV infection often follows a progressive course over many years and can ultimately result in cirrhosis, HCC, and the need for liver transplantation. Cirrhosis secondary to hepatitis C remains the leading indication for liver transplantation in the United States, Europe, and Japan. The decision to treat a patient with chronic HCV infection is complex and involves consideration of multiple factors including the natural history of the disease, stage of fibrosis, and the efficacy and adverse effects related to the treatment regimen. Patients with genotype 1 are now treated with triple-agent therapy including pegylated interferon, ribavirin, and a protease inhibitor. The protease inhibitors telaprevir and boceprevir were recently approved for the treatment of chronic HCV genotype 1 infection, and their addition to the treatment regimen has been shown to increase the rate of sustained viral response from 40% to 70%. These protease inhibitors do not exhibit significant antiviral activity against

other HCV genotypes, and therefore genotypes 2, 3, and 4 are treated with interferon and ribavirin alone. Genotypes 2 and 3 are generally more responsive to treatment than genotypes 1 and 4, but the therapeutic response also is dependent on other factors such as baseline viral load, ethnicity, and the patient's genetic background and compliance with the regimen.

EVALUATION OF AN INCIDENTAL LIVER MASS

A liver mass often is identified incidentally during a radiologic imaging procedure performed for another indication. For example, a liver mass may be discovered during evaluation for gallbladder disease or kidney stones. In addition, with advances in imaging technology, previously undetected lesions not infrequently are now identified. Although many of these lesions are benign and will require no further treatment, the concern for malignancy requires a thorough evaluation. Thus, an orderly approach should be taken to the workup of an incidental liver lesion to minimize unnecessary testing.⁷⁰

The evaluation of an incidental liver mass begins with a history and physical examination (Fig. 31-17). The patient should be asked about abdominal pain, weight loss, previous

Figure 31-17. Algorithm for diagnostic workup of an incidental liver lesion. The evaluation includes history and physical examination, blood work, imaging studies, and liver biopsy (if needed). AFP = α -fetoprotein; BUN = blood urea nitrogen; CA 19-9 = cancer antigen 19-9; CBC = complete blood count; CEA = carcinoembryonic antigen; creat = creatinine; CT = computed tomography; EGD = esophagogastroduodenoscopy; glu = glucose; Gyn = gynecologic; HTN = hypertension; MRI = magnetic resonance imaging; OCP = oral contraceptive pill; PAP = Papanicolaou; US = ultrasound.

Metastatic neuroendocrine cancer (carcinoid)
Other metastatic cancers

liver disease, cirrhosis, alcohol use, viral hepatitis, blood transfusions, tattoos, oral contraceptive use (in women), and personal or family history of cancer. On physical examination, jaundice, scleral icterus, hepatomegaly, splenomegaly, palpable mass, or stigmata of portal hypertension should be noted. After completion of the history and physical examination, blood work should be performed, including complete blood count; platelet count; measurement of levels of electrolytes, blood urea nitrogen, creatinine, glucose, and albumin; liver function tests; serum ammonia level; coagulation studies; hepatitis screen; and measurement of levels of the tumor markers carcinoembryonic antigen, AFP, and cancer antigen 19-9.

The differential diagnosis for an incidental liver mass includes cysts, benign solid lesions, and primary or metastatic cancers (Table 31-6). Ultrasound or CT is commonly performed to evaluate respiratory or abdominal symptoms, and these imaging studies usually lead to the discovery of an incidental liver lesion. Further radiologic evaluation by dual- or triple-phase CT scan or MRI is often necessary to fully characterize the extent and nature of the lesion. Different types of liver masses have distinct appearances and patterns of contrast enhancement on these studies, facilitating the clinician in the diagnosis and formulation of the treatment plan. The use of liver-specific contrast agents in MRI provides information on hepatocyte function in combination with the structural data obtained during a standard MRI, and yields improved detection and characterization of liver lesions. CT cholangiography or MRCP can be obtained, particularly when visualization of the biliary tract is desired. These modalities may be useful in the depiction of benign or malignant strictures resulting in biliary obstruction. In the evaluation of metastases to the liver from a variety of primary cancers, FDG-PET/CT has emerged as an indispensable tool in disease staging and in the follow-up after treatment. The techniques available for imaging of liver lesions are described in detail earlier in the section “Radiologic Evaluation of the Liver.”

Liver biopsy is indicated when biochemical analysis and diagnostic imaging fail to lead to a definitive diagnosis. Percutaneous liver biopsy with ultrasound or CT guidance is the simplest, fastest, and most commonly performed approach to obtain hepatic tissue for histologic examination. Absolute contraindications to percutaneous liver biopsy include significant coagulopathy (as in patients with decompensated cirrhosis), biliary

dilatation, and suspicion for hemangioma or echinococcal cyst. Obesity and the presence of ascites are relative contraindications that can present a challenge to the percutaneous approach. In these patients, laparoscopic liver biopsy can be considered. The laparoscopic technique is likely to have a higher diagnostic yield in cirrhotic patients with ascites and/or coagulopathy, in whom bleeding risk is excessive by the percutaneous route. Laparoscopy also offers the opportunity to stage the extent of disease in patients with various intra-abdominal malignancies.

HEPATIC CYSTS

Congenital Cysts

The majority of hepatic cysts are asymptomatic. Hepatic cysts are usually identified incidentally and can occur at any time throughout life. The most common benign lesion found in the liver is the congenital or simple cyst. The exact prevalence of simple hepatic cysts in the U.S. population is not known, but the female to male ratio is approximately 4:1, and the prevalence is approximately 2.8% to 3.6%.⁷¹ Simple cysts are the result of excluded hyperplastic bile duct rests. Simple cysts usually are identified in hepatic imaging studies as thin-walled, homogeneous, fluid-filled structures with few to no septations. The cyst epithelium is cuboidal and secretes a clear nonbilious serous fluid. With the exception of large cysts, simple cysts are usually asymptomatic. Large simple cysts may cause abdominal pain, epigastric fullness, and early satiety. Occasionally the affected patient presents with an abdominal mass.

Asymptomatic simple cysts are best managed conservatively. The preferred treatment for symptomatic cysts is ultrasound- or CT-guided percutaneous cyst aspiration followed by sclerotherapy. This approach is approximately 90% effective in controlling symptoms and ablating the cyst cavity. If percutaneous treatment is unavailable or ineffective, treatment may include either laparoscopic or open surgical cyst fenestration. The laparoscopic approach is being used more frequently and is 90% effective. The excised cyst wall is sent for pathologic analysis to exclude the presence of carcinoma, and the remaining cyst wall must be carefully inspected for evidence of neoplastic change. If such change is present, complete resection is required, either by enucleation or formal hepatic resection.

Biliary Cystadenoma

Biliary cystadenomas are slow-growing, unusual, benign lesions that most commonly present as large lesions in the right lobe of the liver. Although these lesions are usually benign, they can undergo malignant transformation. Patients with biliary cystadenomas commonly present with abdominal pain. An abdominal mass occasionally can be identified on physical examination. In contrast to simple cysts, biliary cystadenomas have walls that appear thicker with soft tissue nodules and septations that usually enhance. The protein content of the fluid can be variable and can affect the radiographic images on CT and MRI. Surgical resection is the preferred mode of treatment.

Polycystic Liver Disease

Adult polycystic liver disease (PCLD) occurs as an autosomal dominant disease and usually presents in the third decade of life. Approximately 44% to 76% of affected families are found to have mutations of *PKD1*, and approximately 75% have mutations of *PKD2*.⁷² The prevalence and number of hepatic cysts

are higher in females and increase with advancing age and with increasing severity of renal cystic disease and renal dysfunction. Patients with a small number of cysts or with small cysts (<2 cm) usually remain asymptomatic. In contrast, patients who develop many or large cysts, with a cyst-to-parenchymal volume ratio of >1, usually develop clinical symptoms, including abdominal pain, distension, shortness of breath, and early satiety. Disease progression often results in renal failure and the need for hemodialysis. In most patients, the liver parenchymal volume and synthetic function are preserved despite extensive cystic disease. Hepatic decompensation, variceal hemorrhage, ascites, and encephalopathy develop rarely in patients with PCLD and only in those with massive cystic disease. The most common liver-specific complications associated with PCLD are intracystic hemorrhage, infection, and posttraumatic rupture. The most common abnormal biochemical test finding is a modestly elevated γ -glutamyltransferase level, and the most useful imaging tests are CT or MRI of the abdomen, which will demonstrate the characteristic polycystic appearance. Other conditions that may be associated with PCLD include cerebral aneurysm, diverticulosis, mitral valve prolapse, and inguinal hernia.

The principal aim of treatment for PCLD is to ameliorate symptoms by decreasing liver volume. Medical therapy options for PCLD remain experimental at this time. Somatostatin analogs such as octreotide and lanreotide have been shown to modestly reduce liver volume and are generally well tolerated. Sirolimus and other mammalian target of rapamycin (mTOR) inhibitors possess antiproliferative effects and thus have been postulated to slow disease progression. The effectiveness of these medical measures in relieving symptoms among patients with PCLD, however, remains to be proven.⁷³

Cyst aspiration and sclerotherapy entail puncture of a cyst with an aspiration needle followed by injection of a sclerosing agent that causes destruction of the epithelial lining thereby inhibiting fluid production. Common agents used for sclerosis include ethanol, minocycline, and tetracycline. This technique may be considered if the patient has one or a few dominant cysts, each measuring over 5 cm. Appropriate candidates for sclerotherapy can experience a complete resolution of symptoms, but patients with numerous cysts often do not improve when this technique is used. This procedure is generally well tolerated, with the most common complication being pain from the instillation of ethanol.

Cyst fenestration, or surgical unroofing of the cyst, can be performed via an open or laparoscopic approach in symptomatic patients.⁷⁴ This approach allows multiple cysts to be treated during a single procedure, but carries the risk of potential surgical complications, including ascites, pleural effusion, hemorrhage, and biliary leakage. Immediate symptom relief can be achieved in up to 92% of cases, but 22% of patients eventually develop recurrence of their symptoms.

Hepatic resection can be considered for PCLD patients with massive hepatomegaly, when fenestration alone is unlikely to significantly reduce liver volume. Appropriate candidates are those with portions of liver that harbor numerous cysts, but have at least one spared segment with predominantly normal liver parenchyma. Because the intrahepatic vascular and biliary anatomy can be distorted by the cysts, PCLD patients undergoing hepatic resection are at increased risk for hemorrhagic and biliary complications. Furthermore, adhesion formation after liver resection can increase the technical complexity of future OLT.

Significant symptom relief has been reported in up to 86% of PCLD patients following hepatic resection.

OLT represents the only definitive therapy for patients with symptomatic PCLD. This therapeutic option is indicated in patients with severely disabling symptoms that lead to a poor quality of life or in those who have developed untreatable complications such as portal hypertension and nutritional deprivation. If the patient has severe renal insufficiency from polycystic kidney disease, consideration should be given to combined liver-kidney transplantation. Because of the genetic basis of PCLD, living-donor transplantation should be considered only if the presence of PCLD in the donor can be ruled out.

Caroli's Disease

Caroli's disease is a syndrome of congenital ductal plate malformations of the intrahepatic bile ducts and is characterized by segmental cystic dilatation of the intrahepatic biliary radicals.⁷⁴ Caroli's disease also is associated with an increased incidence of biliary lithiasis, cholangitis, and biliary abscess formation. Caroli's disease usually occurs in the absence of cirrhosis and is associated with cystic renal disease.⁷⁵ The most common presenting symptoms include fever, chills, and abdominal pain. Most patients present by the age of 30 years, and males and females are affected equally. Rarely, patients can present later in life with complications secondary to portal hypertension. Approximately 33% of affected patients develop biliary lithiasis, and 7% develop cholangiocarcinoma. The diagnosis of Caroli's disease is made based on imaging studies. Magnetic resonance cholangiopancreatography, ERCP, and percutaneous transhepatic cholangiography provide more detailed imaging of the biliary tree and confirm communication of the intrahepatic cysts with the biliary tree, which is necessary to solidify the diagnosis. Treatment consists of biliary drainage, with ERCP and percutaneous transhepatic cholangiography serving as first-line therapeutic modalities. If the disease is limited to a single lobe of the liver, hepatic resection can be beneficial. Liver resection can be considered in the patient with hepatic decompensation or unresponsive recurrent cholangitis and possibly in the patient with a small (T1 or T2) cholangiocarcinoma.

BENIGN LIVER LESIONS

The liver is an organ that is commonly involved either primarily or secondarily with vascular, metabolic, infectious, and malignant processes. Many classification schemes are used to help narrow the differential diagnosis of liver lesions: solid or cystic, single or multiple, cell of origin (hepatocellular, cholangiocellular, or mesenchymal), and benign or malignant. Benign liver lesions occur in up to 20% of the general population and are much more common than malignant tumors. The most common **6▶** benign lesions are cysts, hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (see Table 31-6). Many of these lesions have typical features in imaging studies that help confirm the diagnosis.

Cyst

Hepatic cysts are the most frequently encountered liver lesion overall and are described in detail in the section "Hepatic Cysts." Cystic lesions of the liver can arise primarily (congenital) or secondarily from trauma (seroma or biloma), infection (pyogenic or parasitic), or neoplastic disease. Congenital cysts are usually simple cysts containing thin serous fluid and are

reported to occur in 5% to 14% of the population, with higher prevalence in women. In most cases, congenital cysts are differentiated from secondary cysts (infectious or neoplastic origin) in that they have a well-defined thin wall and no solid component and are filled with homogeneous, clear fluid. For benign solid liver lesions, the differential diagnosis includes hemangioma, adenoma, FNH, and bile duct hamartoma.

Hemangioma

Hemangiomas (also referred to as *hemangiomata*) are the most common solid benign masses that occur in the liver. They consist of large endothelial-lined vascular spaces and represent congenital vascular lesions that contain fibrous tissue and small blood vessels that eventually grow. They are predominantly seen in women and occur in 2% to 20% of the population. They can range from small (≤ 1 cm) to giant cavernous hemangiomas (10 to 25 cm). Most hemangiomas are discovered incidentally with little clinical consequence. However, large lesions can cause symptoms as a result of compression of adjacent organs or intermittent thrombosis, which in turn results in further expansion of the lesion. Spontaneous rupture (bleeding) is rare, but surgical resection can be considered if the patient is symptomatic. Resection can be accomplished by enucleation or formal hepatic resection, depending on the location and involvement of intrahepatic vascular structures and hepatic ducts.

The majority of hemangiomas can be diagnosed by liver imaging studies. On biphasic contrast CT scan, large hemangiomas show asymmetrical nodular peripheral enhancement that is isodense with large vessels and exhibit progressive centripetal enhancement fill-in over time (Fig. 31-18). On MRI, hemangiomas are hypointense on T1-weighted images and hyperintense on T2-weighted images.⁷⁶ With gadolinium enhancement, hemangiomas show a pattern of peripheral nodular enhancement similar to that seen on contrast CT scans. Caution should be exercised in ordering a liver biopsy if the suspected diagnosis is hemangioma because of the risk of bleeding from the biopsy site, especially if the lesion is at the edge of the liver.

Adenoma

Hepatic adenomas are benign solid neoplasms of the liver. They are most commonly seen in premenopausal women older than 30 years of age and are typically solitary, although multiple adenomas also can occur. Prior or current use of estrogens (oral contraceptives) is a clear risk factor for development of liver adenomas, although they can occur even in the absence of oral contraceptive use. On gross examination, they appear soft and encapsulated and are tan to light brown. Histologically, adenomas lack bile duct glands and Kupffer cells, have no true lobules, and contain hepatocytes that appear congested or vacuolated due to glycogen deposition. On CT scan, adenomas usually have

Figure 31-18. Computed tomographic scans showing classic appearance of benign liver lesions. Focal nodular hyperplasia (FNH) is hypervascular on arterial phase, isodense to liver on venous phase, and has a central scar (*upper panels*). Adenoma is hypovascular (*lower left panel*). Hemangioma shows asymmetrical peripheral enhancement (*lower right panel*).

sharply defined borders and can be confused with metastatic tumors. With venous phase contrast, they can look hypodense or isodense in comparison with background liver, whereas on arterial phase contrast, subtle hypervascular enhancement often is seen (see Fig. 31-18). On MRI scans, adenomas are hyperintense on T1-weighted images and enhance early after gadolinium injection. With the use of liver-specific MRI contrast agents such as gadoxetate (Eovist or Primovist, Bayer-Schering, Berlin, Germany), hepatic adenomas can be better distinguished from FNH by their enhancement characteristics during the hepatobiliary phase of imaging. The new MRI contrast agent, gadobenate dimeglumine (MultiHance, Bracco Diagnostics, Milan, Italy), is eliminated through both renal and biliary excretion. Therefore, liver lesions that contain hepatocytes with intact biliary excretion mechanism will take up this contrast agent and be easily distinguished from lesions that do not. This contrast agent has improved our ability to differentiate hepatic adenoma from FNH with a high degree of accuracy.

Hepatic adenomas carry a significant risk of spontaneous rupture with intraperitoneal bleeding. The clinical presentation may be abdominal pain, and in 10% to 25% of cases, hepatic adenomas present with spontaneous intraperitoneal hemorrhage. Hepatic adenomas also have a risk of malignant transformation to a well-differentiated HCC. Therefore, it usually is recommended that large hepatic adenomas (>4–5 cm) be surgically resected.

Focal Nodular Hyperplasia

FNH is a solid, benign lesion of the liver believed to be a hyperplastic response to an anomalous artery. Similar to adenomas, they are more common in women of childbearing age, although the link to oral contraceptive use is not as clear as with adenomas. A good-quality biphasic CT scan usually is diagnostic of FNH, on which such lesions appear well circumscribed with a typical central scar (see Fig. 31-18). They show intense homogeneous enhancement on arterial phase contrast images and are often isodense or invisible compared with background liver on the venous phase. On MRI scans, FNH lesions are hypointense on T1-weighted images and isointense to hyperintense on T2-weighted images. After gadolinium administration, lesions are hyperintense but become isointense on delayed images. The fibrous septa extending from the central scar are also more readily seen with MRI. Unlike adenomas, FNH lesions usually do not rupture spontaneously and have no significant risk of malignant transformation. Therefore, the management of FNH is usually reassurance and prospective observation irrespective of size. Surgical resection can be recommended, however, when patients are symptomatic or when hepatic adenoma or HCC cannot be definitively excluded. Oral contraceptive or estrogen use should be stopped when either FNH or adenoma is diagnosed.

Bile Duct Hamartoma

Bile duct hamartomas are typically small liver lesions, 2 to 4 mm in size, visualized on the surface of the liver at laparotomy. They are firm, smooth, and whitish yellow in appearance. They can be difficult to differentiate from small metastatic lesions, and excisional biopsy often is required to establish the diagnosis.

MALIGNANT LIVER TUMORS

Malignant tumors in the liver can be classified as primary (cancers that originate in the liver) or metastatic (cancers that

spread to the liver from an extrahepatic primary site) (see Table 31-6). Primary cancers in the liver that originate from hepatocytes are known as hepatocellular carcinomas (HCCs or hepatomas), whereas cancers arising in the bile ducts are known as cholangiocarcinomas.

In the United States, approximately 150,000 new cases of colorectal cancer are diagnosed each year, and the majority of patients (approximately 60%) will develop hepatic metastases over their lifetime. Hence, the most common tumor seen in the liver is metastatic colorectal cancer. This compares with approximately 30,000 new cases of HCC diagnosed annually in the United States. Interestingly, in a Western series of 1000 consecutive new liver cancer patients seen at a university medical center, 47% had HCC, 17% had colorectal cancer metastases, 11% had cholangiocarcinomas, 7% had neuroendocrine metastases, and 18% had other tumors.⁷⁷ Although these figures do not reflect the incidence or prevalence of these liver cancers, they are indicative of referral patterns in a tertiary academic medical center with a large liver transplantation team and active hepatology clinic.

Hepatocellular Carcinoma

HCC is the fifth most common malignancy worldwide, with an estimated 750,000 new cases diagnosed annually. Because of its high fatality, it is the third most common cause of cancer death worldwide.⁷⁸ Major risk factors are viral hepatitis (B or C), alcoholic cirrhosis, hemochromatosis, and NASH. In Asia, the risk is as high as 35 to 117 per 100,000 persons per year, whereas in the United States, the risk is only 7 per 100,000 persons per year.⁷⁸ Although cirrhosis is not present in all cases, it has been estimated to be present 70% to 90% of the time. In a person with cirrhosis, the annual conversion rate to HCC is 2% to 6%.⁷⁹ In patients with chronic HCV infection, cirrhosis usually is present before the HCC develops; however, in cases of hepatitis B virus infection, HCC tumors can occur before the onset of cirrhosis. HCCs are typically hypervascular with blood supplied predominantly from the hepatic artery. Thus, the lesion often appears hypervascular during the arterial phase of CT studies (Fig. 31-19) and relatively hypodense during the delayed phases due to early washout of the contrast medium by the arterial blood. MRI imaging also is effective in characterizing HCC. HCC is variable on T1-weighted images and usually hyperintense on T2-weighted images. As with contrast CT, HCC enhances in the arterial phase after gadolinium injection because of its hypervascularity and becomes hypointense in the delayed phases due to contrast washout. HCC has a tendency to invade the portal vein, and the presence of an enhancing portal vein thrombus is highly suggestive of HCC.

The treatment of HCC is complex and is best managed by a multidisciplinary liver transplant team. A complete algorithm for the evaluation and management of HCC is shown **7▶** in Fig. 31-20. For patients without cirrhosis who develop HCC, resection is the treatment of choice. For patients with Child's class A cirrhosis with preserved liver function and no portal hypertension, resection also is considered. If resection is not possible because of poor liver function and the HCC meets transplant criteria (discussed later), liver transplantation is the treatment of choice.^{80,81}

The Barcelona-Clinic Liver Cancer Group has refined its HCC management strategy and has developed the American Association for the Study of Liver Diseases Practice Guidelines.⁸² Management guidelines vary slightly in Asia, Europe, the

Figure 31-19. Computed tomographic (CT) images of hepatocellular carcinoma (HCC) and peripheral cholangiocarcinoma. CT scans reveal a large (*upper panel*) and small (*middle panel*) hypervascular HCC. A hypovascular left lobe peripheral cholangiocarcinoma (CholangioCA) is also shown (*lower panel*).

United States, and other countries based in part on availability of organ donors for liver transplantation. Living donor liver transplantation also is an alternative for patients with HCC awaiting transplantation to avoid dropout as a candidate for cadaveric donor liver transplantation due to tumor progression.⁸¹ Specific treatment options are described in the next section.

Cholangiocarcinoma

Cholangiocarcinoma, or bile duct cancer, is the second most common primary malignancy of the liver. Cholangiocarcinoma is an adenocarcinoma of the bile ducts; it forms in the biliary epithelial cells and can be subclassified into peripheral (intrahepatic) bile duct cancer and central (extrahepatic) bile duct

cancer. Extrahepatic bile duct cancer can be located distally or proximally. When proximal, it is referred to as a hilar cholangiocarcinoma (*Klatskin's tumor*). Hilar cholangiocarcinoma originates in the wall of the bile duct at the hepatic duct confluence and usually presents with obstructive jaundice rather than an actual liver mass. In contrast, a peripheral (or intrahepatic) cholangiocarcinoma represents a tumor mass within a hepatic lobe or at the periphery of the liver. A biopsy specimen from the cholangiocarcinoma will show adenocarcinoma, but pathologists are often unable to differentiate metastatic adenocarcinoma to the liver from primary bile duct adenocarcinoma. Therefore, a search for a primary site should be undertaken in cases in which an incidentally discovered liver lesion is proven to be an adenocarcinoma on biopsy.

Hilar cholangiocarcinoma is difficult to diagnose and typically presents as a stricture of the proximal hepatic duct causing painless jaundice. It preferentially grows along the length of the bile ducts, often involving the periductal lymphatics with frequent lymph node metastases. Surgical resection offers the only chance for cure of cholangiocarcinoma.⁸³ The location and extent of tumor dictate the operative approach. In one series of 225 patients with hilar cholangiocarcinoma, 65 (29%) were deemed to have unresectable tumors by initial imaging.⁸⁴ Of the remaining 160 patients who underwent exploratory surgery with curative intent, 80 (50%) were found to have inoperable tumors. Histologically negative margins, concomitant hepatic resection, and well-differentiated tumor histology were associated with improved outcome after resection. In another series of 61 patients undergoing surgical exploration for hilar cholangiocarcinoma, the 5-year actuarial survival rates for an R0 or R1 resection were 45% and 26%, respectively.⁸⁵ In a large series reported by Nagino and colleagues, 132 patients with hilar cholangiocarcinoma underwent extended hepatectomy with resection of the caudate lobe and extrahepatic bile duct, and/or portal vein resection (n = 63) after portal vein embolization.⁸⁶ The 3- and 5-year survival rates were 41.7% and 26.8%, respectively.

In the absence of associated primary sclerosing cholangitis (PSC), surgical resection is the treatment of choice for hilar cholangiocarcinoma. However, approximately 10% of patients with cholangiocarcinoma have PSC.⁸⁷ Furthermore, cholangiocarcinoma in the setting of PSC is frequently multicentric and often is associated with underlying liver disease, with eventual cirrhosis and portal hypertension. As a result, experience has shown that resection of cholangiocarcinoma in patients with PSC yields dismal results. This led transplant centers to consider OLT for patients with hilar cholangiocarcinoma. The initial results of transplantation were disappointing, however, with high recurrence and overall 3-year survival rates of <30%.⁸⁸

Because the growth of hilar cholangiocarcinoma indicates that this disease spreads in a locoregional manner, a rationale for the use of neoadjuvant chemoradiation was developed by the transplant team at the University of Nebraska in the late 1980s. This was adapted in 1993 by the transplant team at the Mayo Clinic, which led to the current Mayo Clinic protocol.⁸⁹ The pretransplant Mayo protocol consists of external-beam radiation therapy plus a protracted course of intravenous 5-fluorouracil followed by iridium-192 brachytherapy.⁹⁰ Patients then undergo an abdominal exploration with staging. If findings are negative, patients are given capecitabine for 2 of every 3 weeks until transplantation. Even after restaging with CT/MRI and endoscopic ultrasonography, approximately 15% to 20% of patients will have positive findings for tumor on abdominal

Figure 31-20. Algorithm for the management of hepatocellular carcinoma (HCC). The treatment algorithm for HCC begins with determining whether the patient is a resection candidate or liver transplant candidate. Bili = bilirubin level (in milligrams per deciliter); Child's = Child-Turcotte-Pugh class; lap = laparoscopic; LDLT = living-donor liver transplantation; LN = lymph node; MELD = Model for End-Stage Liver Disease; OLTx = orthotopic liver transplantation; Perc = percutaneous; RFA = radiofrequency ablation; TACE = transarterial chemoembolization; Tx = transplantation; UNOS = United Network for Organ Sharing; vasc. = vascular.

exploration.^{87,90} The 5-year survival rate for those undergoing transplantation for cholangiocarcinoma at the Mayo Clinic is approximately 70% and compares favorably with the rate for resection.^{87,90} Current eligibility criteria for this Mayo Clinic protocol include unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma with PSC. The tumor must have a radial dimension of ≤ 3 cm with no intrahepatic or extrahepatic metastases, and the patient must not have undergone prior radiation therapy or transperitoneal biopsy.⁹⁰ Many centers have adopted similar protocols with comparable results.⁹¹

Peripheral, or intrahepatic, cholangiocarcinoma is less common than hilar cholangiocarcinoma. In a series of 53 patients at Memorial Sloan-Kettering Cancer Center who underwent surgical exploration for a diagnosis of intrahepatic cholangiocarcinoma, 33 (62%) were found to have resectable tumors.⁹² Actuarial 3-year survival for patients undergoing resection was 55%. Factors predictive of poor survival included vascular invasion, histologically positive margins, and multiple tumors. In a large series in Taiwan, 373 patients with peripheral cholangiocarcinoma underwent surgical treatment from 1977 to 2001. Absence of mucobilia, nonpapillary tumor type, tumor of advanced stage, nonhepatectomy, and lack of postoperative chemotherapy were five independent prognostic factors that adversely affected overall survival.⁹³ Liver transplantation has been performed for peripheral cholangiocarcinoma⁹⁴; however, currently all but one center in the United States have eschewed this approach because of organ shortages and relatively high recurrence rates.

Gallbladder Cancer

Gallbladder cancer is a rare aggressive tumor with a very poor prognosis. Over 90% of patients have associated cholelithiasis. In one study examining the mode of presentation over a 10-year period from 1990 to 2000 in 44 patients diagnosed

with gallbladder cancer, the diagnosis was found to be made preoperatively in 57%, intraoperatively in 11%, and incidentally after cholecystectomy in 32%.⁹⁵ Surgical approaches can be classified into (a) reoperation for an incidental finding of gallbladder cancer after cholecystectomy, and (b) radical resection in patients with advanced disease. The results are dismal for radical resection in patients with advanced disease and positive hilar lymph nodes.^{96,97} For incidental gallbladder cancer beyond stage T1, reoperation with central liver resection, hilar lymphadenectomy, and evaluation of cystic duct stump is most commonly performed.^{98,99} The role of formal lobectomy or extended lobectomy as well as common bile duct resection is more controversial. In a single-center study of 23 patients undergoing attempted curative treatment by surgical resection, survival was 85% at 1 year, 63% at 2 years, and 55% at 3 years.⁹⁹ In a multicenter study encompassing 115 patients with incidentally discovered gallbladder cancer who underwent re-resection,⁹⁸ residual disease in the liver was identified in 46% of patients (0% of those with stage T1 disease, 10% of those with T2 tumors, and 36% of those with T3 disease). T stage also was associated with the risk of metastasis to locoregional lymph nodes (lymph node metastasis for T1 of 13%; for T2, 31%; and for T3, 46%). In another study, a German registry of incidental gallbladder cancer identified 439 patients. Patients with tumors staged as T2 or T3 after cholecystectomy had better survival if they underwent reoperation than if they were managed with observation.¹⁰⁰ Hence, reoperation should be considered for all patients who have T2 or T3 tumors or for whom the accuracy of staging is in question.

Metastatic Colorectal Cancer

Over 50% to 60% of patients diagnosed with colorectal cancer will develop hepatic metastases during their lifetime. Resection for hepatic metastases has been a routine part of treatment for

colorectal cancer since the publication of a large single-center experience demonstrating its safety and efficacy.¹⁰¹ Predictors of poor outcome in that study included node-positive primary, disease-free interval <12 months, more than one tumor, tumor size >5 cm, and carcinoembryonic antigen level >200 ng/mL. Traditional teaching suggested that hepatic resection for metastatic colorectal cancer to the liver, if technically feasible, should be performed only for fewer than four metastases.¹⁰² However, later studies challenged this paradigm. In a series of 235 patients who underwent hepatic resection for metastatic colorectal cancer, the 10-year survival rate of patients with four or more nodules was 29%, nearly comparable to the 32% survival rate of patients with only a solitary tumor metastasis.¹⁰³ In the Memorial Sloan-Kettering Cancer Center series of 98 patients with four or more colorectal hepatic metastases who underwent resection between 1998 and 2002, the 5-year actuarial survival was 33%.¹⁰⁴ Furthermore, improved chemotherapeutic regimens and surgical techniques have produced aggressive strategies for the management of this disease. Many groups now consider volume of future liver remnant and the health of the background liver, and not actual tumor number, as the primary determinants in selection for an operative approach.^{105,106} Hence, resectability is no longer defined by what is actually removed, but indications for hepatic resection now center on what will remain after resection.¹⁰⁷ Use of neoadjuvant chemotherapy, portal vein embolization, two-stage hepatectomy, simultaneous ablation, and resection of extrahepatic tumor in select patients have increased the number of patients eligible for a surgical approach.^{108,109}

Neuroendocrine Tumors

Hepatic metastases from neuroendocrine tumors have a protracted natural history and commonly are associated with debilitating endocrinopathies. Several groups have advocated an aggressive surgical approach of debulking surgery, both to control symptoms and to extend survival.^{110,111} In a series of 170 patients undergoing resection of hepatic metastases from neuroendocrine tumors between 1977 and 1998 at the Mayo Clinic, overall survival was 61% and 35% at 5 and 10 years, respectively.¹¹² There was no difference in survival between patients with carcinoid tumors and those with islet cell tumors. Major hepatectomy was performed in 91 patients (54%), and recurrence rate was 84% at 5 years. Belghiti's group has described a two-stage strategy used in 41 patients with a primary neuroendocrine tumor and synchronous bilobar liver metastases.¹¹³ In the first stage, the primary tumor is resected and limited resection of metastases in the left hemiliver, combined with right portal vein ligation, is performed. After 8 weeks of hypertrophy, a right hepatectomy or extended right hepatectomy (also referred to as a right trisectionectomy; resection of Couinaud's segments IV, V, VI, VII, and VIII of the liver) is performed.¹¹³ In patients treated using this strategy, the 2-, 5-, and 8-year Kaplan-Meier overall survival rates were 94%, 94%, and 79%, respectively, and disease-free survival rates were 85%, 50%, and 26%, respectively. Because systemic therapy has had little success in the treatment of advanced tumors, a broader approach using multimodal therapy has been used to increase survival and improve hormone-related symptoms. These therapies include radiofrequency or microwave ablation and intra-arterial therapy with chemoembolization or radioembolization (yttrium-90). Some centers perform liver transplantation for selected patients (carcinoid histology; primary tumor removed with curative resection;

primary tumor drained by portal system; ≤50% hepatic parenchyma involved; good response or stable disease for at least 6 months during pretransplantation period; and age 55 years or younger), although this is not routine.¹¹⁴

Other Metastatic Tumors

Nearly every cancer has the propensity to metastasize to the liver. Historically, enthusiasm was low for resecting metastases other than those from a colorectal cancer primary. This was due in part to the recognition that many other primary cancers (such as breast cancer) represent a systemic disease when liver metastases are present. However, more recent studies have shown acceptable 5-year survival rates in the 20% to 40% range for resection of hepatic metastases from breast, renal, and other GI tumors.^{115,116} In a large study of hepatic resection for noncolorectal, nonendocrine liver metastases in 1452 patients, negative prognostic factors were nonbreast origin, age >60 years, disease-free interval of <12 months, need for major hepatectomy, performance of R2 resection, and presence of extrahepatic metastases.¹¹⁵

TREATMENT OPTIONS FOR LIVER CANCER

In general, the major treatment options for liver cancer can be categorized as shown in Table 31-7. The decision making for any given patient is complex and is best managed by a multidisciplinary liver tumor board. The treatments listed in Table 31-7 are not mutually exclusive; the important point is to select the most appropriate initial treatment after a complete evaluation. In general, surveillance imaging (CT or MRI) is performed every 3 to 4 months during the first year after diagnosis to observe for response, progression, or recurrence. The treatment plan is individualized and modified according to the response of the patient.

Hepatic Resection

For primary liver cancers or hepatic metastases, hepatic resection is the gold standard and treatment of choice. Although there are anecdotal reports of long-term survival after ablation and other regional liver therapies, liver resection remains the only real option for cure. For HCC in the setting of cirrhosis, liver transplantation also offers the potential for long-term survival, albeit with the consequences of immunosuppression. Hepatic resection

External-beam radiation therapy
• Stereotactic radiosurgery (CyberKnife, Trilogy, Synergy)
• Intensity-modulated radiation therapy
Systemic chemotherapy
Multimodality approach

also has been advocated for HCC in select patients with cirrhosis before secondary liver transplantation, although not without some controversy.¹¹⁷ Many large series of patients undergoing major hepatectomy now report mortality rates of <5%.¹¹⁸⁻¹²¹ Previously, a 1-cm tumor margin was considered desirable; however, recent studies have reported comparable survival rates with smaller margins.¹²²⁻¹²⁴ Technical innovation in liver surgery and a better understanding of perioperative care have even allowed surgeons to perform resections in cases with IVC involvement with extracorporeal liver surgery.¹²⁵ The technical aspects of anatomic hepatic lobectomies are described later.

Liver Transplantation

The rationale supporting OLT for HCC includes the fact that most HCCs (>80%) arise in the setting of cirrhosis.^{88,126} The cirrhotic liver often does not have enough reserve to tolerate a formal resection. Also, HCC tumors are commonly multifocal and are underestimated by current CT or MRI imaging.¹²⁷ Furthermore, recurrence rates are high at 5 years after resection (>50%). Hence, OLT is an appealing treatment because it removes both the cancer and the cirrhotic liver that leads to cancer. More than 7000 liver transplantations are performed each year in the United States, with 1-year survival rates approaching 90%. In May 2017, approximately 14,463 patients were on the waiting list for liver transplantation.¹²⁸

Initial series of OLT for HCC reported in the 1990s included advanced cases of HCC, and the 5-year survival rates were only 20% to 50%.⁸⁸ This compared poorly with overall 5-year survival rates of 70% to 75% for OLT in the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database. Mazzaferro and colleagues at Milan subsequently showed that survival rates were markedly improved when OLT was limited to patients with early-stage HCC (stage I or stage II) with one tumor \leq 5 cm, or up to three tumors no larger than 3 cm, along with the absence of gross vascular invasion or extrahepatic spread.¹²⁹ Multiple studies have validated these findings, and many groups have proposed an expansion of the Milan criteria.⁸¹

As noted previously, the 6- to 40-point MELD score was adopted by OPTN/UNOS in 2002 for allocation of deceased donor liver organs in the United States. In an attempt to prioritize patients with preserved liver function and progressive HCC, patients with stage II HCC are allocated exception points (currently 28 MELD points which activates 6 months after liver transplant listing, increasing every 3 months and capping at 34 points as long as they continue to meet transplant criteria). This allocation has had a positive effect for HCC liver transplant candidates, leading to decreased waiting list dropout and increased transplant rates with excellent long-term outcomes.¹³⁰ The goal is to better equate death rates on the liver transplant waiting list for patients with stage I or stage II HCC with rates for patients with chronic liver disease without HCC. Although indications for liver transplantation have increased, the supply of donor livers has failed to keep pace with the numbers of potential recipients. A partial solution has been the use of living donor grafts. This is especially true in Asia where the incidence of HCC is high and the rate of cadaveric donation is low. Living donor grafts include right and left lobes, as well as dual grafts from separate donors to provide adequate hepatic mass to the recipient. The use of living donor grafts also allows for transplant programs to push the boundaries by accepting patients beyond the Milan criteria with good results.¹¹²

Radiofrequency Ablation

In 1891, d'Arsonval discovered that radiofrequency (RF) waves delivered as an alternating electric current (>10 kHz) could pass through living tissue without causing pain or neuromuscular excitation. The resistance of the tissue to the rapidly alternating current produced heat. This discovery contributed to the development of the surgical application of electrocautery. In 1908, Beer used RF coagulation to destroy urinary bladder tumors. Cushing and Bovie later applied RF ablation to intracranial tumors. In 1961, Lounsberry studied the histologic changes of the liver after RF ablation (RFA) in animal models. He found that RF caused local tissue destruction with uniform necrosis. In the early 1990s, two groups proposed that RFA can be an effective method for destroying unresectable malignant liver tumors.^{132,133} Both groups found that RFA produced lesions with well-demarcated areas of necrosis without viable tumor cells present. Clinical reports after short-term follow-up suggested that RFA was safe and effective in the treatment of liver tumors.¹³⁴⁻¹³⁶ However, Abdalla and colleagues examined data for 358 consecutive patients with colorectal liver metastases treated with curative intent over a 10-year period (1992 to 2002).¹³⁷ Liver-only recurrence after RFA was four times the rate after resection (44% vs. 11% of patients), and RFA alone or in combination with resection did not provide survival rates comparable to those with resection alone. Nonetheless, RFA remains a common procedure that can be performed by a percutaneous, minimally invasive laparoscopic, or open approach.^{138,139} It also has been used successfully to ablate small HCCs as a bridge to liver transplantation.¹⁴⁰ Results were reported for the first randomized clinical trial involving RFA treatment for HCC in 291 Chinese patients with three or fewer HCC tumors ranging in size from 3 to 7.5 cm.¹⁴¹ Patients were randomly assigned to treatment arms of RFA alone (n = 100), transarterial chemoembolization (TACE) alone (n = 95), or combined TACE plus RFA (n = 96). At a median follow-up of 28.5 months, median survival was 22 months in the RFA group, 24 months in the TACE group, and 37 months in the TACE plus RFA group. Patients treated with TACE plus RFA had significantly better overall survival than those treated with TACE alone ($P < .001$) or RFA alone ($P < .001$). Sucandy and colleagues examined long-term 5- and 10-year overall survival in 320 patients that had hepatic RFA for HCC or colorectal cancer liver metastases (CLM).¹⁴² The majority of patients (71%) had a single tumor ablation. Minimum 5-year follow-up was available in 89% patients, with a median follow-up of 115.3 months. In the HCC group, the 5- and 10-year overall survivals were 38.5% and 23.4%, respectively, while in the CLM group, the 5- and 10-year overall survivals were 27.6% and 15%, respectively.

Ethanol Ablation, Cryosurgery, and Microwave Ablation

Percutaneous ethanol injection has been shown to be a safe and effective treatment for small HCCs.¹³⁶ The ethanol usually is delivered by percutaneous injection under ultrasound or CT guidance. Percutaneous ethanol injection also is used to treat small HCC tumors as a bridge to liver transplantation in some centers to avoid patient dropout.⁸⁰ Although cryosurgery was used in the late 1980s and 1990s for ablation of liver tumors, many have abandoned this approach in favor of RFA because of the latter's fewer side effects and ease of use. Microwave ablation is a thermal ablative technique used in the management of unresectable liver tumors to produce a coagulation necrosis.

In a multicenter phase 2 U.S. trial using a 915-MHz microwave generator, 87 patients underwent 94 ablation procedures for 224 hepatic tumors.¹⁴³ Forty-five percent of the procedures were performed using an open approach, 7% laparoscopically, and 48% percutaneously. The average tumor size was 3.6 cm (range, 0.5 to 9.0 cm). At a mean follow-up of 19 months, 47% of the patients were alive with no evidence of disease. Local recurrence at the ablation site occurred in 2.7% of tumors, and regional recurrence occurred in 43% of patients. There were no procedure-related deaths. Further studies are required to define the role of this technology in relation to the other ablation options available.

Chemoembolization and Hepatic Artery Pump Chemoperfusion

Chemoembolization is the process of injecting chemotherapeutic drugs combined with embolization particles into the hepatic artery that supplies the liver tumor using a percutaneous, transfemoral approach. It is most commonly used for treatment of unresectable HCC. Three randomized trials and a meta-analysis have shown a survival benefit with chemoembolization.¹⁴⁴⁻¹⁴⁷ In a study by Lo and colleagues, 80 Asian patients were randomly assigned to receive either chemoembolization with cisplatin in lipiodol or symptomatic treatment only.¹⁴⁴ Chemoembolization resulted in a marked tumor response, and the actuarial survival was significantly better in the chemoembolization group (1- and 3-year survival of 57% and 26%, respectively) than in the control group (1- and 3-year survival of 32% and 3%, respectively). In another randomized trial, a Barcelona group compared chemoembolization with doxorubicin versus supportive care and showed that chemoembolization significantly improved survival.¹⁴⁵ Finally, in a large prospective cohort study of 8510 patients with unresectable HCC in Japan who received transcatheter arterial lipiodol chemoembolization, the 5-year survival rate was 26% and median survival time was 34 months.¹⁴⁶ The TACE-related mortality rate after the initial therapy was 0.5%. Complications of TACE include liver dysfunction or liver failure, hepatic abscess, and hepatic artery thrombosis. Multiple studies also have shown promising results for chemoembolization with drug-eluting beads in treatment of HCC.¹⁴⁸

In the 1990s, hepatic artery pump chemoperfusion with floxuridine for colorectal cancer metastases to the liver was used both for treatment of inoperable disease and in the adjuvant setting.¹⁴⁹ However, in the modern era of improved chemotherapeutic options, this treatment modality is seldom used outside of a clinical trial.

Yttrium-90 Microspheres

Selective internal radioembolization or transarterial radioembolization (TARE) is a promising new treatment modality for patients with inoperable primary or metastatic liver tumors. The treatment is a minimally invasive transcatheter therapy in which radioactive microspheres are infused into the hepatic arteries via a transfemoral percutaneous approach. The yttrium-90 microspheres are directly injected into the hepatic artery branches that supply the tumor. Once infused, the microspheres deliver doses of high-energy, low-penetration radiation selectively to the tumor. The main indications are inoperable HCC¹⁵⁰ and colorectal cancer hepatic metastases for which systemic chemotherapy has failed.^{151,152} In a study involving 137 patients with unresectable chemorefractory liver metastases treated with radioembolization, there was a response rate of 42.8% (2.1% complete

response, 40.7% partial response) according to World Health Organization criteria.¹⁵² One-year survival rate was 47.8%, and 2-year survival rate was 30.9%. Median survival was 457 days for patients with colorectal tumor metastases, 776 days for those with neuroendocrine tumor metastases, and 207 days for those with noncolorectal, nonneuroendocrine tumor metastases. The two products available in the United States are SIR-Spheres (Sirtex, Sydney, Australia) and TheraSphere (Nordian, Ottawa, Canada).

Stereotactic Radiosurgery and Intensity-Modulated Radiation Therapy

Although stereotactic radiosurgery (with CyberKnife and other systems) is in widespread use for brain and spinal tumors, body application to HCC or metastatic liver tumors has only recently occurred. In a phase 1 study, 31 patients with unresectable HCCs and 10 with unresectable cholangiocarcinomas completed a six-fraction course of stereotactic body radiotherapy.¹⁵³ The treatment was well tolerated, and median survival was 11.7 and 15.0 months for the two groups, respectively. A similar safety profile was observed in a study in the Netherlands.¹⁵⁴ Further clinical trials are required to define the future role of stereotactic radiosurgery in treatment of HCC and metastatic tumors. Intensity-modulated radiation therapy (IMRT) is another technologic advancement that facilitates the targeted delivery of external-beam radiation. Early clinical data suggested favorable outcomes with IMRT for the treatment of patients with unresectable HCC, and ongoing trials are further examining the role of IMRT for these locally advanced tumors.

Downstaging

In more advanced-stage patients not eligible for MELD exception points, hepatic-directed therapy including TACE and tumor ablation with radiofrequency, microwave, and ethanol ablation have been found to be effective in shrinking tumors to meet Milan criteria (downstaging). Multiple centers have used downstaging to allow for OLT in patients whose tumors responded and shrank to meet eligibility criteria.^{155,156}

Systemic Chemotherapy

Chemotherapy has not demonstrated great efficacy in patients with HCC, especially in patients with significant cirrhosis. For treatment of HCC, the multikinase inhibitor sorafenib has shown some efficacy in a phase 3 randomized international multicenter trial. The SHARP trial (Sorafenib HCC Assessment Randomized Protocol) enrolled 602 patients with Child's class A cirrhosis and inoperable HCC. At interim analysis, the trial was discontinued because a survival benefit was found in the treatment group. The median overall survival for patients receiving sorafenib was 10.7 months versus 7.9 months for patients in the control arm. Based on these findings, sorafenib received accelerated Food and Drug Administration approval for the treatment of advanced unresectable HCC.¹⁵⁷ Future studies will likely examine the role of other molecularly targeted agents and combinations of sorafenib with other treatment modalities.

HEPATIC RESECTION SURGICAL TECHNIQUES

Nomenclature

Due to the confusion in language with regard to anatomic descriptions of hepatic resections, a common nomenclature was introduced at the International Hepato-Pancreato-Biliary Association

Table 31-8

Brisbane 2000 liver terminology

OLDER HEPATIC RESECTION TERMINOLOGY	BRISBANE 2000 HEPATIC RESECTION TERMINOLOGY
Right hepatic lobectomy	Right hepatectomy or right hemihepatectomy (V, VI, VII, VIII)
Left hepatic lobectomy	Left hepatectomy or left hemihepatectomy (II, III, IV)
Right hepatic trisegmentectomy	Right trisectionectomy or extended right hepatectomy (or hemihepatectomy, IV, V, VI, VII, VIII)
Left hepatic trisegmentectomy	Left trisectionectomy or extended left hepatectomy (or hemihepatectomy, II, III, IV, V, VIII)
Left lateral segmentectomy	Left lateral sectionectomy or bisegmentectomy (II, III)
Right posterior lobectomy	Right posterior sectionectomy (VI, VII)
Caudate lobectomy	Caudate lobectomy or segmentectomy (I)
	ALTERNATIVE "SECTOR" TERMINOLOGY
	Right anterior sectorectomy
	Right posterior sectorectomy or right lateral sectorectomy
	Left medial sectorectomy or left paramedian sectorectomy (bisegmentectomy, III, IV)
	Left lateral sectorectomy (segmentectomy, II)

meeting in Brisbane, Australia, in 2000 (Table 31-8).^{158,159} The goal was to provide universal terminology for liver anatomy and hepatic resections because there was much overlap among the designations for hepatic lobes, sections, sectors, and segments used by surgeons worldwide (Fig. 31-21). The most common or prevailing anatomic pattern was used as the basis for naming liver anatomy, and the surgical procedure nomenclature adopted for hepatic resections was based on the assigned anatomic terminology.¹⁶⁰ Adoption of a common language should enable hepatic surgeons to better understand and interpret liver surgery publications from different continents and disseminate their knowledge to the next generation of hepatobiliary surgeons. Nonetheless, even today, the literature is full of both old and new liver resection terminology, so the surgeon in training must be familiar with all the various classifications.

Techniques and Devices for Dividing the Hepatic Parenchyma

Hepatic resection surgery has evolved over the past 50 years. A better understanding of liver anatomy and physiology, coupled with improved anesthesia techniques and widespread use of intraoperative ultrasound, has led to virtually "bloodless" liver surgery in the modern era (the year 2000 to the present). Innovations in technology have expanded the list of liver parenchymal transection devices¹⁶¹⁻¹⁶³ and hemostatic agents (Table 31-9). Use of each device or agent has a learning curve, and undoubtedly every experienced hepatic surgeon has his or her personal preferences.

One major trend has been the application of vascular stapling devices for division of the hepatic and portal veins.¹⁶⁴⁻¹⁶⁶ Based on early reports of successful stapling of extrahepatic

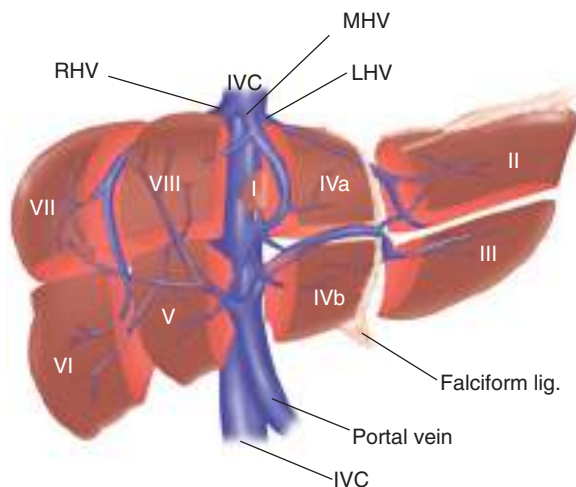

Figure 31-21. Hepatic anatomy. Hepatic segments removed in the formal major hepatic resections are indicated. IVC = inferior vena cava; LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

Table 31-9

InLine bipolar linear coagulator
Topical agents (fibrin glues, Surgicel, Gelfoam, Avitene, Tisseel, Floseal, Crosseal)

vessels, stapling devices are now being used in the parenchymal transection phase, which remains a source of potential blood loss due to back bleeding from the middle hepatic vein.^{167,168} One advantage of the stapling technique is the speed with which the transection can be performed, which minimizes surface bleeding and period of ischemia for the remnant liver. However, a major disadvantage of the stapling technique is the cost of multiple stapler cartridges. This is balanced by the decreased expenses reported with avoidance of ICU admission and blood transfusion, as well as shortened operating room time. Another consideration in the use of staplers for parenchymal transection is the potential for bile leaks. However, in a large series of 101 consecutive right hemihepatectomies performed using the stapling technique, there was only one reported bile leak (1%), which sealed after ERCP.¹⁶⁸

Steps in Commonly Performed Hepatic Resections

A fundamental understanding of hepatic anatomy is vital for any surgeon with the desire to perform hepatobiliary surgery. Each hepatic resection surgery can be broken down into a series of orderly steps. The key to being a proficient hepatic surgeon is not to operate swiftly but rather to accomplish the operation by completing the steps in an orchestrated fashion. Mastery of the operative steps coupled with knowledge of liver anatomy and the common anatomic variants provides the foundation for safe hepatic surgery. There are many different techniques and sequences for accomplishing each of the anatomic (and nonanatomic) hepatic operations. The authors present their preferred approach in a stepwise fashion for right hepatic lobectomy (right hemihepatectomy), left hepatic lobectomy (left hemihepatectomy), and left lateral segmentectomy (left lateral sectionectomy). Provision of a detailed approach for every type of liver resection is beyond the scope of this chapter, and readers are referred to several excellent descriptions.¹⁶⁹

Steps Common to All Open Major Hepatic Resections

1. Make the skin incision—right subcostal with or without a partial or complete left subcostal extension across the midline, depending on the patient's habitus and liver/tumor anatomy.
2. Open and explore the abdomen, and place a fixed table retractor (e.g., Thompson or Bookwalter).
3. Examine the liver with bimanual palpation. Perform liver ultrasound, and confirm the operation to be performed.
4. Take down the round and falciform ligaments, and expose the anterior surface of the hepatic veins.
5. For a left hepatectomy, divide the left triangular ligament; for a right hepatectomy, mobilize the right lobe from the right coronary and triangular ligaments.
6. Open the gastrohepatic ligament, palpate the porta hepatis, and assess for accessory or replaced hepatic arteries.
7. Perform a cholecystectomy; leave the gallbladder with the cystic duct intact if the gallbladder is involved by the tumor.

Right Hepatic Lobectomy (Right Hepatectomy or Hemihepatectomy)

8. Mobilize the liver from the anterior aspect of the IVC in "piggyback" fashion; ligate the short hepatic veins up to the right hepatic vein (RHV).
9. Perform a right hilar dissection—gently lower the hilar plate, then doubly ligate and divide the right hepatic artery (RHA), superior to the right side of the common bile duct.

10. Doubly ligate and divide a replaced or accessory RHA if present.
11. Expose the portal vein, identifying its right and left branches. There is a small lateral portal vein branch off the right portal vein (RPV) to the caudate lobe that should be controlled and ligated to allow the exposure of additional length on the RPV. Divide the RPV either with a vascular stapler or between vascular clamps.
12. Dissect the avascular tissue along the suprahepatic vena cava between the right and middle hepatic veins. Pass a silastic tube of a Jackson-Pratt drain through this gap.
13. Notch or divide the caudate process crossing to the right hepatic lobe, and bring the drain up and through this notch.
14. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
15. Repeat ultrasound and confirm the transection plane, staying just to the right of the middle hepatic vein (MHV) unless the tumor extends over it.
16. Cauterize approximately 1 cm into the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
17. Continue parenchymal division until the RHV is encountered. During this division, identification, control, ligation, and transection of the right hepatic duct (RHD) are obtained late in the parenchymal transection process.
18. Divide the RHV between vascular clamps and suture ligate the RHV.
19. Examine the transected liver edge for bleeding; place a figure-of-eight ligating vascular suture if bleeding is encountered.
20. Ensure hemostasis of the transected liver edge with an argon beam coagulator and suture ligation.
21. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Applying a dilute solution of hydrogen peroxide can facilitate the visualization of bile leaks.
22. Inspect the IVC and right retroperitoneal space for hemostasis.
23. Perform completion ultrasound to confirm left portal vein (LPV) inflow and outflow in the remaining hepatic veins.
24. Fix the proximal falciform ligament back to the diaphragm side with figure-of-eight sutures.
25. Apply tissue sealant to the cut surface of the liver, and place a Jackson-Pratt drain in the right subphrenic space and close the abdomen (Fig. 31-22).

Comments Although some liver surgeons advocate a one-step division of the entire intrahepatic Glissonian pedicle as described by Launois and Jamieson,¹⁷⁰ it is the authors' preference to divide the RHA, RHD, and RPV in an extrahepatic fashion. As for the transection plane, the key is to perform accurate ultrasound visualization and mapping of the MHV and to stay just to the right of it. Weaving in and out or bisecting the MHV can lead to torrential back bleeding. Also, for bulky right lobe tumors adherent to the diaphragm or retroperitoneum, an anterior approach with division of the parenchyma can be performed before right lobe mobilization.^{152,153}

Left Hepatic Lobectomy (Left Hepatectomy or Hemihepatectomy)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory left hepatic artery (LHA) if present.

Figure 31-22. Completed right hepatic lobectomy (right hepatectomy) with the right portal vein, right hepatic artery, and right bile duct ligated and divided. The right hepatic vein is ligated and divided. Middle hepatic vein branches inside the liver are divided.

10. Clamp the round ligament (ligament teres) and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Dissect the left hilum at the base of the umbilical fissure and lower the hilar plate anterior to the left portal pedicle.
13. Incise the peritoneum overlying the hilum from the left side, and doubly ligate the LHA (after test clamping and confirming a palpable pulse in the RHA).
14. Dissect the portal vein at the base of the umbilical fissure (it will take a nearly 90° bend from the transverse to the umbilical portion).
15. Expose the portal vein, identifying the right and left branches. Control the small portal vein branch off the LPV to the caudate lobe to allow the exposure of additional length. Divide the LPV either with a vascular stapler or between vascular clamps.
16. Ligate and divide the ligamentum venosum caudally.
17. Identify the long extrahepatic course of the left hepatic duct (LHD) behind the portal vein. Ligate and divide the LHD at the umbilical fissure.
18. Fold the left lateral segment up and back to the right, exposing the window at the base of the left hepatic vein (LHV) as it enters the IVC. This is facilitated by dividing any loose areolar tissue overlying the ligamentum venosum, which is divided proximally.
19. Pass a large, blunt right-angle clamp in the window between the RHV and the MHV, and hug the back of the MHV, aiming for the deep edge of the LHV. *Do not force it or perforate the IVC or MHV.*
20. Pass the silastic tube of a Jackson-Pratt drain through this window.
21. Notch or divide the caudate process crossing to the left hepatic lobe and bring the drain up and through this notch.

22. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
23. Repeat ultrasound and confirm the transection plane on the anterior surface, staying close to the demarcated line. Do not bisect the MHV as it passes tangentially from the left to the right lobe.
24. Cauterize down approximately 1 cm in the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
25. Continue parenchymal division until the left/middle hepatic veins are encountered.
26. Divide the LHV and MHV between vascular clamps and suture ligate the LHV/MHV.
27. Check the transected edge of the liver for surgical bleeding; ensure hemostasis of the transected edge with an argon beam coagulator and suture ligation.
28. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Apply dilute solution of hydrogen peroxide to facilitate the visualization of bile leaks.
29. Perform completion ultrasound to confirm RPV inflow and RHV outflow.
30. Apply tissue sealant to the transected surface of the liver. Place a Jackson-Pratt drain in the left subphrenic space and close the abdomen (Fig. 31-23).

Comments Because the right posterior duct arises from the left hepatic duct (LHD) in approximately 20% of cases (see Fig. 31-9) and the right anterior duct comes off the LHD in approximately 5% of cases,⁶ it is vital to divide the LHD at the base of the umbilical fissure and not more centrally in the hilum as it bifurcates. If the LHD were divided as it appears to bifurcate from the right hepatic duct, then approximately 20% to

Figure 31-23. Completed left hepatic lobectomy (left hepatectomy) resecting segments II, III, and IV.

25% of the time, either the right posterior or right anterior duct would be transected. After the LHD is divided as described earlier (Step 17), the liver parenchyma is scored and divided horizontally approximately 1 cm above the left hilum; the surgeon thus assumes that an aberrant right anterior or posterior duct is coming off the LHD in the hilum and preserves it. Then as the parenchymal transection reaches the left side of the gallbladder fossa, the transection plane turns vertical to run parallel to Cantlie's line (or the left edge of the gallbladder bed). The left lobe of the liver will be well demarcated at this point (after the vascular inflow has been divided), which guides the transection plane on the anterior surface. In general, the transection plane should be close to the demarcation line to minimize the amount of devascularized liver remaining. When dividing the LHV and MHV, the surgeon should keep in mind that they have a common trunk approximately 90% of the time. If it is not easy to open the window deep to the MHV and LHV, then division of the MHV and LHV can be accomplished after the parenchymal transection.

Left Lateral Segmentectomy (Left Lateral Sectionectomy)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory LHA if present.
10. Clamp the round ligament and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Carry the dissection down from the end of the round ligament, and the segment III pedicle will be encountered.
13. Incise the peritoneal reflection on the left side of the round ligament as it inserts into the umbilical fissure. This will facilitate encircling the segment III and II pedicles, which can be divided separately. When encircling the segment II pedicle, take care to avoid injury to the caudate inflow vessels coming off the LPV.
14. Divide the liver parenchyma, staying flush on the left side of the falciform ligament using Bovie electrocautery.
15. Divide the LHV as the parenchymal transection is complete.
16. A Pringle maneuver usually is not required for a left lateral sectionectomy because complete devascularization occurs before transection and little back bleeding is encountered.

Comments If the segment III and II LHA branches are large, they can be individually ligated in the left hilum before the pedicles (with portal vein and hepatic duct branches) are taken. If the tumor is more peripheral in the left lateral segment, then the segment III and II pedicles can be divided with a vascular stapler inside the liver during the parenchymal transection.

Pringle and Ischemic Preconditioning

Pringle described clamping of the portal triad a century ago in the landmark paper "Notes on the Arrest of Hepatic Hemorrhage Due to Trauma."¹⁷⁴ Although the Pringle maneuver was initially described for controlling bleeding due to traumatic liver injury, it is commonly used during elective hepatic resections.^{173,174} The goal is to minimize blood loss and hypotension, which add significant morbidity to the operation. Furthermore, intraoperative blood transfusion has been shown to be an independent risk factor for increased postoperative infection as well as worse patient survival in some studies. Therefore, all efforts should be made to minimize blood loss during hepatic resection.

Although the liver has been shown to tolerate up to 1 hour of warm ischemia, some technical variations of the Pringle maneuver include intermittent vascular occlusion with cycles of approximately 15 minutes on and 5 minutes off. Experimental and clinical studies have demonstrated the efficacy of intermittent vascular occlusion in decreasing ischemia/reperfusion injury compared with continuous vascular occlusion, with less elevation of postoperative liver enzyme levels.¹⁷⁵ Another variation is selective hemihepatic vascular occlusion, which can reduce the severity of visceral congestion and total liver ischemia. In one prospective trial of total versus selective portal triad clamping, both techniques of inflow clamping were found to be equally effective for patients with normal livers, but greater liver damage was observed with total inflow occlusion in patients with cirrhotic livers.¹⁷⁶

In an attempt to decrease the ischemic damage associated with inflow occlusion, some hepatic surgeons have advocated the use of ischemic preconditioning.¹⁷⁷ *Ischemic preconditioning* refers to the brief interruption of blood flow to an organ, followed by a short reperfusion period, and then a more prolonged period of ischemia. In a randomized clinical trial involving 100 patients undergoing major hepatic resection, Clavien and colleagues reported significantly less liver injury in the group who received ischemic preconditioning with a 10-minute clamp, a 10-minute reperfusion, and then a 30-minute clamp than in those who received a 30-minute clamp alone.¹⁷⁸ Patients with steatosis also were especially protected by ischemic preconditioning, and the mechanism was shown to be related in part to preservation of the adenosine triphosphate content of liver tissue.

Preoperative Portal Vein Embolization

The observation that tumor thrombosis of a major portal vein branch induced ipsilateral lobar atrophy and contralateral lobe hypertrophy led to the concept of intentional preoperative portal vein embolization (PVE) to induce compensatory hypertrophy of the remnant liver. This procedure was first described in the 1980s and is accomplished via a percutaneous, transhepatic route.^{160,161} Numerous studies have subsequently confirmed that PVE is effective in inducing hypertrophy of nonembolized hepatic segments.^{86,181} PVE usually is performed in the setting of a planned right trisectionectomy or extended left hepatectomy (also referred to as a left trisectionectomy; resection of Couinaud's segments II, III, IV, V, and VIII of the liver) or extended hepatic lobectomy when it is thought that the patient's remnant liver will be too small to support liver function. The future liver remnant volume (e.g., the volume of segments II, III, and I) in a patient undergoing a planned right trisectionectomy can be directly measured by helical CT and then divided by the total estimated liver volume to calculate the percentage of the future liver remnant. If the future liver remnant is thought to be too small, then PVE should be considered to increase the size of the future liver remnant.¹⁸² In general, surgery is planned approximately 4 weeks after PVE to allow adequate time for hypertrophy.

There is no universal agreement on what constitutes a future liver remnant adequate to avoid postoperative liver failure. It is thought that 25% to 30% of the total liver volume is adequate in patients with a normal liver.¹⁸³ Vauthey and associates reported that major postoperative complications were increased when the estimated future liver remnant was <25%.¹⁸⁴ Farges and colleagues conducted a prospective study to assess the benefits of PVE before right hepatectomy. They demonstrated

that PVE had no beneficial effect on the postoperative course in patients with normal livers but significantly reduced postoperative complications in patients with chronic liver diseases.¹⁸⁵ A larger remnant may be necessary even in patients with normal livers when a complex hepatectomy is planned or when the background liver is steatotic.¹⁸⁶ This is especially relevant with the increased incidence of fatty liver disease. A larger remnant may also be needed when patients have received preoperative chemotherapy. Some have suggested that 40% of the total hepatic volume should remain to minimize postoperative complications in patients who have underlying liver disease or who have received preoperative chemotherapy for colorectal cancer metastases.^{187,188} In a recent study encompassing 112 patients who underwent PVE, major complications, hepatic insufficiency, length of hospital stay, and 90-day mortality rate were significantly greater in patients with a standardized future liver remnant of $\leq 20\%$ or a degree of hypertrophy of $< 5\%$ than in patients with higher values.¹⁸⁹ In another study, the authors performed PVE during neoadjuvant chemotherapy for colorectal cancer metastases. After a median wait of 30 days after PVE, patients receiving neoadjuvant chemotherapy showed median liver growth of 22% in the contralateral (nonembolized) lobe compared with 26% for those not receiving chemotherapy (not a statistically significant difference), which indicated that liver growth occurs after PVE even when cytotoxic chemotherapy is administered.¹⁹⁰ PVE-related complications occur at a relatively low rate and include bleeding, hemobilia, liver abscess, incomplete embolization, and small bowel obstruction. To augment the ability to increase liver function reserve in patients who have undergone PVE, some groups have added ipsilateral hepatic artery embolization and ipsilateral hepatic vein embolization.¹⁹¹

Staged Hepatectomy, ALPPS, and Repeat Hepatic Resection for Recurrent Liver Cancer

A two-stage hepatectomy is a sequential resection strategy to remove all metastatic liver tumors when it is impossible to resect all disease in a single operative procedure. The first-stage hepatectomy usually consists of clearance of the left hemiliver by nonanatomic resection, followed by right portal vein ligation or embolization to induce left lobe hypertrophy.^{192,193} This is followed by a second-stage major right hepatectomy or extended right hepatectomy to resect the right liver metastases. This approach is most commonly used in cases of initially unresectable colorectal hepatic metastases and has yielded very good results.¹⁹³

Another technique to increase future liver remnant to avoid post-hepatectomy liver failure is known as “Associating Liver Partition and Portal Vein Ligation for Staged Hepatectomy (ALPPS)” and was described in 2012. This technique consists of operative portal vein ligation with *in situ* liver transection along the future line of resection leaving the arterial and hepatic vein branches intact.¹⁹⁴ There have been several technical modifications to the original description, and this remains a hot topic that is actively debated (ALPPS vs. PVE) at the current liver surgery meetings.

The majority of patients undergoing hepatic resection for colorectal cancer metastases experience a recurrence. For those with limited disease recurrence confined to the liver, repeat hepatectomy is a reasonable option and can be performed with low morbidity and mortality in experienced hands.¹⁹⁵ In one study, 126 patients who underwent a second liver resection for colorectal cancer metastases had 1-, 3-, and 5-year survival rates

of 86%, 51%, and 34%, respectively. By multivariate analysis, the presence of more than one lesion and a tumor size of > 5 cm were independent prognostic indicators of reduced survival.¹⁹⁶ In another study, 40 patients underwent a second hepatectomy for liver metastases from colorectal cancer and experienced a survival benefit similar to that from the first hepatectomy; however, the results suggested that this approach should be limited to those patients who do not have extrahepatic disease and for whom > 1 year has elapsed since the first operation.¹⁹⁷ A meta-analysis of 21 studies examining clinical outcomes after first and second liver resections for colorectal cancer metastases showed that repeat hepatectomy was safe and provided a survival benefit equal to that from the first liver resection.¹⁹⁸

Repeat hepatectomy also has been performed in patients with HCC. Nakajima and colleagues reported on follow-up of 94 patients who underwent curative liver resection for HCC from 1991 to 1996.¹⁹⁹ Of these, 57 patients had isolated recurrent disease in the liver. Twelve of these 57 patients underwent repeat hepatic resection, whereas the other 45 patients received ablation therapy. The overall survival rate in those undergoing a second hepatectomy was 90% at 2 years; however, the disease-free survival rate was only 31% at 2 years, significantly lower than the 62% rate after initial hepatectomy. Likewise, in another group of 84 patients who underwent second hepatectomy for recurrent HCC, the overall 5-year survival rate was 50%, but the recurrence-free survival rate was only 10%.²⁰⁰ In a report of 67 patients undergoing a second resection for HCC, overall 1-, 3-, and 5-year survival rates were 93%, 70%, and 56%, respectively.²⁰¹ Multivariate analysis showed that absence of portal invasion at the second resection, single HCC at primary hepatectomy, and disease-free interval of ≥ 1 year after primary hepatectomy were independent prognostic factors after the second resection.

LAPAROSCOPIC LIVER RESECTION

Cherqui and colleagues first reported in 2000 that laparoscopic hepatic surgery was feasible.²⁰² Since this initial report, laparoscopic liver surgery has expanded from the simple unroofing of hepatic cysts to resection of peripheral benign lesions to formal anatomic lobectomies for malignancy and laparoscopic hepatectomy for living donor liver transplantation. While minimally invasive approaches have been widely adopted in other areas of abdominal surgery, there was initial apprehension regarding laparoscopic liver resection (LLR), hampering its widespread adoption.²⁰³ Great strides have been made in the past decade with techniques of laparoscopic liver resection,^{204,205} and two International Laparoscopic Liver Resection Consensus Conferences have been convened in Louisville (2008) and Morioko (2014).^{206,207} Indications for liver resection should not be altered by the availability of minimally invasive liver resection techniques. Currently, over 9500 cases of laparoscopic liver resection have been reported worldwide, with over 50% of the cases being done for malignancy.²⁰⁸

Pure laparoscopic and hand-assisted laparoscopic liver resection are the two most commonly used techniques for minimally invasive liver resection surgery,^{209,210} while robotic liver resection is being used by several groups.²¹¹ Advantages of the hand-port include tactile feedback, facilitation of liver mobilization, and ease of ability to control bleeding. Also, when doing a large parenchymal resection, the hand-port can be comparable in size to the extraction port utilized in the purely laparoscopic

approach. The hand-assisted approach can be ideal for surgeons beginning the transition to laparoscopic liver resection and for more experienced laparoscopic HPB surgeons doing laparoscopic major hepatectomies or as an alternative to conversion to open surgery.

Benefits of laparoscopic liver resection include less blood loss, decreased morbidity, decreased postoperative pain and narcotic requirements, faster return of bowel function, and shorter length of hospital stay compared to open hepatic resection.²¹² Long-term oncologic outcomes for HCC and CLM have been shown to be comparable for laparoscopic vs. open liver resection using propensity score matching and meta-analysis studies.²¹³⁻²¹⁵ The learning curve for laparoscopic liver resection has been reported to be around 60 cases,²¹⁶ although this may be greater for laparoscopic major hepatectomy.²¹⁷⁻²¹⁹ Cost analysis has shown that laparoscopic liver resection is cost effective compared to open liver resection, where the added cost of the operating room disposables are more than offset by the savings associated with ~50% reduction in the hospital length of stay.^{221,222}

Initial experience with laparoscopic living-donor hepatectomy for transplantation was with left lateral segmentectomy during liver allograft procurement for pediatric transplants.²²² With continued advances in laparoscopic liver surgery, LLR has been applied to adult-to-adult donor right hepatectomy,^{223,224} although this approach remains controversial.

In summary, laparoscopic liver resection can now be performed safely by experienced surgeons in selected patients. Compared to open hepatic resection, the laparoscopic approach has benefits of less blood loss, reduced postoperative pain, and a shorter length of hospital stay, with similar oncologic outcomes for resection of HCC and limited colorectal liver metastases.

ANATOMY

Gallbladder

The gallbladder is a pear-shaped sac that measures around 7 to 10 cm long, with an average capacity of 30 to 50 mL. When obstructed, the gallbladder can distend markedly and contain up to 300 mL of fluid. The gallbladder is located in an anatomic fossa on the inferior surface of the liver. Cantle's line, a vertical plane running from the gallbladder fossa anteriorly to the inferior vena cava (IVC) posteriorly divides the liver into right and left lobes. The gallbladder itself is divided into four anatomic areas: the fundus, the body, the infundibulum, and the neck. The fundus is the rounded, blind end that normally extends 1 to 2 cm beyond the liver's margin and contains most of the smooth muscle of the organ. The body functions as the main storage area and contains most of the elastic tissue allowing for distention. As the body tapers towards the neck of the gallbladder, a mucosal outpouching is present at the junction of the neck and the cystic duct, known as the infundibulum or Hartmann's pouch. Beyond this, the neck of the gallbladder lies in the deepest part of the gallbladder fossa and can extend slightly into the free portion of the hepatoduodenal ligament, where it connects with the cystic duct (Fig. 32-1).¹

The same peritoneal lining that covers the liver extends to cover the fundus and the inferior surface of the gallbladder. Occasionally, part or all of the gallbladder is embedded deep inside the liver parenchyma (an intrahepatic gallbladder).

Rarely, the gallbladder has a complete peritoneal covering on all sides and is suspended in a mesentery off the inferior surface of the liver.

The mucosal lining of the gallbladder is formed by a single, highly redundant, simple columnar epithelium that contains cholesterol and fat globules. The mucus secreted into the gallbladder originates in tubuloalveolar glands that are found in the mucosal lining of the infundibulum and neck of the gallbladder, but are absent from the body and fundus. The epithelial lining of the gallbladder is supported by a lamina propria. The gallbladder differs histologically from the rest of the gastrointestinal (GI) tract in that it lacks a muscularis mucosa and submucosa. The muscular layer has circular, longitudinal, and oblique fibers, but without well-defined layers. The adventitia contains connective tissue, nerves, vessels, lymphatics, and adipocytes. The gallbladder is covered by serosa except where the gallbladder is embedded in the liver.

The cystic artery that supplies the gallbladder is usually a branch of the right hepatic artery (>90% of the time). The course of the cystic artery may vary, but it nearly always is found within the hepatocystic triangle (triangle of Calot), the area bound by the cystic duct, common hepatic duct, and the inferior edge of the liver. When the cystic artery reaches the neck of the gallbladder, it divides into anterior and posterior divisions. Venous return is carried either through small veins that enter directly into the liver or, rarely, to a large cystic vein that carries blood back to the portal vein. Gallbladder lymphatics drain into nodes

Key Points

- 1▶ The physiology of the gallbladder, biliary tree, and sphincter of Oddi are regulated by a complex interplay of hormones and neuronal inputs designed to coordinate bile release with food consumption. Dysfunctions related to this activity are linked to the development of gallbladder pathologies as described in this chapter.
- 2▶ In Western countries, the most common type of gallstones are cholesterol stones. The pathogenesis of these stones relates to supersaturation of bile with cholesterol and subsequent precipitation.
- 3▶ Laparoscopic cholecystectomy has been demonstrated to be safe and effective, and it has become the treatment of choice for symptomatic gallstones. Knowledge of the various anatomic anomalies of the cystic duct and artery is critical in guiding the dissection of these structures and avoiding injury to the common bile duct during cholecystectomy.
- 4▶ Common bile duct injuries, although uncommon, can be devastating to patients. Proper exposure of the hepatocystic (Calot's) triangle to obtain the critical view of safety and careful identification of the anatomic structures are keys to avoiding these injuries. Once a bile duct injury is diagnosed, the best outcomes are seen at large referral centers with experienced biliary surgeons, and patient transfer may be required.
- 5▶ The main risk factor for gallbladder disease in Western countries is cholelithiasis. The main complications include cholecystitis, choledocholithiasis, cholangitis, and biliary pancreatitis. Cholelithiasis is also the major risk factor for the development of gallbladder cancer.
- 6▶ Carcinomas of the gallbladder or bile ducts generally have a poor prognosis because patients usually present late in the disease process and have poor response to chemotherapy and radiation. Surgery offers the best chance for survival and has good long-term outcomes in patients with early-stage disease.

at the neck of the gallbladder. Frequently, a visible lymph node (Lund's or Mascagni's node, often referred to as Calot's node) overlies the insertion of the cystic artery into the gallbladder wall. The gallbladder receives parasympathetic, sympathetic

and sensory innervation through nerve fibers running largely through the gastrohepatic ligament. Parasympathetic (cholinergic) fibers arise from the hepatic branches of the vagus nerve to stimulate activity in the gallbladder, bile ducts, and liver. These vagal branches also have peptide-containing nerves containing agents such as substance P, somatostatin, enkephalins, and vasoactive intestinal polypeptide (VIP).² The sympathetic and sensory branches of the gallbladder, liver, and bile ducts pass through the celiac plexus and control gallbladder relaxation and mediate the pain of biliary colic.

Figure 32-1. Anterior aspect of the biliary anatomy. a = right hepatic duct; b = left hepatic duct; c = common hepatic duct; d = portal vein; e = proper hepatic artery; f = gastroduodenal artery; g = right gastroepiploic artery; h = common bile duct; i = fundus of the gallbladder; j = body of gallbladder; k = infundibulum of the gallbladder; l = cystic duct; m = cystic artery; n = superior pancreaticoduodenal artery; o = neck of the gallbladder; p = pancreatic duct; q = common hepatic artery; r = right gastric artery; s = ampulla of Vater; t = supraduodenal artery. Note the situation of the hepatic bile duct confluence anterior to the right branch of the portal vein, and the posterior course of the right hepatic artery behind the common hepatic duct.

Bile Ducts

The extrahepatic biliary tree consists of the right and left hepatic ducts, the common hepatic duct, the cystic duct, and the common bile duct. Exiting the liver, the left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join close to their emergence from the liver to form the common hepatic duct. The common hepatic duct typically extends 1 to 4 cm, has a diameter of approximately 4 mm, and lies anterior to the portal vein and to the right of the hepatic artery.

The cystic duct exits the gallbladder and joins the common hepatic duct at an acute angle to form the common bile duct. The segment of the cystic duct immediately adjacent to the gallbladder neck bears a variable number of mucosal folds called the *spiral valves of Heister*. While they do not have any valvular function, they can make cannulation of the cystic duct difficult. The length and course of the cystic duct can be quite variable. It may be short or absent and have a high union with the hepatic duct, or it may be long and running parallel to, behind, or spiraling around to the common hepatic duct before joining it, sometimes as far distally as at the duodenum. Variations of the cystic duct and its point of union with the common hepatic duct are surgically important and misidentification can lead to bile duct injuries (Fig. 32-2).

The union of the cystic duct and the common hepatic duct marks the start of the common bile duct. This segment is typically about 7 to 11 cm in length and 5 to 10 mm in diameter,

Figure 32-2. Variations of the cystic duct anatomy. **A.** Low junction between the cystic duct and common hepatic duct. **B.** Cystic duct adherent to the common hepatic duct. **C.** High junction between the cystic and the common hepatic duct. **D.** Cystic duct drains into right hepatic duct. **E.** Long cystic duct that joins common hepatic duct behind the duodenum. **F.** Absence of cystic duct. **G.** Cystic duct crosses posterior to common hepatic duct and joins it anteriorly. **H.** Cystic duct courses anterior to common hepatic duct and joins it posteriorly.

though its diameter can increase slightly with age and following cholecystectomy. The upper third (supraduodenal portion) passes downward in the free edge of the hepatoduodenal ligament, to the right of the hepatic artery and anterior to the portal vein. The middle third (retroduodenal portion) of the common bile duct curves behind the first portion of the duodenum and diverges laterally from the portal vein and the hepatic arteries. The lower third (pancreatic portion) can curve behind the head of the pancreas in a groove, or traverse through it to enter the wall of the second portion of the duodenum. The duct then runs obliquely downward within the wall of the duodenum for 1 to 2 cm before opening on a papilla of mucous membrane (ampulla of Vater), about 10 cm distal to the pylorus.

The union of the common bile duct and the main pancreatic duct follows one of three configurations. In about 70% of people, these ducts unite outside the duodenal wall and traverse the duodenal wall as a single duct. In about 20%, they join within the duodenal wall and have a short or no common duct, but open through the same opening into the duodenum. In about 10%, they exit via separate openings into the duodenum, termed pancreas divisum. The sphincter of Oddi, a thick coat of circular smooth muscle, surrounds the common bile duct at the ampulla of Vater (Fig. 32-3). It controls the flow of bile, and in some cases pancreatic juice, into the duodenum.

The extrahepatic bile ducts are lined by a columnar mucosa with numerous mucous glands that are concentrated in the common bile duct. A fibroareolar tissue containing scant smooth muscle cells surrounds the mucosa. A distinct muscle layer is not present in the human common bile duct. The arterial supply to the bile ducts is derived from the gastroduodenal and the right hepatic arteries, with major trunks running along the medial and

lateral walls of the common duct (sometimes referred to as 3 o'clock and 9 o'clock). The nerve supply to the common bile duct is the same as for the gallbladder, with the density of nerve fibers and ganglia increasing near the sphincter of Oddi.^{1,2}

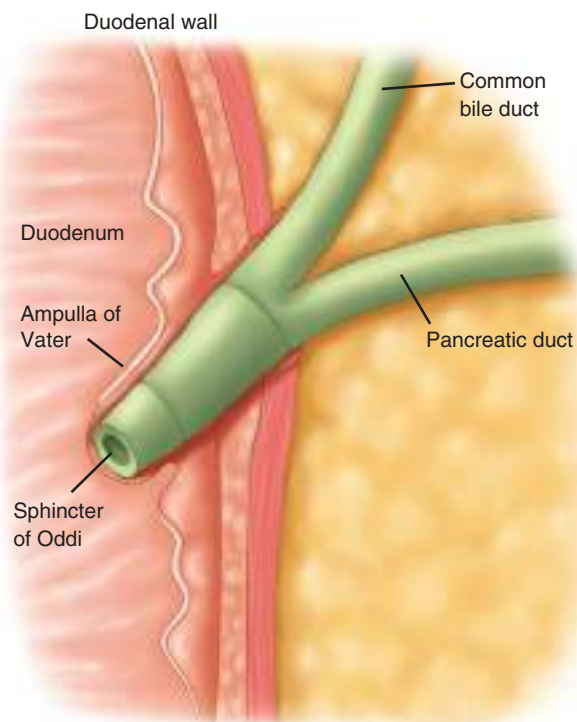

Figure 32-3. The sphincter of Oddi.

Anatomic Variants

The classic description of the extrahepatic biliary tree and its arteries applies only in about one-third of patients.³ The gallbladder may have abnormal positions, be intrahepatic, be rudimentary (a small, nonfunctional hypoplastic remnant), or have anomalous forms or duplications. A partially or completely intrahepatic gallbladder is associated with an increased incidence of cholelithiasis, and may be encountered at the time of cholecystectomy. Isolated congenital absence of the gallbladder is very rare, with a reported incidence of 0.03%. Before the diagnosis is made, the presence of an intrahepatic gallbladder or anomalous position must first be ruled out. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of about one in every 4000 persons. This occurs in two major varieties: the more common form in which each gallbladder has its own cystic duct that empties independently into the same or different parts of the extrahepatic biliary tree, and the less common variant in which the two cystic ducts merge before they enter the common bile duct. Duplication is only clinically important when some pathologic process affects one or both organs. Even rarer variants include a left-sided gallbladder (often with a cystic duct that empties into the left hepatic or common bile duct), retrodisplacement of the gallbladder at the posterior-inferior surface of the liver, transverse positioning of the gallbladder, or a floating gallbladder in which the gallbladder is hanging by a mesentery (Fig. 32-4).

Additional small bile ducts (of Luschka) may drain directly from the liver fossa into the body of the gallbladder. If present, but not recognized at the time of a cholecystectomy, a bile leak and subsequent accumulation of bile (biloma) may occur in the abdomen. An accessory right hepatic duct occurs in about 5% of cases. Variations in how the common bile duct enters the duodenum are described earlier, in the “Bile Ducts” section.

Anomalies of the hepatic artery and the cystic artery are quite common, occurring in as many as 50% of cases. While the right hepatic artery usually originates from the proper hepatic branch of the celiac trunk, up to 20% of patients will have a replaced right hepatic artery coming off the superior mesenteric artery. In about 5% of cases, there are two right hepatic arteries, one from the proper hepatic artery and the other from the superior mesenteric artery (accessory right hepatic artery). While the right hepatic artery typically runs posterior to the bile ducts, variations may allow it to course anterior to the common duct, making it vulnerable during surgical procedures, particularly if it runs parallel to the cystic duct or in the mesentery of the gallbladder. The cystic artery arises from the right hepatic artery in about 90% of cases, but it may arise from the left hepatic, common hepatic, gastroduodenal, or superior mesenteric arteries (Fig. 32-5).³

Figure 32-4. Floating gallbladder suspended on mesentery

Figure 32-5. Variations in the arterial supply to the gallbladder. **A.** Cystic artery from right hepatic artery, about 80% to 90%. **B.** Cystic artery off the right hepatic artery arising from the superior mesenteric artery (accessory or replaced), about 10%. **C.** Two cystic arteries, one from the right hepatic, the other from the common hepatic artery, rare. **D.** Two cystic arteries, one from the right hepatic, the other from the left hepatic artery, rare. **E.** The cystic artery branching from the right hepatic artery and running anterior to the common hepatic duct, rare. **F.** Two cystic arteries arising from the right hepatic artery, rare.

PHYSIOLOGY

Bile Formation and Composition

The liver produces bile continuously and excretes it into the bile canaliculi. Bile leaves the liver through the right and left hepatic ducts, into the common hepatic duct and then the common bile duct. With an intact sphincter of Oddi, tonic contraction diverts bile flow into the gallbladder for storage, while mealtime stimulation allows for its passage into the duodenum. The normal adult consuming an average diet produces 500 to 1000 mL of bile a day. The secretion of bile is responsive to neurogenic, hormonal, and chemical stimuli. Parasympathetic stimulation from the hepatic branches of the vagus nerve increases secretion of bile, whereas sympathetic nerve stimulation via the celiac plexus results in decreased bile flow. Hydrochloric acid, partly digested proteins, and fatty acids entering the duodenum from the stomach after a meal stimulate the release of secretin from the S-cells of the duodenum, and increases bile production and flow.

Bile is mainly composed of water, mixed with bile salts and acids, cholesterol, phospholipids (lecithin), proteins, and bilirubin. It also contains several minor components such as

electrolytes and vitamins. Sodium, potassium, calcium, and chlorine have the same concentration in bile as in plasma or extracellular fluid. The pH of hepatic bile is usually neutral or slightly alkaline, though a high protein diet will shift the bile to a more acidic pH. The primary bile salts, cholate and chenodeoxycholate, are synthesized in the liver from cholesterol metabolism. They are conjugated there with taurine and glycine and act within the bile as anions (bile acids) that are balanced by sodium. These bile acids are then excreted into the bile by hepatocytes and aid in the digestion and absorption of fats in the intestines.⁴ About 80% of the secreted conjugated bile acids are reabsorbed in the terminal ileum. The remainder is dehydroxylated (deconjugated) by gut bacteria, forming the secondary bile acids deoxycholate and lithocholate. These are absorbed in the colon and can then be transported back to the liver. Eventually, about 95% of the bile acid pool is reabsorbed, the so-called enterohepatic circulation. Only a small amount (5%) is excreted in the stool, allowing the relatively small quantity of bile acids produced to have maximal effect.

The color of the bile is due to the presence of the pigment bilirubin (orange or yellow) and its oxidized form, biliverdin (green), which are the metabolic products of the breakdown of hemoglobin, and are present in bile in concentrations 100 times greater than in plasma. Bilirubin conjugated in the liver can be excreted through the urine as urobilinogen (yellow). Remaining excess bile pigment passes into the intestines where bacteria convert it into stercobilinogen (brown), which is excreted through the stool.

Gallbladder Function

The gallbladder, bile ducts, and the sphincter of Oddi act together to store and regulate the flow of bile. The main function of the gallbladder is to concentrate and store hepatic bile in order to deliver it in a coordinated fashion to the duodenum in response to a meal.

Absorption and Secretion. In the fasting state, approximately 80% of the bile secreted by the liver is stored in the gallbladder. This storage is made possible by the fact that the gallbladder mucosa has the greatest absorptive power per unit area of any structure in the body. It rapidly absorbs sodium, chloride, and water against significant gradients, concentrating the bile as much as 10-fold and leading to a marked change in bile composition. This rapid absorptive capacity is one of the protective mechanisms that prevent a potentially dangerous rise in pressure within the biliary system as bile is produced and stored. In addition, gradual relaxation of the gallbladder as well as routine emptying of the gallbladder's excess bile stores during the fasting period also play a role in maintaining a low resting intraluminal pressure in the biliary tree.

The mucosal cells of the gallbladder itself secrete at least two important products into the gallbladder lumen: glycoproteins and hydrogen ions. The mucosal glands in the infundibulum and the neck of the gallbladder secrete mucus glycoproteins that are believed to protect the mucosa from the corrosive action of bile and to facilitate the passage of bile through the cystic duct. This same mucus creates the colorless "white bile" seen in hydrops of the gallbladder as a result of cystic duct obstruction blocking the entry of bile pigments into the gallbladder. The transport of hydrogen ions by the gallbladder epithelium also plays an important role in decreasing the pH of stored bile. This acidification helps prevent the precipitation of calcium salts, which can act as a nidus for stone formation.⁴

Motor Activity. Normal gallbladder filling is facilitated by tonic contraction of the sphincter of Oddi, which creates a small but effective pressure gradient between the bile ducts and the gallbladder. In association with phase II of the interdigestive migrating myenteric motor complex (MMC) in the gut, the gallbladder repeatedly empties small volumes of bile into the duodenum. This process is mediated at least in part by the hormone motilin. In response to a meal, the gallbladder delivers larger volumes to the intestine by a combination of gallbladder contraction and synchronized sphincter of Oddi relaxation. One of the main stimuli to this coordinated effort of gallbladder emptying is the hormone cholecystokinin (CCK). CCK is released endogenously from the enteroendocrine cells in the duodenum in response to a meal.⁵ When stimulated by eating, the gallbladder empties 50% to 70% of its contents within 30 to 40 minutes. Over the following 60 to 90 minutes, the gallbladder gradually refills as CCK levels drop. Other minor hormonal and neural pathways also are involved in the coordinated action of the gallbladder and the sphincter of Oddi. Defects in the motor activity of the gallbladder that inhibit correct emptying are thought to play a role in cholesterol nucleation and gallstone formation.

Neurohormonal Regulation. Neurally mediated reflexes are very important in maintaining the functions of the gallbladder, sphincter of Oddi, stomach, and duodenum to coordinate the flow of bile into the intestines at the correct times. The vagus nerve stimulates contraction of the gallbladder by parasympathetic innervation while splanchnic sympathetic nerves from the celiac plexus are inhibitory to its motor activity. For this reason, parasympathomimetic or cholinergic drugs, including nicotine and caffeine, contract the gallbladder. Conversely, anticholinergic drugs such as atropine lead to gallbladder relaxation. Antral distention of the stomach causes both gallbladder contraction and relaxation of the sphincter of Oddi.

In addition to neural inputs, hormonal receptors are located on the smooth muscles, vessels, nerves, and epithelium of the gallbladder and biliary tree. CCK is a peptide that comes from the enteroendocrine cells of the duodenum and proximal jejunum. CCK is released into the bloodstream in response to the presence of hydrochloric acid, fat, and amino acids in the duodenum.⁶ CCK has a plasma half-life of 2 to 3 minutes and is metabolized by both the liver and the kidneys. CCK acts directly on smooth muscle receptors of the gallbladder and stimulates gallbladder contraction. It also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum to allow forward bile flow. CCK stimulation of the gallbladder and biliary tree is also mediated by cholinergic vagal neurons. For this reason, patients who have had a vagotomy may have a diminished response to CCK stimulation, resulting in an increase in the size and volume of the gallbladder.

Hormones such as vasoactive intestinal polypeptide (VIP) and somatostatin are potent inhibitors of gallbladder contraction. Patients treated with somatostatin analogues and those with somatostatinomas have a high incidence of gallstones, presumably due to the inhibition of gallbladder contraction and emptying. Other hormones such as substance P and enkephalin affect gallbladder motility, but their exact physiologic role is less clear.⁵

Sphincter of Oddi

The sphincter of Oddi regulates the flow of bile and pancreatic juice into the duodenum, prevents the regurgitation of duodenal contents into the biliary tree, and diverts bile into

the gallbladder. It is a complex structure that is functionally independent from the duodenal musculature and creates a high-pressure zone between the bile duct and the duodenum. The sphincter of Oddi spans approximately 4 to 6 mm in length and has a basal resting pressure of about 13 mmHg above the duodenal pressure. On manometry, the sphincter shows phasic contractions with a frequency of about four per minute and amplitude of 12 to 140 mmHg. The spontaneous motility of the sphincter of Oddi is regulated by the interstitial cells of Cajal through intrinsic and extrinsic inputs from hormones and neurons acting on the smooth muscle cells.⁷ Relaxation occurs in response to raising levels of the gastrointestinal hormones CCK, glucagon, and secretin. This leads to diminished amplitude of phasic contractions and reduced basal pressure of the sphincter, allowing increased flow of bile into the duodenum. During fasting, the sphincter of Oddi activity is coordinated with the periodic partial gallbladder emptying that occurs during phase II of the migrating myoelectric motor complexes.⁸ Pharmacologic administration of certain gastrointestinal hormones, such as glucagon, can temporarily decrease sphincter of Oddi baseline pressure and facilitate diagnostic studies.⁷

DIAGNOSTIC STUDIES

A variety of diagnostic modalities are available for the patient with suspected disease of the gallbladder or bile ducts. In 1924, the diagnosis of gallstones was revolutionized by the introduction of oral cholecystography by Graham and Cole. For decades, it was the mainstay of investigation for gallstones. It involved oral administration of a radiopaque compound that is absorbed, excreted by the liver, and passed into the gallbladder. Stones are noted on a film as filling defects in a visualized, pacified gallbladder. In the later half of the 20th century, biliary imaging improved dramatically with the development of hepatobiliary scintigraphy (radionucleotide scanning), as well as transhepatic and endoscopic retrograde cholangiography (ERCP), which allowed for more detailed imaging of the biliary tree. Later, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) would further improve the ability to image the biliary tract.

Blood Tests

When patients with suspected diseases of the gallbladder or the extrahepatic biliary tree are evaluated, a complete blood count and liver function tests are routinely requested. An elevated white blood cell (WBC) count may indicate or raise suspicion of acute cholecystitis (infection within the gallbladder). If associated with an elevation of bilirubin, alkaline phosphatase, and transaminases, cholangitis (infection within the biliary tree) should be suspected. Cholestasis (an obstruction to bile flow) is generally characterized by an elevation of conjugated bilirubin and a rise in alkaline phosphatase, but it may have no transaminitis. Such a pattern may suggest choledocholithiasis (stones in the common bile duct) or an obstructing lesion such as a stricture or cholangiocarcinoma. In patients with simple symptomatic cholelithiasis, biliary colic, or chronic cholecystitis (a chronic inflammatory state of the gallbladder without infection), blood tests will often be normal.

Transabdominal Ultrasonography

Transabdominal ultrasound is the initial investigation of any patient suspected to have disease of the biliary tree.⁹ It is non-invasive, painless, does not submit the patient to radiation, and

Figure 32-6. An ultrasonography of the gallbladder. *White arrows* indicate stones within the gallbladder; *black arrowheads* show acoustic shadows from stones.

can be performed on critically ill patients. Adjacent organs can also frequently be examined at the same time. However, its reliability and interpretation are dependent upon the skills and experience of the operator. In addition, obese patients, patients with ascites, and patients with distended bowel may be difficult to examine with ultrasound as the quality of the images obtained in these situations can be poor.

Ultrasound will show stones in the gallbladder with sensitivity and specificity of >90%, and can also reliably detect other pathologies of the biliary tree. Stones are acoustically dense and reflect the ultrasound waves back to the ultrasonic transducer. Because stones block the passage of sound waves to the region behind them, they also produce an acoustic shadow (Fig. 32-6). Stones move with changes in position. Polyps, on the other hand, may be calcified and reflect shadows, but they do not move with change in posture. Some stones form a layer in the gallbladder; others form sediment or sludge. A thickened gallbladder wall, pericholecystic fluid, and local tenderness with direct pressure by the ultrasound probe over the fundus of the gallbladder (sonographic Murphy's sign) may indicate acute cholecystitis. When a stone obstructs the neck of the gallbladder, the gallbladder may become very large, but thin walled. A contracted, thick-walled gallbladder can be indicative of chronic cholecystitis.

The extrahepatic bile ducts are also well visualized by transabdominal ultrasound, with the exception of the retroduodenal portion. Dilation of the biliary tree in a patient with jaundice suggests an extrahepatic obstruction as the cause for the jaundice. Frequently, the site and, sometimes, the cause of the obstruction can be determined by ultrasound. Small stones in the common bile duct frequently get lodged at the distal end of it, behind the duodenum, and are, therefore, difficult to detect. A dilated common bile duct on ultrasound, small stones in the gallbladder, and a classic clinical presentation allows one to assume that a stone or stones are causing the obstruction. Periampullary tumors can be difficult to diagnose on ultrasound, but above the retroduodenal portion, the level of obstruction and the cause may be visualized quite well. Ultrasound can also be helpful in evaluating tumor invasion and flow in the portal vein, an important guideline for resectability of periampullary tumors.¹⁰

Computed Tomography

Abdominal CT scans are frequently used in the workup of undifferentiated abdominal pain and thus often diagnose gallbladder

Figure 32-7. Computed tomography scan of the upper abdomen from a patient with cancer of the distal common bile duct. The cancer obstructs the common bile duct as well as the pancreatic duct. 1 = the portal vein; 2 = a dilated intrahepatic bile duct; 3 = dilated cystic duct and the neck of the gallbladder; 4 = dilated common hepatic duct; 5 = the bifurcation of the common hepatic artery into the gastroduodenal artery and the proper hepatic artery; 6 = dilated pancreatic duct; 7 = the splenic vein.

disease. CT scanning is inferior to ultrasonography in diagnosing gallstones but is similar in sensitivity for acute cholecystitis. The major application of CT scan, however, is to define the course and status of the extrahepatic biliary tree and adjacent structures, and to evaluate for alternate causes of a patient's clinical presentation.¹¹ CT is also the initial test of choice in evaluating patients with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs such as the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice of unknown origin (Fig. 32-7).

Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy, or hepatobiliary iminodiacetic acid (HIDA) scanning, is another option for noninvasive

evaluation of the liver, gallbladder, bile ducts, and duodenum that provides both anatomic and functional information. ^{99m}Tc-labeled derivatives of iminodiacetic acid are injected intravenously, taken up by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is usually detected within 10 minutes, and the gallbladder, bile ducts, and duodenum are typically visualized within 60 minutes in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. The lack of gallbladder filling is due to inflammatory closure of the cystic duct preventing bile backflow into the gallbladder (Fig. 32-8). Evidence of cystic duct obstruction on biliary scintigraphy is highly diagnostic for acute cholecystitis. The sensitivity and specificity for the diagnosis are about 95% each. False-positive results can occur in patients in the nonfasting state, those receiving parenteral nutrition, or in the setting of gallbladder stasis, recent narcotic use, or alcoholism. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.¹² HIDA scanning with evaluation of the gallbladder ejection fraction with or without CCK provocation may also be helpful in diagnosing chronic biliary dyskinesia in patients with atypical symptoms. While an ejection fraction of <35% is considered abnormal, the exact interpretations and clinical implications of this finding remain a matter of some debate.¹³

Magnetic Resonance Imaging

Available since the mid-1990s, MRI provides anatomic details of the liver, gallbladder, and pancreas similar to those obtained from CT. Many MRI techniques (i.e., heavily T2-weighted sequences, pulse sequences with or without contrast materials) can generate high-resolution anatomic images of the biliary tree and the pancreatic duct. MRI with magnetic resonance cholangiopancreatography (MRCP) offers a focused, noninvasive test for the diagnosis of biliary tract and pancreatic disease (Fig. 32-9).¹⁴ It has a sensitivity and specificity of 95% and 89%, respectively, for detecting choledocholithiasis.¹⁵ In many centers, MRCP is the preferred imaging modality for precise evaluation of biliary and pancreatic duct pathology, reserving endoscopic retrograde cholangiopancreatography (ERCP) for therapeutic purposes only.

Figure 32-8. HIDA scanning. **A.** Normal HIDA scan showing filling of the extrahepatic biliary tree and gallbladder (white arrow). **B.** HIDA scan in a patient with acute cholecystitis showing no filling of the gallbladder.

Figure 32-9. Magnetic resonance cholangiopancreatography. This view shows the course of the extrahepatic bile ducts (*arrow*) and the pancreatic duct (*arrowheads*).

Endoscopic Retrograde Cholangiopancreatography

While the use of endoscopic retrograde cholangiopancreatography (ERCP) in biliary disease is particularly valuable for its therapeutic capabilities, its diagnostic role should not be overlooked. Using a side-viewing endoscope, the common bile duct can be cannulated through the ampulla of Vater and a cholangiogram performed using fluoroscopy (Fig. 32-10).

The procedure requires at least intravenous (IV) sedation and in some cases general anesthesia. The advantages of ERCP include direct visualization of the ampullary region and direct access to the distal common bile duct for cholangiography or choledochoscopy. The test is rarely needed for uncomplicated gallstone disease. However, for cases of choledocholithiasis, obstructive jaundice, biliary strictures, or cholangitis, ERCP has the advantage of being both diagnostic and therapeutic. If ductal stones are identified on the endoscopic cholangiogram, biliary sphincterotomy and stone extraction can be performed, clearing the common bile duct of stones. If another etiology such as a biliary stricture is found, diagnostic brushings can be obtained at the time of the procedure. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is >90%. Notable complications of diagnostic ERCP include pancreatitis, which occurs in approximately 3.5% of patients, as well as rare occurrences of bleeding, perforation, or infection (cholangitis).^{16,17}

Endoscopic Choledochoscopy

The development of small fiber-optic cameras that can be threaded through endoscopes used for endoscopic retrograde cholangiopancreatography (ERCP) has facilitated the development of intraductal endoscopy. By providing direct visualization of the biliary and pancreatic ducts, this technology has been shown to increase the effectiveness of ERCP in the diagnosis of certain biliary diseases.¹⁸ Intraductal endoscopy has been shown to have therapeutic applications that include biliary stone lithotripsy and directed stone extraction in high-risk surgical patients.¹⁹ It can also allow for direct visualization and sampling of concerning lesions in order to evaluate for malignancy (Fig. 32-11). Studies have thus far shown intraductal endoscopy to be safe and effective, though complications such as bile duct perforation, minor bleeding, and cholangitis have

been described.²⁰ Further refinement of this technology will likely enhance ERCP as a diagnostic and therapeutic tool.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS) has improved significantly in recent years and offers additional diagnostic utility to the workup of biliary disease. It requires a specialized 30° endoscope with either a radial or linear ultrasound transducer at its tip. The results are operator dependent and require a skilled endoscopist but offer noninvasive imaging of the bile ducts and adjacent structures. Endoscopic ultrasound can also be used to identify choledocholithiasis. It is useful for evaluation of the retroduodenal portion of the bile duct, which is difficult to visualize with transabdominal ultrasonography. Although EUS is less sensitive than ERCP for biliary stones, the technique is less invasive as it does not require cannulation of the sphincter of Oddi. EUS is also of particular value in the evaluation of tumors near or behind the duodenum and their resectability. Using a linear EUS scope that has a biopsy channel, fine-needle aspiration (FNA) of tumors or lymph nodes, therapeutic injections, or drainage procedures under direct ultrasonic guidance can be performed.²¹

Percutaneous Transhepatic Cholangiography

In settings in which the biliary tree cannot be accessed endoscopically, antegrade cholangiography can be performed by accessing the intrahepatic bile ducts percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is inserted and a catheter is passed over the wire (Fig. 32-12). Through the catheter, an antegrade cholangiogram can be obtained and therapeutic interventions such as tissue sampling, biliary drain insertions, or stent placements performed. Percutaneous transhepatic cholangiography (PTC) can also be performed through previously placed percutaneous biliary drainage tubes, if present. PTC has little role in the management of patients with uncomplicated gallstone disease but can be useful in patients with bile duct strictures or

tumors, as it can define the anatomy of the biliary tree proximal to the affected segment. As with any invasive procedure, there are potential risks. For PTC, these are mainly bleeding, cholangitis, bile leak, and other catheter-related problems.¹²

GALLSTONE DISEASE

Prevalence and Incidence

Gallstone disease (cholelithiasis) is one of the most common afflictions of the digestive tract. Autopsy reports show that gallstones are present in between 10% and 15% of adults.²² The prevalence of gallstones is related to many factors, including diet, age, gender, BMI, and ethnic background with increased prevalence in patients of Native American and Latin American descent. Certain conditions also predispose to the development of gallstones including pregnancy, non-HDL hyperlipidemia, Crohn's disease, and certain blood disorders such as hereditary spherocytosis, sickle cell disease, and thalassemia. Surgeries that alter the normal neural or hormonal regulation of the biliary tree including terminal ileal resection and gastric or duodenal surgery increase the risk of cholelithiasis. Rapid weight loss following bariatric surgery or lifestyle changes can also precipitate gallstone formation by creating an imbalance in bile composition. Medications such as somatostatin analogues and estrogen-containing oral contraceptives are also associated with an increased risk of developing gallstones.²² Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a twofold greater prevalence, possibly indicating a genetic predisposition.²³

Natural History

Despite the high prevalence of cholelithiasis, most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons, some patients progress to a symptomatic stage, with typical symptoms of postprandial right upper quadrant pain (biliary colic) caused by a stone obstructing the cystic duct. In addition to pain, gallstones may progress to cause complications such as acute cholecystitis, choledocholithiasis, cholangitis, gallstone pancreatitis, gallstone ileus, and gallbladder cancer. Rarely, one of these complications of gallstones may be the initial presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally during unrelated abdominal imaging or at the time of surgery for an unrelated diagnosis. Several studies have examined the likelihood of developing biliary colic or developing significant complications of gallstone disease after incidental diagnosis in the asymptomatic patient. About 80% of these patients will remain symptom free.²⁴ However, 2% to 3% will become symptomatic per year (i.e., develop biliary colic). Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease (cholecystitis, choledocholithiasis, gallstone pancreatitis, etc.) develops in 3% to 5% of symptomatic patients per year.²⁵

Because few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones is rarely indicated.²⁴ Exceptions exist for individuals who will be isolated from medical care for extended periods of time, or in populations with increased risk of gallbladder cancer, in which case a prophylactic cholecystectomy may be advisable. The presence of porcelain gallbladder, marked by significant calcifications thought to be related to

gallstones, is a rare premalignant condition and is an absolute indication for cholecystectomy, even when asymptomatic.

Gallstone Formation

Gallstones form as a result of solids settling out of solution. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80% of gallstones are cholesterol

stones and about 15% to 20% are black pigment stones.²² Brown pigment stones account for only a small percentage. Both types of pigment stones are more common in Asia.

Cholesterol Stones. Pure cholesterol stones are uncommon and account for <10% of all stones. They usually occur as a single large stone with a smooth surface. The majority of cholesterol stones are mixed but are at least 70% cholesterol by weight in addition to variable amounts of bile pigments and calcium. These stones are usually multiple, of variable size, and may be

hard and faceted or irregular, multilobed, and soft (Fig. 32-13). Colors range from whitish yellow to green or black. Most cholesterol stones (>90%) are radiolucent, though some have a high calcium carbonate component and become radiopaque.

The primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol. Cholesterol is highly nonpolar and its solubility in water and bile depends on the relative concentration of cholesterol, bile salts, and lecithin (the main phospholipid in bile). Cholesterol is secreted into bile and is surrounded by bile salts and phospholipids to form a soluble vesicle complex. When cholesterol hypersecretion is present, either through increased intake or dysfunctional processing,

Figure 32-14. The three major components of bile plotted on triangular coordinates, cholesterol, bile salts and phospholipids (lecithin). A given point represents the relative molar ratios of each. The area labeled “micellar liquid” shows the range of concentrations in which cholesterol is fully solubilized. The shaded area directly above this region corresponds to a metastable zone, supersaturated with cholesterol. Above the shaded area, bile has exceeded the solubilization capacity of cholesterol and precipitation of cholesterol crystals and stones occurs.

supersaturation occurs. When cholesterol concentrations exceed the ability of the bile salts and phospholipid to maintain solubility, the cholesterol precipitates out of solution into a solid, forming a cholesterol stone (Fig. 32-14).²⁶ Cholesterol hypersecretion is almost always the cause of supersaturation rather than reduced secretion of phospholipid or bile salts.²

Pigmented Stones. Pigmented stones contain <20% cholesterol and are dark because of the presence of calcium bilirubinate. Black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, dark, and sometimes spiculated. They are formed by supersaturation of unconjugated bilirubin within the bile. Deconjugation of bilirubin occurs normally in bile at a slow rate. Thus, excessive levels of conjugated bilirubin excretion, as occurs in hemolytic disorders like hereditary spherocytosis and sickle cell disease will lead to an increased rate of production of unconjugated bilirubin. Cirrhosis and hepatic dysfunction may also lead to increased secretion of unconjugated bilirubin directly from the liver. The insoluble unconjugated bilirubin will then precipitate with calcium as insoluble calcium bilirubinate, forming a pigment stone. Due to their high calcium content, pigment stones are often radiopaque. Like cholesterol stones, they almost always form in the gallbladder. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually <1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts secondary to bacterial infection and bile stasis. Bacteria such as *Escherichia coli* secrete β -glucuronidase that enzymatically cleaves conjugated bilirubin to produce the insoluble unconjugated bilirubin. This unconjugated bilirubin then precipitates with calcium, and along with dead bacterial cell bodies, forms soft brown stones in the biliary tree. Brown stones are typically found in Asian populations and are associated with stasis secondary to parasite infection with *Ascaris lumbricoides*

(roundworm) or *Clonorchis sinensis* (liver fluke). In Western populations, brown stones most often occur as primary bile duct stones in patients with biliary strictures or other common bile duct stones that cause stasis and bacterial contamination.^{2,27}

Symptomatic Gallstones

Symptomatic Cholelithiasis. Patients with symptomatic gallstone disease typically present with recurrent attacks of pain. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall as it contracts in response to a meal. This postprandial right upper quadrant or epigastric pain is often referred to as *biliary colic*. If untreated, about two-thirds of these patients will develop chronic noninfectious inflammation of the gallbladder wall, termed chronic cholecystitis. The pathologic changes, which often do not correlate well with symptoms, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with transmural fibrosis and adhesions to nearby structures. The mucosa is initially normal or hypertrophied but later becomes atrophied, with the epithelium protruding into the muscle coat, leading to the formation of the so-called Aschoff-Rokitansky sinuses.

Clinical Manifestations The chief symptom associated with symptomatic cholelithiasis is pain (biliary colic). The pain is constant and increases in severity over the first half hour or so after a meal and can last 1 to 5 hours. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between the scapulae (Fig. 32-15). The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. Patients generally suffer discrete, recurrent attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical examination is usually unremarkable. Laboratory values, such as WBC count and liver function tests, are usually normal in patients with uncomplicated gallstones.

Atypical presentations of gallstone disease are common and a high index of suspicion for biliary disease must be maintained when evaluating patients with abdominal complaints. Association with meals is present in only about 50% of patients. Some patients report milder attacks of pain but relate it to meals. The pain may be located primarily in the back or the left upper or right lower quadrant. Bloating and belching may be present and associated with the attacks of pain. In patients with atypical presentations, other conditions that may be causing upper abdominal pain should be ruled out, even in the presence of gallstones. These include but are not limited to peptic ulcer disease, gastroesophageal reflux disease, herpes zoster, abdominal wall hernias, inflammatory bowel disease, diverticular disease, pancreatitis, liver disease, renal calculi, pleuritic pain, and cardiac pain.

When the pain lasts >24 hours without resolving, an impacted stone in the cystic duct or acute cholecystitis (see later “Acute Cholecystitis” section) should be suspected. An impacted stone without cholecystitis will result in what is called *hydrops of the gallbladder*. Bile will be unable to enter the gallbladder due to the obstructed cystic duct, but the gallbladder epithelium will continue to secrete mucus, and the gallbladder will become distended with clear-white mucinous material. The gallbladder may be palpable but usually is not tender. Hydrops of the gallbladder may result in edema of the gallbladder wall, inflammation, infection, and perforation. Although hydrops

Figure 32-15. A. Sites of the most severe pain during an episode of biliary colic in 107 patients with gallstones (% values add up to >100% because of multiple responses). Sites of pain radiation (%) during an episode of biliary colic in the same group of patients.

may persist with few consequences, early cholecystectomy is generally indicated to avoid complications.

Diagnosis The diagnosis of symptomatic cholelithiasis or chronic cholecystitis depends on the presence of typical symptoms and the demonstration of stones on diagnostic imaging. An abdominal ultrasound is the standard diagnostic test for gallstones as it is noninvasive and highly sensitive (see earlier “Ultrasonography” section).²⁸ Gallstones are occasionally identified on abdominal CT scans that were obtained as part of a broader workup of abdominal pain. In these cases, if the patient has typical symptoms, it is reasonable to proceed with intervention. Stones diagnosed incidentally on CT or plain radiographs in patients without symptoms should be left in place. Occasionally, patients with typical attacks of biliary pain have no evidence of stones on ultrasound but have evidence of sludge in the gallbladder. If a patient has attacks of typical biliary pain and sludge is detected, cholecystectomy is warranted.

In addition to sludge and stones, cholesterosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasound or CT. Cholesterosis is caused by the accumulation of cholesterol in macrophages in the

gallbladder lamina propria, either locally or as polyps. It produces the classic studded macroscopic appearance of a “strawberry gallbladder.” Adenomyomatosis (cholecystitis glandularis proliferans) is characterized on microscopy by hypertrophic smooth muscle bundles and by the ingrowths of mucosal glands into the muscle layer (epithelial sinus formation). Granulomatous polyps develop in the lumen at the fundus, and the gallbladder wall is thickened. Septae or strictures may be seen within the gallbladder. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.²⁹

Treatment Nonsurgical management of gallstone disease using medications or lithotripsy has had disappointing long-term results. These modalities are not considered to be part of the primary treatment algorithm for gallstone disease.³⁰ Surgical cholecystectomy offers the best long-term results for patients with symptomatic gallstones. About 90% of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms such as dyspepsia, flatulence, belching, bloating, and dietary fat intolerance, the results are not as favorable. The laparoscopic approach has been proven to be safe and effective and has become the standard of care for symptomatic gallstone disease, replacing open cholecystectomy in routine cases.^{29,31}

3▶ Due to the possibility of developing complications related to gallstone disease, patients with symptomatic cholelithiasis should be offered elective cholecystectomy. While waiting for surgery, or if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should be encouraged to have a cholecystectomy promptly, as they are more prone to developing severe acute cholecystitis. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy. The operation should be performed during the second trimester if possible.

Acute Cholecystitis. Acute cholecystitis, or infection of the gallbladder, is associated with gallstones in 90% to 95% of cases. Rarely, acalculous cholecystitis can occur, usually in patients with other acute systemic diseases (see later “Acalculous Cholecystitis” section). Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. In <1% of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Why inflammation develops only occasionally with cystic duct obstruction is unknown, but it is probably related to the duration of obstruction. Initially, acute cholecystitis is an inflammatory process, probably mediated by the mucosal toxin lysolecithin, a product of lecithin, as well as bile salts and platelet-activating factor. An increase in prostaglandin synthesis amplifies the inflammatory response. In acute cholecystitis, the gallbladder wall becomes grossly thickened and reddish with subserosal hemorrhages. Pericholecystic fluid often is present. The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5% to 10%, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.

Not all episodes of uncomplicated acute cholecystitis involve infection. Secondary bacterial contamination is thought to occur in only 15% to 30% of patients. With some severe infections, gangrenous cholecystitis can develop, and an abscess or perforation may occur. When they happen, perforations are usually contained in the subhepatic space by the omentum and

adjacent organs. However, free perforation with peritonitis, intrahepatic perforation with intrahepatic abscesses, and perforation into adjacent organs (duodenum or colon) with cholecystoenteric fistula have been described. When gas-forming organisms are part of the secondary bacterial infection, gas may be seen in the gallbladder lumen and in the wall of the gallbladder on abdominal radiographs and CT scans, an entity called *emphysematous cholecystitis*.

Clinical Manifestations About 80% of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis often begins as an attack of biliary colic with relapsing and remitting pain in the right upper quadrant or epigastrium that may radiate to the right back or interscapular area. In contrast to biliary colic, the pain of acute cholecystitis does not subside. It is unremitting, may persist for several days, and is usually more severe than the pain associated with uncomplicated gallstone disease. The patient is often febrile, complains of anorexia, nausea, and vomiting, and may be reluctant to move as the inflammatory process creates focal peritonitis. On physical examination, tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent identification of this. Murphy’s sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

Laboratory evaluation commonly reveals a mild to moderate leukocytosis (12,000–15,000 cells/mm³). However, a normal WBC does not rule out the diagnosis. An unusually high WBC count (>20,000 cells/mm³) suggests a complicated form of cholecystitis such as gangrenous cholecystitis, perforation, or associated cholangitis. In uncomplicated acute cholecystitis, serum liver chemistries are usually normal, but a mild elevation of serum bilirubin (<4 mg/mL) may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase.²⁸ Severe jaundice is suggestive of obstruction of the bile ducts. This can be a result of common bile duct stones or severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct, known as Mirizzi’s syndrome (Fig. 32-16). In elderly patients and in those with diabetes mellitus, acute cholecystitis may have a subtle

Figure 32-16. Mirizzi’s syndrome. Impaction of a large stone in the neck of the gallbladder causing obstruction at the level of the confluence of the cystic duct and common hepatic duct.

Figure 32-17. Ultrasonography from a patient with acute cholecystitis. The *white arrowheads* indicate the thickened gallbladder wall. There are several stones in the gallbladder (*white arrows*) throwing acoustic shadows (*black arrowheads*). Trace pericholecystic fluid can be seen surrounding the gallbladder (*black arrows*).

presentation resulting in a delay in diagnosis. These patients may also have higher rates of treatment related morbidity compared to younger and healthier patients.

The differential diagnosis for acute cholecystitis includes but is not limited to peptic ulcer disease, pancreatitis, appendicitis, hepatitis, perihepatitis (Fitz-Hugh–Curtis syndrome), myocardial ischemia, pneumonia, pleuritis, and herpes zoster involving the intercostal nerve.

Diagnosis Ultrasonography is considered the most useful initial radiologic test for diagnosing acute cholecystitis, with a sensitivity and specificity of 70% to 90%. Ultrasound is effective at documenting the presence or absence of stones, and it can show gallbladder wall thickening and pericholecystic fluid, both of which are highly suggestive of acute cholecystitis (Fig. 32-17). Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy's sign) also supports the diagnosis of acute cholecystitis. Biliary scintigraphy (HIDA scanning) may be of help in atypical cases if the diagnosis remains in question after initial workup. Lack of filling of the gallbladder after 4 hours indicates an obstructed cystic duct and, in the clinical setting of suspected acute cholecystitis, confirms the diagnosis with a reported sensitivity above 90%.³² Conversely, a normal HIDA scan with clear filling of the gallbladder rules out the diagnosis of acute cholecystitis. CT scans are frequently performed on patients with acute abdominal pain of unknown etiology, as they can evaluate for a number of potential pathologic processes at once. In patients with acute cholecystitis, a CT scan can demonstrate thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones, but it is somewhat less sensitive than ultrasonography.

Treatment Patients who present with acute cholecystitis should receive IV fluids, broad-spectrum antibiotics, and analgesia. The antibiotics should cover gram-negative enteric organisms as well as anaerobes. Although the inflammation in acute cholecystitis may be sterile in some patients, it is difficult to know who is secondarily infected. Therefore, antibiotics have become a standard part of the initial management of acute cholecystitis in most centers.

Cholecystectomy is the definitive treatment for acute cholecystitis. In the past, the timing of cholecystectomy has been

a matter of debate. Early cholecystectomy performed within 72 hours of the onset of the illness is preferred over delayed cholecystectomy that is performed 6 to 10 weeks after initial medical treatment and recuperation. Several studies have shown that unless the patient is unfit for surgery, early cholecystectomy should be recommended as soon as possible, as it offers the patient a definitive solution in one hospital admission, quicker recovery times, similar complication rates, and an earlier return to work.^{33,34}

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy has fallen in recent years to less than 5% as laparoscopic equipment and experience has improved.³⁵ While laparoscopic cholecystectomy for acute cholecystitis may be more tedious and take longer than an elective cholecystectomy for symptomatic cholelithiasis, the laparoscopic approach remains safe and effective, even in the setting of acute and sometimes severe inflammation. Open cholecystectomy must remain an option in particularly difficult cases, or in patients suspected of having prohibitive intraabdominal adhesions, but it is rarely the primary treatment choice.

When patients are medically unfit for surgery due to the severity of their illness or medical comorbidities, they can be treated with antibiotics and biliary decompression with cholecystostomy tube placement, which is usually effective in stabilizing the patient.³⁶ For those who do recover after cholecystostomy, the tube can be removed once the track is mature (approximately 4 weeks) and cholangiography through it shows a patent cystic duct. Elective laparoscopic cholecystectomy can be scheduled within approximately 6 to 8 weeks, assuming their medical fitness recovers.³⁷ Failure to improve after cholecystostomy may be due to gangrene of the gallbladder or perforation, in which case, damage control surgery may be unavoidable.

Choledocholithiasis. Common bile duct (CBD) stones may be small or large, single or multiple, and are found in 6% to 12% of patients with stones in the gallbladder. The incidence increases with age. About 20% to 25% of patients above the age of 60 with symptomatic gallstones have stones in the common bile duct as well as in the gallbladder.³⁸ The vast majority of ductal stones in

Western countries are formed within the gallbladder and migrate down the cystic duct into the common bile duct. These are classified as secondary CBD stones, in contrast to the primary CBD stones that form in the bile duct itself. Secondary stones are usually cholesterol stones, whereas primary stones are usually of the brown pigment type. The primary stones are associated with biliary stasis and infection, and they are more commonly seen in Asian populations. Biliary stasis leading to the development of primary CBD stones can be caused by biliary strictures, papillary stenosis, tumors, or other (secondary) stones.

Clinical Manifestations Choledochal stones may be silent and often are discovered incidentally. They may cause complete or incomplete obstruction, or they may manifest with cholangitis or gallstone pancreatitis. The typical pain caused by a stone in the bile duct is very similar to that of biliary colic caused by impaction of a stone in the cystic duct. Nausea and vomiting are common. Physical examination may be normal, but mild epigastric or right upper quadrant tenderness as well as mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally, the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one-third of patients with common bile duct stones, the liver chemistries are normal, particularly if the obstruction is incomplete or intermittent.

Diagnosis Ultrasonography is useful for documenting stones in the gallbladder (if still present), as well as determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct behind the duodenum, bowel gas can preclude their detection on ultrasonography. A dilated common bile duct (>8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. If the presence of bile duct stones is in question, magnetic resonance cholangiopancreatography (MRCP) provides excellent anatomic detail and has a sensitivity and specificity of 95% and 89%, respectively, for detecting choledocholithiasis.¹⁴ Endoscopic

retrograde cholangiopancreatography (ERCP) is highly effective at diagnosing choledocholithiasis and in experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in >90% of cases. However, due to the risks associated with the procedure, it is rarely used as a purely diagnostic modality, rather being reserved for cases in which a therapeutic intervention such as stone extraction or sphincterotomy is planned. Endoscopic ultrasound has been demonstrated to be as good as ERCP for detecting common bile duct stones (sensitivity of 95% and specificity of 97%). However, EUS has fewer therapeutic capabilities and requires endoscopic expertise, making it less desirable except in specific clinical scenarios.³⁹ Percutaneous transhepatic cholangiography (PTC) is rarely needed in patients with common bile duct stones but can be performed for both diagnostic and therapeutic reasons in patients with contraindications to endoscopic or surgical approaches.

Treatment For patients with symptomatic gallstones and suspected common bile duct stones, bile duct clearance and cholecystectomy are indicated. This may be safely achieved either with preoperative ERCP followed by surgery or by going directly to surgery with intraoperative cholangiogram and common bile duct exploration to address retained stones. Both approaches are considered safe and effective, and no formal recommendation exists to definitively support one over the other.^{40,41}

If upfront laparoscopic cholecystectomy is pursued, the surgery should include an intraoperative cholangiogram to document the presence or absence of bile duct stones. If stones are identified, laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see “Choledochal Exploration” section). If the expertise and/or instrumentation for laparoscopic common bile duct exploration are not available, the patient can be awoken and scheduled for ERCP with sphincterotomy the following day. An open common bile duct exploration is an option if the endoscopic and laparoscopic methods are not feasible. If a choledochotomy is performed, primary repair can be considered in large ducts, while smaller ducts should be repaired over a T-tube. To do this, a standard T-tube should be modified by cutting the ends short enough to allow placement within the duct and dividing the T longitudinally to facilitate easy removal from the duct later on (Fig. 32-18). If a common

Figure 32-18. T-tube placement. **A.** A standard T-tube that has been cut and modified for use in the biliary tract. **B.** The T-tube is placed through a ductotomy in the common bile duct with the defect closed over the tube. The opposite end is brought out through the abdominal wall for decompression of the bile ducts.

bile duct exploration was performed and a T tube left in place, a T-tube cholangiogram should be obtained before its removal, at least several weeks after its placement.

In very severe cases, stones impacted in the ampulla may be unable to be cleared by endoscopic approaches or common bile duct exploration (open or laparoscopic). In these cases, transduodenal sphincterotomy can be considered. If one is entirely unable to disimpact the duct, choledochoduodenostomy or Roux-en-Y choledochojejunostomy may be the only option to restore biliary continuity.⁴²

If the stones were left in place at the time of surgery or diagnosed shortly after the cholecystectomy, they are classified as *retained*. Those diagnosed months or years later are termed *recurrent* (Fig. 32-19). Retained or recurrent stones following cholecystectomy are best treated endoscopically. A generous sphincterotomy will allow for stone retrieval as well as spontaneous passage of stones. Alternately, retained stones can be

cleared via a mature T-tube tract (4 weeks) if one was placed at the time of surgery. To do this, the T-tube is removed and a catheter passed through the tract into the common bile duct. Under fluoroscopic guidance, the stones can be retrieved with baskets or balloons. A similar approach will allow for stone clearance by percutaneous transhepatic cholecystostomy (PTC) if there is no other way to reach the duct. Repeat surgery should be a last resort if other interventions have failed.

Cholangitis. Cholangitis is one of the main complications of choledochal stones. Acute cholangitis is an ascending bacterial infection associated with partial or complete obstruction of the bile ducts.⁴³ Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous antegrade bile flow and by the presence of antibacterial substances in bile, such as immunoglobulin. Mechanical hindrance to bile flow facilitates ascending bacterial contamination from the bowel. Positive bile cultures are common in the presence of bile duct stones as well as with other causes of obstruction. Biliary bacterial contamination alone does not lead to clinical cholangitis; the combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis. Other causes include primary sclerosing cholangitis, benign and malignant strictures, parasites, instrumentation of the ducts, and indwelling stents, as well as partially obstructed biliary-enteric anastomoses. The most common organisms cultured from bile in patients with cholangitis include *E coli*, *Klebsiella pneumoniae*, *Streptococcus faecalis*, *Enterobacter*, and *Bacteroides fragilis*.⁴³

Clinical Manifestations Cholangitis may present as anything from a mild, self-limited episode to a fulminant, potentially life-threatening septicemia. Patients with gallstone-induced cholangitis are most commonly older and female. The most common presentation is fever, epigastric or right upper quadrant pain, and jaundice. These classic symptoms, known as *Charcot's triad*, are present in about two-thirds of patients. The illness can progress rapidly with the development of shock and altered mental status, known as *Reynolds' pentad* (e.g., fever, jaundice, right upper quadrant pain, septic shock, and mental status changes). However, the presentation may be atypical, with little if any fever, jaundice, or pain. This occurs most commonly in the elderly, who may have unremarkable symptoms until the process is already quite advanced. Patients with indwelling stents are at particularly high risk for cholangitis, though rarely become jaundiced as a patent stent will prevent the obstruction of bile flow. On abdominal examination, the findings are indistinguishable from those of acute cholecystitis.⁴⁴

Diagnosis Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common and, when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful, as it will document the presence of gallbladder stones, demonstrate dilated ducts, and possibly pinpoint a site of obstruction. CT scanning and MRI can show pancreatic and periampullary masses, if present, in addition to the ductal dilatation. However, abdominal imaging will rarely elucidate the exact cause of cholangitis, and the initial diagnosis is generally made clinically.

Treatment The initial treatment of patients with cholangitis includes broad-spectrum IV antibiotics to cover enteric organisms and anaerobes, fluid resuscitation, and rapid biliary

Figure 32-19. Retained common bile duct stones. The patient presented 3 weeks after laparoscopic cholecystectomy. **A.** An ultrasound shows a normal or mildly dilated common bile duct with a stone. Note the location of the right hepatic artery anterior to the common hepatic duct (an anatomic variation). **B.** An endoscopic retrograde cholangiography from the same patient shows multiple stones in the common bile duct. Only the top one showed on ultrasound as the other stones lie in the distal common bile duct behind the duodenum.

decompression. This is most often accomplished through ERCP and sphincterotomy. ERCP will show the level and the reason for the obstruction, allow for culture of the bile, permit the removal of stones if present, and accomplish drainage of the bile ducts. Placement of drainage catheters or stents can also be performed if needed. In cases in which ERCP is not available, PTC, EUS, or surgical drainage can be utilized. The selection of the appropriate approach will depend on the type and location of the suspected obstruction as well as the availability of local resources and expertise. Cholecystostomy tubes are not indicated in the acute management of cholangitis as the primary source of the infection is extrinsic to the gallbladder.

Patients with cholangitis can deteriorate rapidly and may require intensive care unit monitoring and vasopressor support. However, most patients will respond to biliary decompression and supportive measures. In the current era, acute cholangitis is associated with an overall mortality rate of approximately 5%. When associated with renal failure, cardiac impairment, hepatic abscesses, and malignancies, the morbidity and mortality rates are much higher. Patients who have suffered an episode of acute cholangitis related to gallstone disease should be recommended to undergo elective cholecystectomy approximately 6 weeks after the resolution of their cholangitis.⁴⁵ Those whose cholangitis was related to another cause of biliary obstruction should be followed and treated for the specific etiology of their obstruction but do not necessarily require cholecystectomy if gallstones were not the causative etiology of their cholangitis. Patients with indwelling stents and cholangitis usually require repeated imaging and stent exchange to mitigate the risk of recurrent infections.

Gallstone Pancreatitis. Gallstones in the common bile duct can provoke attacks of acute pancreatitis through transient or persistent obstruction of the pancreatic duct by a stone passing through or impacted in the ampulla. The exact mechanism by which obstruction of the pancreatic duct leads to pancreatitis is unclear, but it may be related to increased ductal pressures causing leakage of pancreatic enzymes into the glandular tissue. The initial management of gallstone pancreatitis is supportive,

including admission for bowel rest, IV hydration, and pain control. Antibiotics are not indicated in the absence of signs of infected pancreatic necrosis. Imaging of the biliary tree with ultrasound, CT, or MRCP is essential to confirm the diagnosis. When gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients, a cholecystectomy with intraoperative cholangiogram is indicated as soon as the pancreatitis has clinically resolved. It is strongly recommended that cholecystectomy be performed during the same admission whenever possible due to the high rate of recurrence and increased morbidity of subsequent attacks of pancreatitis.⁴⁶ If gallstones are present obstructing the duct and the pancreatitis is severe, an ERCP with sphincterotomy and stone extraction may be necessary. This must be balanced with the risk of ERCP-induced pancreatitis and thus is usually only employed if supportive measures are failing.

Gallstone Ileus. Gallstone ileus can occur when a large gallstone erodes through the wall of the gallbladder directly into the intestine via a cholecystoenteric fistula (Fig. 32-20A). These stones can then pass through the intestinal tract until they reach an area of fixed obstruction. Proximal stones can become impacted in the pylorus or proximal duodenum causing gastric outlet obstruction (Bouveret syndrome). Those that travel distally may become lodged at surgical anastomoses or the ileocecal valve, where they can become impacted and cause small bowel obstruction. Gallstone ileus is responsible for less than 1% of all intestinal obstructions.⁴⁷ These patients present with symptoms of obstipation, nausea, and abdominal pain. Plain films may show an obstructive bowel gas pattern but may fail to identify a radiolucent stone. Ultrasound evaluation may be limited by extensive bowel gas. CT is highly sensitive and specific for gallstone ileus and will help to determine the location of the obstruction. Management of gallstone ileus focuses on relieving the intestinal obstruction and removing the stone. In cases of very proximal obstructions in the stomach or duodenum, endoscopic retrieval can be effective. For more distal stones, surgical enterolithotomy can be accomplished either laparoscopically or open. This procedure entails the removal of the stone through

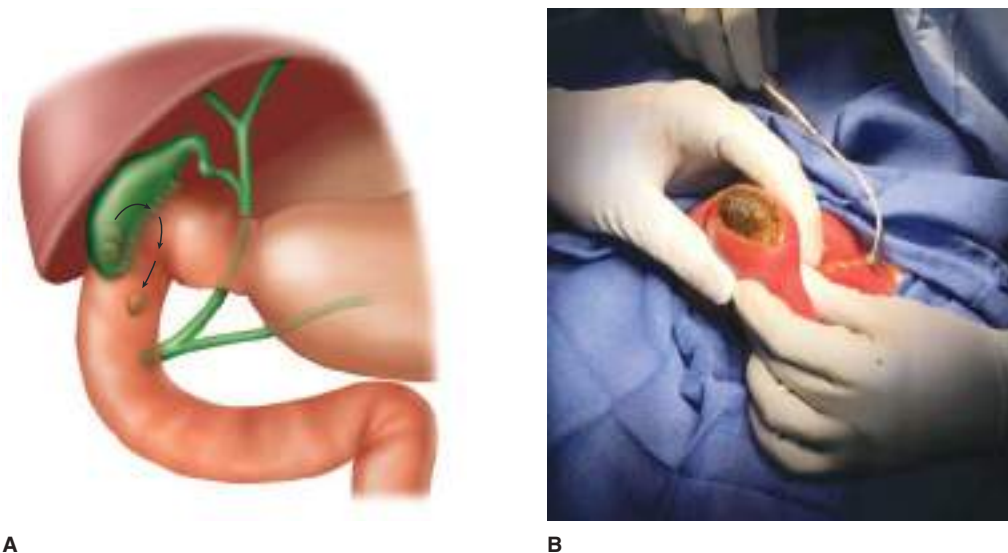

Figure 32-20. Gallstone Ileus. **A.** A cholecystoenteric fistula has formed between the gallbladder and the duodenum, allowing a gallstone to pass into the intestinal tract. **B.** Intraoperative photo showing a longitudinal enterotomy and extraction of an impacted stone from the distal small bowel.

an enterotomy that is then either repaired or resected depending on its size (Fig. 32-20B). Stones that have successfully traversed the ileocecal valve are likely to pass without further intervention. The role of pursuing cholecystectomy and/or choledochenteric fistula closure at the time of enterolithotomy or addressing it at a later time remains a topic of debate, but it should be considered to reduce the risk of recurrence.⁴⁷

Cholangiohepatitis

Cholangiohepatitis, also known as *recurrent pyogenic cholangitis*, is endemic to the Orient. It also has been encountered in Asian population in the United States, Europe, and Australia. It affects both sexes equally and occurs most frequently in the third and fourth decades of life. Cholangiohepatitis is caused by bacterial contamination (commonly *E coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*) of the biliary tree, and often it is associated with biliary parasites such as *Clonorchis sinensis*, *Opisthorchis viverrini*, and *A lumbrioides*. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones, the nucleus of which may contain an adult *Clonorchis* worm, an ovum, or an ascarid. These stones can form throughout the biliary tree and cause partial obstructions that contribute to repeated bouts of cholangitis, biliary strictures, further stone formation, infection, hepatic abscesses, or liver failure (secondary biliary cirrhosis).⁴⁸

Patients with cholangiohepatitis usually present with pain in the right upper quadrant or epigastrium, fever, and jaundice. Relapsing symptoms are one of the most characteristic features of the disease. The episodes may vary in severity but, without intervention, will gradually lead to malnutrition and hepatic insufficiency. An ultrasound may detect stones in the biliary tree, pneumobilia from infection by gas-forming organisms, liver abscesses, and, occasionally, strictures. The gallbladder may be thickened and inflamed in about 20% of patients but rarely contains gallstones. ERCP or MRCP can be utilized for biliary imaging for cholangiohepatitis. They can detect obstructions and define strictures and stones. ERCP (or PTC if necessary) has the additional benefit of allowing for emergent decompression of the biliary tree in the septic patient. Hepatic abscesses may be drained percutaneously. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures, and in severe, refractory cases in which stones and strictures cannot be relieved, it may require a hepaticojejunostomy to reestablish biliary–enteric continuity. Occasionally, resection of involved areas of the liver may offer the best form of treatment. Recurrences are common, and the prognosis is poor once hepatic insufficiency has developed.⁴⁹

PROCEDURAL INTERVENTIONS FOR GALLSTONE DISEASE

Percutaneous Transhepatic Cholecystostomy Tubes

In cases in which a patient with cholecystitis is deemed to be too ill to safely undergo cholecystectomy, a cholecystostomy tube may be placed into the gallbladder to decompress and drain a distended, inflamed, hydropic, or purulent gallbladder.³⁶ Surgical cholecystostomy with a large catheter placed under local anesthesia is rarely required today. Rather, percutaneous transhepatic cholecystostomy (PTC) tubes are most often pigtail catheters inserted percutaneously under ultrasound guidance.⁵⁰

Figure 32-21. Percutaneous cholecystostomy. A pigtail catheter has been placed through the abdominal wall, the right lobe of the liver, and into the gallbladder.

The catheter is inserted over a guidewire that has been passed through the abdominal wall, the liver, and into the gallbladder (Fig. 32-21). By passing the catheter through the liver, the risk of uncontrolled bile leak around the catheter and into the peritoneal cavity is minimized. The catheter can be removed when the inflammation has resolved and the patient's condition has improved. A patent cystic duct should be confirmed by a tube cholangiogram prior to its removal. Interval cholecystectomy should be considered if the patient's fitness has improved, particularly in individuals whose etiology of cholecystitis was gallstones.

Endoscopic Interventions

Endoscopic advances in the last few decades have made endoscopy and ERCP a valuable therapeutic tool in the management of gallstone disease, particularly in the setting of common bile duct stones or abnormalities. Using a 90-degree side-viewing endoscope, the duodenum can be entered and the ampulla of Vater on the medial wall of the second portion of the duodenum visualized. This can then be cannulated to allow wire and catheter access to the biliary tree, facilitating retrograde cholangiogram, diagnostic brushings, stenting, dilations, or fluoroscopically guided basket or balloon retrieval of common bile duct stones. When CBD stones are present, endoscopic sphincterotomy should be performed, which will allow for passage of larger stones both at the time of bile duct clearance and in the case of any ongoing choledocholithiasis (Fig. 32-22). In the hands of experts, ERCP has high rates of successful cannulation and bile duct clearance, and it is a safe and tolerable procedure. Debate remains when comparing ERCP to surgical common bile duct exploration in terms of timing and outcomes for choledocholithiasis, but both are considered acceptable treatments.⁴¹ In special cases, such as the presence of Roux-en-Y anatomy or a previous hepaticojejunostomy, ERCP can be difficult. However, such anatomy does not preclude the option for endoscopic intervention. Laparoscopic-assisted ERCP (in which the remnant stomach is accessed surgically and the endoscope passed into the duodenum) or double-balloon ERCP can be utilized to reach the biliary tree.

Cholecystectomy

Cholecystectomy is one of the most common abdominal surgeries performed in Western countries, with over 750,000

Figure 32-22. An endoscopic sphincterotomy. **A.** The sphincterotome in place. **B.** Completed sphincterotomy. **C.** Endoscopic picture of ampulla before and after sphincterotomy.

being performed each year in the United States alone.⁵¹ Carl Langenbuch performed the first successful open cholecystectomy in 1882, and for >100 years, it was the standard treatment for symptomatic gallbladder stones. In 1987, laparoscopic cholecystectomy was introduced by Philippe Mouret in France and quickly revolutionized the treatment of gallstone disease. It not only supplanted open cholecystectomy, but it also more or less ended attempts for noninvasive management of gallstones (such as extracorporeal shock wave or cholangioscopic lithotripsy) or medical therapies (such as bile salts). Laparoscopic cholecystectomy offers a cure for gallstones with a minimally invasive procedure, minor pain and scarring, and early return to full activity. Today, laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones and the complications of gallstone disease.

Few absolute contraindications exist to laparoscopic cholecystectomy, but they include hemodynamic instability, uncontrolled coagulopathy, or frank peritonitis. In addition, patients with severe obstructive pulmonary disease (COPD) or congestive heart failure (e.g., cardiac ejection fraction <20%) might not tolerate the increased intraabdominal pressures of pneumoperitoneum with carbon dioxide and may require open cholecystectomy. Conditions formerly believed to be relative contraindications such as acute cholecystitis, gangrene and empyema of the gallbladder, biliary-enteric fistulae, obesity, pregnancy, ventriculoperitoneal shunts, cirrhosis, and previous upper abdominal procedures are now considered risk factors for a potentially difficult cholecystectomy, but they do not preclude

an attempt at laparoscopy. While laparoscopic outcomes have steadily improved and laparoscopic cholecystectomy has been shown multiple times to be safe and feasible, conversion to an open operation should always remain an option, and it is not a failure. Conversion to open may be necessary if the patient is unable to tolerate pneumoperitoneum, a complication occurs that cannot be fixed laparoscopically, important anatomic structures cannot be clearly identified, or when no progress is made over a set period of time. In the elective setting, conversion to an open procedure is needed in about 5% of patients.⁵¹ Emergent procedures or patients with complicated gallstone disease can be more challenging, and the incidence of conversion has been reported to be between 10% and 30%. The possibility of conversion to open should always be discussed with the patient preoperatively.

Serious complications of cholecystectomy are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1%. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure.⁵² While laparoscopic cholecystectomy has historically been associated with a higher rate of injury to the bile ducts than the open approach, modern data appears to show this trend disappearing as familiarity with laparoscopic techniques and technologies have improved.⁵³

Patients undergoing cholecystectomy should have a complete blood count and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low molecular weight heparin or compression stockings is indicated.

The patient should be instructed to empty their bladder before coming to the operating room to avoid the need for urinary catheterization. An orogastric tube can be placed if the stomach is distended with gas, but it is generally removed at the end of the operation.

Laparoscopic Cholecystectomy. The patient is typically positioned supine with the operating surgeon standing at the patient's left side. Split-leg positioning with the surgeon standing between the patient's legs can also provide ergonomic access to the right upper quadrant. Tucking one arm can be helpful if a cholangiogram is planned to allow easier maneuvering of the fluoroscopy machine around the patient. Pneumoperitoneum is established with carbon dioxide gas, either with an open technique (Hasson), optical viewing trocar, or

closed-needle technique (Veress). Typical access is at the supraumbilical region, though in the case of previous surgery or scars, alternate access sites should be considered. Once an adequate pneumoperitoneum is established, a 5- or 10-mm trocar is inserted through the supraumbilical incision, through which a 5- or 10-mm 30° laparoscope is introduced. Traditionally, three additional ports are then placed with a 10- or 12-mm port in the epigastrium, a 5-mm port in the right midclavicular line, and a 5-mm port in the right flank (Fig. 32-23). Additional ports may be placed as needed to aid with retraction in difficult cases.

Through the lateral-most port, the assistant uses a locking instrument to grasp the gallbladder fundus and retract it over the liver edge and upward towards the patient's right shoulder. This will help visualize the body of the gallbladder and the hilar area. Exposure may be facilitated by placing the patient

Figure 32-23. Laparoscopic cholecystectomy. **A.** The trocar placement. **B.** The fundus has been grasped and retracted cephalad to expose the proximal gallbladder and the hepatoduodenal ligament. Another grasper retracts the gallbladder infundibulum posterolaterally to better expose the triangle of Calot (hepatocystic triangle bound by the common hepatic duct, cystic duct, and liver margin). **C.** Intraoperative photo of the critical view of safety. The hepatocystic triangle has been cleared of fat and fibrous tissue, the lower one-third of the gallbladder is separated from the liver to expose the cystic plate, and two and only two structures are seen entering the gallbladder. **D.** A clip is being placed on the cystic duct–gallbladder junction. **E.** A small opening has been made in the cystic duct, and a cholangiogram catheter is being inserted. **F.** Additional clips have been placed, the cystic duct has been divided, and the cystic artery is being divided.

in reverse Trendelenburg position with slight tilting of the table to bring the right side up. Through the midclavicular port, the surgeon uses a grasper in the left hand to retract the gallbladder infundibulum laterally and expose the neck of the gallbladder and hepatoduodenal ligament. It may be necessary to take down any adhesions between the omentum, duodenum, or colon to the gallbladder in order to reach the infundibulum. The majority of the dissection can then be performed with the right hand through the epigastric port, utilizing a combination of electrocautery and sharp and blunt dissection.

Dissection starts at the infundibulum of the gallbladder, just above the takeoff of the cystic duct. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct–gallbladder junction is dissected off and reflected inferiorly toward the bile duct. This is continued until the gallbladder neck and the proximal cystic duct are clearly identified. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct, and often lies behind a prominent lymph node (Lund’s node, often called Calot’s node). At this point, a critical view of safety should be obtained. This requires that the hepatocystic triangle is cleared of fat and fibrous tissue, the lower third of the gallbladder is separated from the liver to expose the cystic plate, and two and only two structures (cystic duct and cystic artery) are going into the gallbladder (see Fig. 32-19).⁵⁴ At this point, an intraoperative cholangiogram can be performed if indicated (see “Intraoperative Cholangiogram” section).

With a critical view of safety obtained, the cystic duct and artery are clipped with two clips at the base and one clip on the gallbladder side. They can then be safely divided. Sometimes, a very dilated cystic duct may be too large for clips. Such ducts can be successfully managed by ligation with an endoloop, laparoscopic stapler, or suture closure. Finally, the gallbladder is dissected off the liver bed using electrocautery while watching for potential abnormal posterior branches of ducts or arteries. Before the gallbladder is completely removed from the liver edge, it can be used as a retractor for a final evaluation of the operative field. The surgeon should be sure to evaluate for bleeding points or bile staining, and confirm placement of the clips on the cystic duct and artery. The gallbladder is then divided from its final attachments and removed either through the epigastric or umbilical incision, often with the aid of a retrieval bag. The fascial defect and skin incision may need to be enlarged in order to remove the specimen, particularly if the stones are large or the gallbladder is very inflamed. Any bile or blood that has accumulated during the procedure should be cleaned away, and if stones were spilled, they should be retrieved and removed. If the gallbladder was severely inflamed or gangrenous, or if any bile or blood is expected to accumulate, a closed-suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa, though this is not routinely required.

Open Cholecystectomy. The same surgical principles apply for laparoscopic and open cholecystectomies. Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. The approach can either be through a midline laparotomy, or more commonly through a right subcostal incision. The gallbladder is dissected free from the liver bed, usually starting at the fundus and working proximally toward the

hepatocystic triangle. Once the cystic artery and cystic duct have been dissected and clearly identified, they are ligated and divided, and the gallbladder is removed. In particularly difficult cases, in which the gallbladder is partially obliterated or ductal or arterial anatomy cannot be identified, a partial cholecystectomy may be performed. This includes removal of as much gallbladder mucosa as possible and attempted closure of the cystic duct stump with wide drainage of the area.

Intraoperative Cholangiogram. Intraoperative cholangiogram is an optional but valuable tool for evaluating the extrahepatic bile ducts, identifying common bile duct stones, or clarifying aberrant ductal anatomy. The use of routine versus selective cholangiography remains a topic of debate with a lack of definitive evidence on either side.⁵⁵⁻⁵⁷ However, routine intraoperative cholangiography will detect stones in approximately 7% of patients, and it assists with outlining anatomy and detecting injury.⁵⁸ Selective intraoperative cholangiogram should be performed when the patient has a history of abnormal liver function tests, pancreatitis, jaundice, a large duct and small stones, a dilated duct on preoperative ultrasonography, or if preoperative endoscopic cholangiography for the aforementioned reasons was unsuccessful. Although there is no consensus recommendation on the use of routine versus selective cholangiography, all surgeons performing cholecystectomy should be familiar with the procedure. If a cholangiogram is to be performed, a clip is placed on the proximal cystic duct, and a small incision is made on its anterior surface, just inferior to the clip. A cholangiogram catheter is passed into the cystic duct and secured with a clamp or clip. The fluoroscopy machine is then positioned over the patient and a cholangiogram performed by injection of contrast through the cholangiocatheter during live fluoroscopic dynamic imaging. An ideal cholangiogram includes filling of the right and left hepatic ducts, emptying into the duodenum, and no visualized filling defects (Fig. 32-24). Care must be taken not to introduce air bubbles into the system during contrast injection as these will appear as filling defects on the cholangiogram images. If no contrast is visualized in the duodenum, a dose of glucagon can be utilized to relax the sphincter of Oddi and facilitate contrast flow. Once the cholangiogram is completed, the catheter is removed. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones, and it is less invasive. However, it requires more skill to perform and interpret and is not always readily available.⁵⁹

Common Bile Duct Exploration

Common bile duct stones that are detected pre- or intraoperatively may be managed with common bile duct exploration (CBDE) at the time of the cholecystectomy. While preoperative ERCP is also an appropriate option for known bile duct stones, laparoscopic CBDE can be used as a primary approach to choledocholithiasis safely and with good outcomes, even in higher risk populations such as the elderly.⁶⁰ If stones in the duct are small, they may sometimes be simply flushed into the duodenum with saline irrigation via the cholangiography catheter. This can be facilitated by the administration of IV glucagon to relax the sphincter of Oddi. If irrigation is unsuccessful, several options exist to clear the duct, including fluoroscopic or endoscopic approaches.

With access to the cystic duct by a small ductotomy, a balloon catheter is used to dilate the cystic duct, and a wire basket can be passed down the common bile duct under fluoroscopic

A

B

Figure 32-24. **A.** An intraoperative cholangiogram. The bile ducts are of normal size, with no intraluminal filling defects. The left and the right hepatic ducts are visualized, the distal common bile duct tapers down, and the contrast empties into the duodenum. Cholangiography grasper that holds the catheter and the cystic duct stump partly projects over the common hepatic duct. **B.** An intraoperative cholangiogram showing a common bile duct stone (*arrow*) with very little contrast passing into the duodenum.

guidance to catch and remove the stones (Fig. 32-25). Alternatively, endoscopic evaluation with a flexible choledochoscope will allow for direct visualization and retrieval of the stones within the common duct. To do this, reliable catheter access must be obtained with an introducer sheath placed either through one of the laparoscopic ports or a new stab incision in the anterior abdominal wall. The cystic duct should first be dilated with a small balloon catheter to allow for passage of the introducer and scope and for effective retrieval of larger stones. Once the scope is within the common bile duct, irrigation is used to distend the lumen. Stones may then be caught in a wire basket under direct visualization or simply pushed into the duodenum. Once the common bile duct has been cleared of stones, the cystic duct is ligated below the level of the ductotomy and divided, and the cholecystectomy is completed.

While the cystic duct is the preferred route of access for common bile duct exploration, occasionally an incision into the common bile duct itself (choledochotomy) is necessary. The flexible choledochoscope is then passed into the duct for visualization and clearance of stones. The choledochotomy can be closed primarily if the duct is very large, or over a T-tube. If available, common bile duct exploration can be highly advantageous as it provides the opportunity to treat the entirety of the disease in a single event, rather than subjecting patients to multiple procedures. However, the procedure can be technically challenging to perform and requires the availability of the proper equipment and surgical expertise.⁶¹

Common Bile Duct Drainage Procedures

In very rare cases in which stones or obstructions cannot be cleared by either ERCP with sphincterotomy or CBDE, and the patient is suffering clinical effects from their common bile duct stones, an additional choledochal drainage procedure may become necessary. In the case of an open operation,

transduodenal sphincterotomy can be attempted by incising the duodenum transversely and cutting the sphincter of Oddi at the 11 o'clock position, taking care to avoid injury to the pancreatic duct. The impacted stones can then be manually removed or simply allowed to pass through the sphincterotomy.

Bypass procedures can also be used to restore continuity of bile flow in the setting of irretrievable impacted stones. For short distance bypasses, a Choledochoduodenostomy is performed by mobilizing the second part of the duodenum (a Kocher maneuver) and anastomosing it side to side with the common bile duct (Fig. 32-26A-C). If the distance is too great to safely complete a choledochoduodenostomy without tension, a choledochojejunostomy can be done by bringing up a roughly 45-cm limb of jejunum and anastomosing it end to side to the common bile duct (Fig. 32-26D-E). If the entirety of the extrahepatic biliary tree must be bypassed, hepaticojejunostomy allows for drainage of the hepatic ducts directly into a loop of jejunum (Fig. 32-26F-G). These choledochal drainage procedures can also be used to manage common bile duct strictures or as a palliative procedure for malignant obstruction in the periampullary region.

OTHER BENIGN DISEASES AND LESIONS

Biliary Dyskinesia and Sphincter of Oddi Dysfunction

Biliary dyskinesia is an umbrella term that refers to disorders affecting the normal motility and function of the gallbladder and sphincter of Oddi. These disorders are becoming increasingly recognized as improvements in imaging allow for more detailed evaluations of biliary tract function. Patients with biliary dyskinesia may present with typical biliary type symptoms, but without evidence of stones or sludge on abdominal imaging.

Figure 32-25. Laparoscopic common bile duct exploration. **I.** Transcystic basket retrieval using fluoroscopy. **A.** The basket has been advanced past the stone and opened. **B.** The stone has been entrapped in the basket, and together, they are removed from the cystic duct. **II.** Transcystic choledochoscopy and stone removal. **C.** The basket has been passed through the working channel of the scope, and the stone is entrapped under direct vision. **D.** Entrapped stone. **E.** A view from the choledochoscope with stone captured in basket. **III.** Choledochotomy and stone removal. **F.** A small incision is made in the common bile duct. **G.** The common bile duct is cleared of stones.

A decreased gallbladder ejection fraction on HIDA scanning (EF <35%) is considered diagnostic of biliary dyskinesia. In these patients, studies suggest that symptoms will be improved or resolved by cholecystectomy in up to 90% of cases.⁶²

Sphincter of Oddi dysfunction can occur as a primary presentation of episodic biliary type pain with abnormal liver function tests or as recurrent biliary type pain after cholecystectomy. More severe cases may present with recurrent jaundice or pancreatitis. If other causes are ruled out, such as retained stones, strictures or periampullary tumors, a stenotic or dyskinetic sphincter of Oddi should be suspected. A benign stenosis of the outlet of the common bile duct is usually associated with inflammation, fibrosis, or muscular hypertrophy. The pathogenesis is unclear, but trauma from the passage of stones, sphincter motility disorders, and congenital anomalies have been suggested. A dilated common bile duct that is difficult to cannulate during ERCP or delayed emptying of contrast from the biliary tree after ERCP are useful diagnostic features. Ampullary manometry and specific provocation tests are available in specialized units to aid in the diagnosis. Once identified, sphincterotomy will typically yield good results.⁶³

Acalculous Cholecystitis

Acalculous cholecystitis is an acute inflammation of the gallbladder that occurs in the absence of gallstones. It is a rare entity that typically develops in critically ill patients in the intensive care unit.⁶⁴ Patients on parenteral nutrition, with extensive burns, sepsis, major operations, multiple trauma, or prolonged illness with multiple organ system failure are at risk for developing acalculous cholecystitis. The cause is unknown, but gallbladder distention, bile stasis, and ischemia have been implicated as causative factors. After resection, pathologic examination of the gallbladder wall after an episode of acalculous cholecystitis reveals edema of the serosa and muscular layers, with patchy thrombosis of arterioles and venules.⁶⁵

The ability to recognize the symptoms and signs of acalculous cholecystitis can depend on the condition and mental status of the patient, but acalculous cholecystitis can be similar to acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. In the sedated or unconscious patient, the clinical features are often masked, but fever and elevated WBC count, as well as elevation of alkaline phosphatase and bilirubin, are indications for

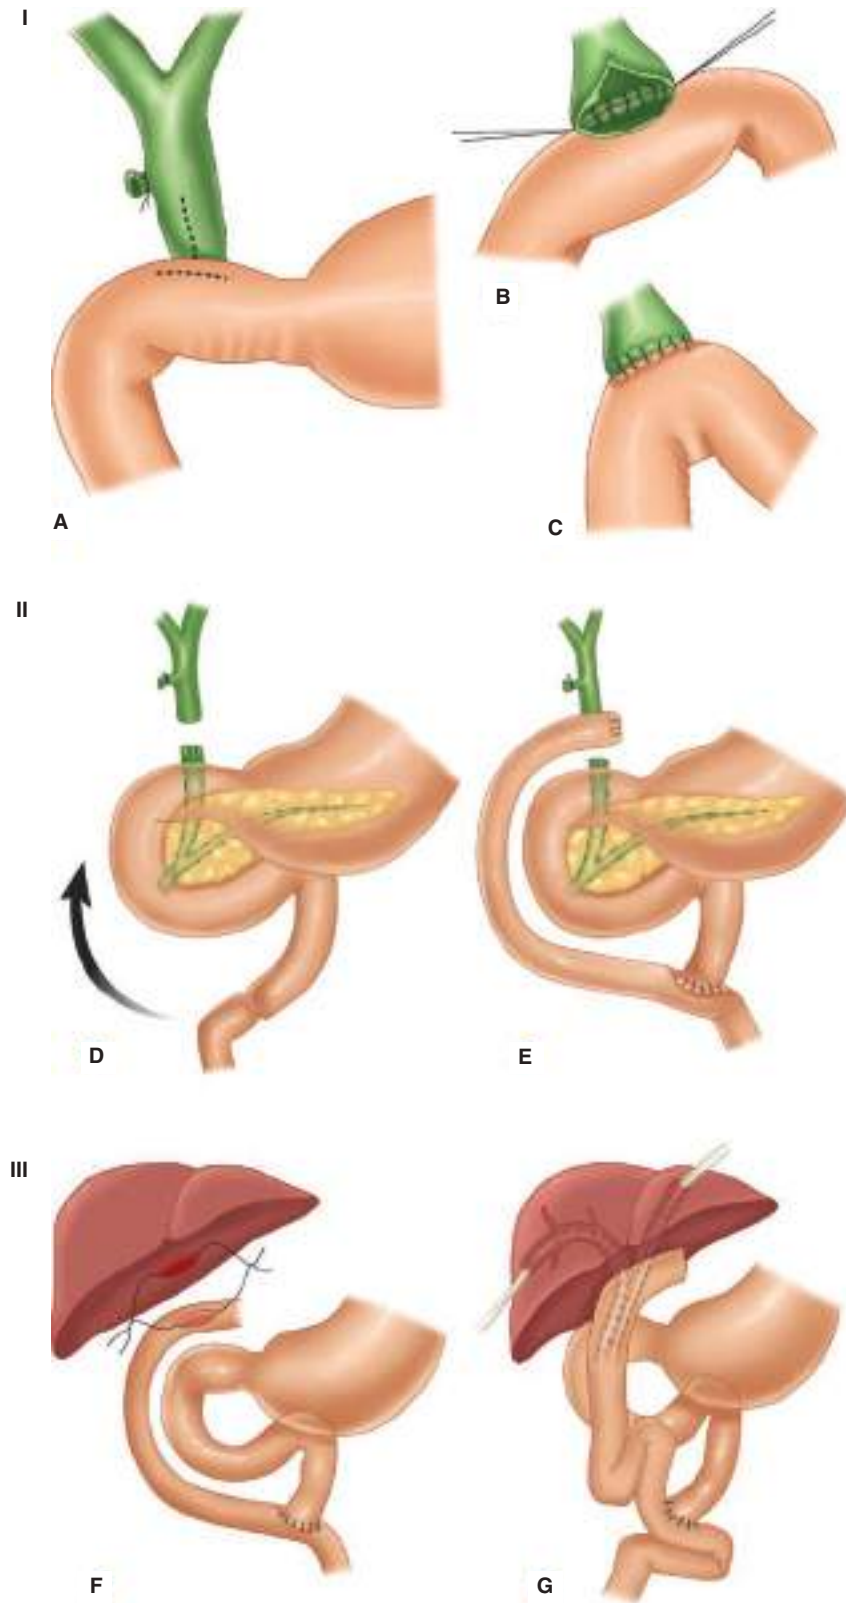

Figure 32-26. Biliary enteric anastomoses. There are three types. I. Choledochoduodenostomy. **A.** The distal common bile duct is opened longitudinally, as is the duodenum. **B.** Interrupted sutures are placed between the common bile duct and the duodenum. **C.** Completed choledochoduodenostomy. II. Choledochojejunostomy. **D.** The common bile duct and small bowel are divided. **E.** A limb of jejunum is brought up in a Roux-en-Y configuration and anastomosed to the bile duct. III. Hepaticojejunostomy. **F.** The entire extrahepatic biliary tree has been resected and the reconstruction completed with a Roux-en-Y limb of jejunum. **G.** Percutaneous transhepatic stents are placed across hepaticojejunostomy (optional).

further investigation. Ultrasonography is usually the diagnostic test of choice, as it can be done bedside in the intensive care unit. It can demonstrate the distended gallbladder with thickened wall, biliary sludge, pericholecystic fluid, and the presence or absence of abscess formation. CT scanning can aid in the diagnosis of acalculous cholecystitis and additionally allows a more general evaluation of the abdomen and chest to rule out other sources of infection. A HIDA scan can also be useful if it shows nonvisualization of the gallbladder, but it is less sensitive and can have higher false-positive rates in patients who are in a prolonged fasting state, on total parenteral nutrition, or have liver disease. Once the diagnosis is confirmed, acalculous cholecystitis requires urgent intervention as rapid deterioration can occur. This should include early broad-spectrum antibiotics and fluid resuscitation. If the patient is stable to undergo an abdominal operation, laparoscopic cholecystectomy is the most definitive treatment, and it can be safely performed even in the setting of severe acute inflammation.⁶⁴ However, if patients are critically ill and unfit for surgery, percutaneous cholecystostomy is the best treatment choice (see Fig. 32-18). About 90% of patients will improve with a percutaneous cholecystostomy tube. Interval cholecystectomy can be discussed with the patient after they have recovered from their acute illness, but it is not strictly required in the absence of gallstone or other identified gallbladder pathology.

Choledochal (Biliary) Cysts

Choledochal cysts are congenital cystic dilatations of the extrahepatic and/or intrahepatic biliary tree. They are rare, with an incidence of between 1:100,000 and 1:150,000 in populations of Western countries, but are more common in populations of Eastern countries occurring in as many as 1:1000 individuals. Choledochal cysts affect females three to eight times more often than males. Although frequently found in infancy or childhood, nearly one-half are diagnosed in adults. The cause is unknown, but it is believed that weakness of the bile duct wall and increased pressure secondary to partial biliary obstruction can contribute to biliary cyst formation. More than 90% of patients have an anomalous pancreaticobiliary duct junction, with the pancreatic duct joining the common bile duct outside the duodenal wall, creating a long common channel (>1.5 cm). This may allow free reflux of pancreatic secretions into the biliary tract, leading to inflammatory changes, increased biliary pressure, and cyst formation. The cysts are lined with cuboidal epithelium and can vary in size from small dilatations to giant cystic masses. The typical clinical triad of biliary cysts includes abdominal pain, jaundice, and a palpable mass, though this constellation is seen in less than one-half of patients. Adults may present with cholangitis. Blood tests will often be normal though elevations of transaminases can be seen in cases of infection or obstruction. Ultrasonography or CT scanning will confirm the diagnosis, but ERCP or MRCP are essential to formally assess the biliary anatomy and to plan the appropriate surgical treatment. The risk of cholangiocarcinoma in patients with choledochal cysts is 20- to 30-fold higher than in the general population and varies with the patient's age and type of cyst. For this reason, excision is recommended whenever possible when high-risk choledochal cysts are diagnosed.

Choledochal cysts are classified into five types depending on the location and structure of the cysts. The subcategories of choledochal cysts are defined in Fig. 32-27. Type I cysts

(fusiform CBD dilations) are the most common form, accounting for approximately 50% of cases, and have the highest risk of malignancy (>60%). For types I and II (saccular diverticula of the common bile duct), excision of the cystic dilations in the extrahepatic biliary tree, including cholecystectomy, with either simple cyst excision or duct resection with Roux-en-Y hepaticojejunostomy is ideal. Type III cysts (intraduodenal) create a treatment challenge as full resection would require pancreaticoduodenectomy. Given that type III cysts are associated with the lowest malignancy risk of any choledochal cyst (~2%), sphincterotomy and surveillance is generally recommended over formal excision.⁶⁶ In Type IV (multiple cysts), excision of all cystic tissue and reconstruction is again recommended. For type IVa, which is characterized by multiple cysts with intrahepatic involvement, additional segmental resection of the liver may be required if intrahepatic stones, strictures, or abscesses are present. Type V choledochal cysts (Caroli disease) are very rare and account for less than 1% of patients with choledochal cysts. These cysts are multiple and can affect the entire liver. In advanced stages, this may result in cirrhosis and liver failure necessitating liver transplantation.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to bile duct stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed *secondary sclerosing cholangitis*. However, primary sclerosing cholangitis is a disease entity of its own, with no clear attributing cause. Autoimmune reaction, chronic low-grade bacterial or viral infection, toxic reaction, and genetic factors have all been suggested to play a role in its pathogenesis. PSC is commonly associated with other autoimmune diseases including ulcerative colitis in about two-thirds of patients, Riedel's thyroiditis, and retroperitoneal fibrosis. The human leukocyte antigen haplotypes HLA-B8, DR3, DQ2, and DRw52A, commonly found in patients with autoimmune diseases, also are more frequently seen in patients with primary sclerosing cholangitis than in controls. The mean age of presentation for PSC is 30 to 45 years, and men are affected twice as often as women. Most patients are symptomatic when diagnosed, and may complain of intermittent jaundice, fatigue, weight loss, pruritus, or abdominal pain. Initial presentation with acute cholangitis is rare without preceding biliary tract intervention or surgery. A minority of patients are diagnosed incidentally by elevated liver function tests, particular when found in a patient with ulcerative colitis. While the clinical presentation and laboratory results may suggest the PSC, ERCP revealing multiple dilatations and strictures (beading) of the intra- and extrahepatic biliary tree confirms the diagnosis. The hepatic duct bifurcation is often the most severely affected segment. A liver biopsy may not be diagnostic, but it is important to determine the degree of hepatic fibrosis and the presence of cirrhosis.

The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. Some patients will remain asymptomatic for years, while others progress rapidly with the obliterative inflammatory changes leading to secondary biliary cirrhosis and liver failure. In patients with associated ulcerative colitis, the course of each disease seems independent of the other and colectomy has no effect on the

Figure 32-27. Classification of choledochal cysts. Type I, fusiform or cystic dilations of the extrahepatic biliary tree, is the most common type, making up >50% of the choledochal cysts. Type II, saccular diverticulum of an extrahepatic bile duct. Rare, <5% of choledochal cysts. Type III, bile duct dilatation within the duodenal wall (choledochoceles), makes up about 5% of choledochal cysts. Types IVa and IVb, multiple cysts, make up 5% to 10% of choledochal cysts. Type IVa affects both extrahepatic and intrahepatic bile ducts, whereas type IVb cysts affect the extrahepatic bile ducts only. Type V (Caroli disease), intrahepatic biliary cysts, is very rare and makes up 1% of choledochal cysts.

course of primary sclerosing cholangitis. Of the patients with sclerosing cholangitis, 10% to 15% will develop cholangiocarcinoma, which can present at any time during the disease process and does not necessarily correlate with the extent of the sclerosing cholangitis or the development of liver failure.⁶⁷ Cholangiocarcinoma in the setting of PSC frequently follows an aggressive course. Patients need to be followed by serial ERCP and liver biopsies to evaluate for the development of complications such as strictures, cancers, or cirrhosis.

There is no known curative treatment for primary sclerosing cholangitis and medical management is largely supportive. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been attempted with disappointing results. If biliary strictures occur, they can be dilated and stented either endoscopically or percutaneously. These measures have given short-term improvements in symptoms and serum bilirubin levels but provide long-term results in less than half of patients. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures, but without cirrhosis or significant hepatic fibrosis.⁶⁸ In patients with primary sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results, with overall 5-year survival as high as 85%. Unfortunately, recurrence of PSC can occur in 10% to 20% of patients and may require retransplantation.⁶⁸

Bile Duct Strictures

Benign bile duct strictures can have numerous causes. However, the vast majority are related to operative injury, most commonly during cholecystectomy. Other causes include fibrosis due to chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction due to cholelithiasis (Mirizzi's syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed can lead to severe complications such as recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.⁶⁹

Bile duct strictures most commonly result in recurrent episodes of cholangitis but may present with isolated jaundice without infection. Liver function tests usually show evidence of cholestasis with elevations of bilirubin and alkaline phosphatase. Imaging with ultrasound or CT can show dilated bile ducts proximal to the stricture, as well as provide information about the level of the stenosis. MRCP gives more detailed anatomic information about the location and the degree of dilatation. If the diagnosis remains in question, cholangiography (endoscopic or more rarely percutaneous) will outline the biliary tree, define the stricture and its location, and allow for therapeutic interventions (Fig. 32-28). The treatment of biliary strictures depends on the location and the cause of the stricture. Percutaneous or endoscopic dilatation and/or stent placement will provide good results in more than one half of

Figure 32-28. An endoscopic retrograde cholangiography showing stricture of the common hepatic duct (*arrow*). The patient had recently had a laparoscopic cholecystectomy; clips from the operation can be seen projected over the common bile duct.

patients. For persistent or complex strictures, surgical resection and reconstruction with Roux-en-Y choledochojejunostomy or hepaticojejunostomy may be necessary and will result in good or excellent outcomes in 80% to 90% of patients.⁷⁰ Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct if a tension free repair can be achieved.

INJURY TO THE BILIARY TRACT

Gallbladder

Injuries to the gallbladder itself are uncommon but can occur in the setting of penetrating trauma (gunshot or stab wounds) or medical procedures (liver biopsy or surgery). Nonpenetrating trauma to the gallbladder is extremely rare but can cause contusion, avulsion, laceration, rupture, or traumatic cholecystitis. Regardless of the etiology of gallbladder injury, the treatment of choice is cholecystectomy. The prognosis is typically good but depends on the extent of related injury, as damage to nearby organs is not uncommon.

Extrahepatic Bile Ducts

Rarely, penetrating trauma to the extrahepatic bile ducts does occur, and it is usually associated with trauma to other viscera. The vast majority of injuries to the extrahepatic biliary system, however, are iatrogenic, usually occurring during cholecystectomy. These injuries are among the most feared and litigated complications in surgery, and can result in significant morbidity.^{71,72} Biliary tract injury can also occur during

common bile duct exploration, division or mobilization of the duodenum during gastrectomy, or dissection of the hepatic hilum during liver resections.

4▶ The incidence of bile duct injury during cholecystectomy is estimated to be relatively low (about 0.2%).⁷³ While initial experience with laparoscopic cholecystectomy appeared to show a higher rate of injury to the bile ducts compared to the open approach, these trends appear to be disappearing as laparoscopic technology and familiarity with the techniques of the procedure have improved.⁵³ A number of different factors are thought to be associated with bile duct injury during laparoscopic cholecystectomy. These include acute or chronic inflammation, obesity, anatomic variations, and surgical technique. Inadequate exposure or failure to correctly identify structures before ligating or dividing them are the most common causes of significant biliary injury (see “Anatomic Variants” section). Excessive cephalad retraction of the gallbladder may align the cystic duct with the common bile duct, and the latter may then be mistakenly clipped and divided. Careless use of electrocautery can lead to thermal injury. Dissection deep into the liver parenchyma may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.^{74,75}

Techniques to avoid injury to the bile ducts during cholecystectomy are important to understand. The use of an angled, 30° or 45° laparoscope instead of an end-viewing camera will help visualize the anatomic structures, in particular those around the triangle of Calot. An angled scope also will aid in the proper placement of clips. The routine use of intraoperative cholangiography during every cholecystectomy as a method to prevent bile duct injury remains controversial.⁵⁵ Nonetheless, the frequency of bile duct injuries is cut by 50% when an intraoperative cholangiogram is performed. Critical to the successful use of cholangiography is accurate interpretation of the imaging. It is important to check that the whole biliary system fills with contrast, including both major ducts on the right and the left hepatic duct, and that there is no extravasation of contrast. While routine use may reduce or limit the extent of injury, or help identify it early, it does not seem to prevent it entirely.⁷⁶ No consensus recommendation exists on the use of selective versus routine cholangiography.

Perhaps the most universally agreed upon method for mitigating the risk of bile duct injury during laparoscopic cholecystectomy is obtaining the critical view of safety. This requires that the hepatocystic triangle is dissected free of fat and fibrous tissue, the lower third of the gallbladder is separated from the cystic plate, and there are two and only two structures running into the gallbladder, the cystic duct, and the cystic artery (see Fig. 32-23).⁵⁴ Newer technologies such as fluorescence cholangiography to help identify biliary anatomy intraoperatively have shown promising early results, though large-scale applications remain to be seen.⁷⁷

Diagnosis. Only about 25% of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of surgery. In these cases, intraoperative bile leakage, recognition of the correct anatomy, or an abnormal cholangiogram led to the diagnosis of a bile duct injury. In those that go unrecognized at the time of surgery, more than half will re-present within the first month postoperatively, though some can present months or years later with strictures, cholangitis, or cirrhosis from a remote bile duct injury.

A

B

Figure 32-29. A. Computed tomographic scan of a patient with bile leak after cholecystectomy. The *short arrows* indicate the intraperitoneal collections. Both air and bile are seen in the gallbladder bed (*long arrow*) as well as a surgical clip. B. An endoscopic retrograde cholangiography from the same patient showing contrast extravasation from the cystic duct stump (*arrow*). Note the filling of the pancreatic duct.

Bile duct injuries typically result in either leaks or obstructions related to strictures. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct, usually presents with abdominal pain, fever, and a mild elevation of liver function tests. If a drain was placed at the time of surgery, bilious fluid may be seen. A CT scan or ultrasound can show either a fluid collection in the gallbladder fossa (biloma), or free fluid (bile) in the peritoneum (Fig. 32-29A). ERCP (Fig. 32-29B) or HIDA scan can be utilized to better localize the site of the bile leak.

Obstruction or stricture should be suspected in patients with progressive elevations of liver function tests or jaundice after cholecystectomy. CT scan or ultrasound can demonstrate the dilated part of the biliary tree, and may identify the level of the bile duct obstruction. MRI cholangiography, if available, provides an excellent, noninvasive delineation of the biliary anatomy both proximal and distal to the injury. Endoscopic or percutaneous cholangiography may also be helpful to confirm the diagnosis, depending on the location and type of injury.

Management. The management of bile duct injuries depends on the type, extent, and level of the injury, as well as the timing of its diagnosis. Initial proper treatment of bile duct injury can avoid the development of further complications or bile duct strictures. If an injury is discovered that exceeds the capacity of the available surgical expertise, the patient should be transferred to a tertiary care center. In these situations, drains should be placed in the surgical bed and antibiotics initiated. If a complete obstructive transection has occurred, it may also be necessary to place a percutaneous transhepatic drainage catheter to decompress the biliary tree prior to transfer.

If identified at the time of surgery, bile leaks from small bile ducts (<3 mm) or those draining a single hepatic segment can safely be ligated. If the injured duct is ≥ 4 mm, however, it is likely to drain multiple segments or an entire lobe and thus needs to be repaired or reimplanted. Minor injuries to the common bile duct or the common hepatic duct are traditionally managed with placement of a T-tube that has been modified by cutting the ends to allow for its placement in and removal from the bile duct (see Fig. 32-18). If the injury is small, the T-tube may be placed through it as if it were a formal choledochotomy.

In more extensive injuries, the T-tube should be placed through a separate choledochotomy and the injury closed over the T-tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries identified intraoperatively such as complete transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries, the bile duct has not only been transected, but a variable length of the duct may have been removed with the surgical specimen. This injury usually requires reconstruction with a biliary-enteric anastomosis, and is best performed as soon as possible following the injury. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a T-tube that is placed through a separate incision. In any repair that is chosen, it is critical to perform a tension-free anastomosis to minimize the high risk of postoperative stricture formation.

Bile leaks identified postoperatively can usually be managed with percutaneous drainage of intra-abdominal fluid collections followed by endoscopic biliary stenting. With most leaks, regardless of the location, stenting of the common bile duct will provide a low resistance route for bile flow into the duodenum, decreasing flow through the leak and allowing it to heal. This is particularly effective for leaks from the cystic duct stump. Rarely, surgery is required to repair a large leak if endoscopic interventions have failed or peritonitis is present.

Major bile duct injuries diagnosed in the later postoperative period may not be amenable to immediate reconstruction due to acute inflammation. They may need to be managed with transhepatic biliary catheter placement for biliary decompression as well as percutaneous drainage of intra-abdominal bile collections, if any. When the acute inflammation has resolved 6 to 8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes endoscopic attempts at dilation or stenting. Balloon dilatation of a stricture usually requires multiple procedures and rarely provides long-term relief. Self-expanding metal or plastic stents can provide temporary or, in the high-risk patient, permanent drainage of the biliary tree. If the stricture is unable to be addressed endoscopically,

percutaneous transhepatic biliary drainage catheter placement may be necessary for decompression, and to define the anatomy, location and extent of the damage. Definitive treatment of refractory biliary strictures entails resection of the affected segment and reconstruction with a biliary-enteric anastomosis.

Outcome. Good results can be expected in the majority of patients with bile duct injuries, with the best results coming when the injury is recognized immediately and repaired by an experienced biliary tract surgeon.⁷⁸ The perioperative mortality rate is reported to be less than 10%, but common morbidities associated with bile duct repairs include cholangitis, external biliary fistula, bile leak, subhepatic and subphrenic abscesses, and hemobilia. Restenosis of a biliary enteric anastomosis occurs in about 10% of patients, and typically presents within 2 years, but can manifest up to 20 years after the initial procedure. In general, treatment of proximal strictures is associated with a lower success rate than distal ones. The worst results are seen in patients with many operative revisions and in those who have evidence of liver failure or portal hypertension. However, previous repair does not preclude a successful outcome, particularly in patients with good liver function. In the most severe cases, patients with refractory strictures and deteriorating liver function may become candidates for liver transplant.

TUMORS

Carcinoma of the Gallbladder

Cancer of the gallbladder is a rare malignancy that occurs predominantly in the elderly. It is an aggressive tumor, with a poor prognosis that is usually not diagnosed until it has become advanced and is causing symptoms. The median survival for gallbladder cancer is around 6 months with a reported 5-year survival rate of 5%.⁷⁹ In a minority of cases, early cancers are

5► identified incidentally following cholecystectomy for cholelithiasis, in which case, 5-year survival is over 80%.⁸⁰

Incidence. Gallbladder cancer is the sixth most common GI malignancy in Western countries.⁸⁰ It accounts for 2% to 4% of all malignant GI tumors, with about 4000 new cases diagnosed annually in the United States. It is two to six times more common in females than males, and the peak incidence is in the seventh decade of life. Its occurrence in random autopsy series is about 0.4%, but 0.3% to 3% of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer.⁸⁰ There are also significant ethnic variations in the incidence of gallbladder cancer, with rates being particularly high in native populations of the United States, Mexico, and Chile. The overall incidence of gallbladder cancer in the United States is approximately 1.5 cases per 100,000 residents. For Native American females with gallstones, the incidence is around 7.1 per 100,000. For women in the native populations of Chile, gallbladder cancer occurs in 27.3 per 100,000 individuals. Asian populations, particularly those of Korean descent, are also at increased risk of developing gallbladder cancer.⁸⁰

Etiology. The pathogenesis of gallbladder cancer has not been fully defined but is likely related to a combination of chronic inflammation, infection, genetics, and environmental exposures such as heavy metals and tobacco. Cholelithiasis is the most important risk factor for gallbladder carcinoma, and up to 85% of patients with carcinoma of the gallbladder have gallstones. However, <3% of patients with gallstones have gallbladder cancer, and the 20-year risk of developing cancer remains low; <0.5% for the overall population and 1.5% for high-risk groups.

Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.⁸¹ The risk of developing cancer of the gallbladder is higher in patients with symptomatic than asymptomatic gallstones, and it is more commonly seen in the setting of cholesterol stones.

Polypoid lesions of the gallbladder, which are present in as many as 5% of adults, are also associated with increased risk of cancer. This is particularly true for polyps measuring >10 mm, which carry a 25% risk of malignancy.⁸² Solitary or sessile polyps, or those showing rapid growth on serial imaging, particularly if in the presence of gallstones or age >50 are also concerning for malignancy. When such findings are identified, the patient should have their gallbladder removed, even if they are asymptomatic. Polyps that are not removed should be monitored on serial imaging. The finding of a “Porcelain” gallbladder, or dense circumferential calcifications of the gallbladder wall, is associated with an approximately 10% risk of gallbladder carcinoma. While this condition was previously considered to be an absolute indication for cholecystectomy, more recent studies suggest that given the low rate of malignancy, observation is safe and acceptable. Nevertheless, resection remains a reasonable option, particularly if the patient is symptomatic, and the decision should ultimately be made only after discussing risks and benefits of each approach with the patient.⁹⁷ Patients with certain types of choledochal cysts also have an increased risk of developing cancer anywhere in the biliary tree, but the incidence is highest in the gallbladder and cholecystectomy should be performed with any surgical intervention on the choledochal cyst. Primary sclerosing cholangitis, anomalous pancreaticobiliary duct junction, and exposure to carcinogens (azotoluene, nitrosamines) also are associated with cancer of the gallbladder, and screening with abdominal ultrasound should be considered in these patients.

Pathology. Between 80% and 90% of gallbladder cancers are adenocarcinomas. Squamous cell, adenosquamous, oat cell, and other anaplastic lesions rarely occur. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Less than 10% are of the papillary type, but these are associated with an overall better outcome, as they are most commonly diagnosed while localized to the gallbladder. Cancer of the gallbladder can spread through lymphatics, venous drainage, or by direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Lund’s node or Calot’s node), then pericholedochal and hilar nodes, and finally to the peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. The gallbladder veins drain directly into the adjacent liver, usually segments IVb and V, where tumor invasion is common (Fig. 32-30). The gallbladder wall differs histologically from the intestines in that it lacks a muscularis mucosa and submucosa. Lymphatics are present in the subserosal layer only. Therefore, cancers that have not grown through the muscular layer have minimal risk of nodal disease. Unfortunately, only a small portion of gallbladder cancers (10–25%) are identified while they are still localized to the gallbladder. The majority will already have nodal involvement, extension into adjacent liver, or distant metastasis at the time of diagnosis.^{80,83}

Clinical Manifestations and Diagnosis. Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis, and this can lead to delays in treatment or misdiagnosis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites,

Figure 32-30. Computed tomography scan of a patient with gallbladder cancer. The image shown is at the level of the liver hilum. The portal vein is bifurcating into the left and right portal branch. The tumor has invaded segment IV of the liver (*arrowheads*) and obstructed the common hepatic duct, resulting in intrahepatic ductal dilatation (*arrows*).

and abdominal masses are less common presenting symptoms. Common misdiagnoses include chronic cholecystitis, acute cholecystitis, choledocholithiasis, hydrops of the gallbladder, and pancreatic cancer. Laboratory findings, if abnormal, are most often consistent with biliary obstruction. Ultrasonography often reveals a thickened, irregular gallbladder wall (>3mm) with hypervascularity or a mass replacing the gallbladder. It may also visualize tumor invasion of the liver, lymphadenopathy, or a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70% to 100%. A CT scan may be helpful in identifying a gallbladder mass and evaluating for nodal spread or local invasion into adjacent organs or vasculature. If questions about local invasion remain, MRCP allows for complete assessment of biliary, vascular, nodal, hepatic, and adjacent organ involvement.⁸⁴ Endoscopic ultrasound (EUS) can be a useful tool in staging and evaluating for local invasion, as well as obtaining tissue diagnosis through fine needle aspiration (FNA). Tissue diagnosis can also be obtained by CT or ultrasound-guided biopsy of the tumor, though this is not required prior to cholecystectomy if the tumor appears resectable on imaging. In jaundiced patients, a percutaneous transhepatic or endoscopic cholangiogram may be helpful to delineate the extent of biliary tree involvement. The role of PET scanning in gallbladder cancer is yet to be fully defined but can be utilized in both staging and surveillance.

Treatment. Surgical resection remains the only curative option for gallbladder cancer. While most patients are unresectable at the time of diagnosis, if preoperative staging suggests a potentially resectable tumor, exploration for tissue diagnosis, formal pathologic staging, and possible curative resection are warranted.

Tumors limited to the lamina propria or muscular layer of the gallbladder (T1) are usually identified incidentally, after laparoscopic cholecystectomy for gallstone disease. There is

near universal agreement that simple laparoscopic cholecystectomy is an adequate treatment for T1 lesions and results in a near 100% overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed.⁸⁵ This includes additional resection of liver segments IVb and V, as well as lymphadenectomy of the cystic duct and pericholedochal, portal, right celiac, and posterior pancreaticoduodenal lymph nodes. Given the extent of this operation, an open approach is standard. One-half of patients with T2 tumors are found to have nodal disease on pathologic examination, highlighting the importance of regional lymphadenectomy as part of surgery for T2 cancers.⁸⁶ For tumors that grow beyond the serosa, or invade the liver or other adjacent organs (T3), there is a higher likelihood of intraperitoneal or distant spread. However, if no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy and possible caudate lobectomy with lymphadenectomy must be performed for adequate tumor clearance. In addition, if a T2 or T3 tumor is identified incidentally after laparoscopic cholecystectomy, and the patient is returning to the OR for liver resection and lymphadenectomy, the previous laparoscopic port sites must also be excised due to the high risk of recurrence in these locations. T4 tumors are those that have grown into major blood vessels or two or more structures outside the liver, and they are typically considered unresectable.

Due to the high frequency of late diagnosis, palliative procedures for unresectable cancer, jaundice, or duodenal obstructions remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. Various regimens of neoadjuvant, adjuvant, and definitive chemoradiotherapy have been trialed in gallbladder cancer. Overall, benefits have been marginal, but treatment may improve survival time by several months. These therapies can be offered to patients in conjunction with resection for curative intent or as definitive therapy, but no standard recommendation exists for their use.⁸⁵⁻⁸⁷

Prognosis. Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The overall 5-year survival rate of all patients with gallbladder cancer is <5%, with a median survival of 6 months.⁸⁷ However, patients with T1 disease treated with cholecystectomy have an excellent prognosis (85–100% 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy (liver segment IVb/V resection) and lymphadenectomy is >70% compared to 25% to 40% for T2 patients treated with simple cholecystectomy. Patients with advanced (T3 or T4) but resectable gallbladder cancer are reported to have 5-year survival rates of 20% to 50%, supporting aggressive resection in those patients who can tolerate surgery. The median survival for patients with distant metastasis at the time of presentation is only 1 to 3 months.

Recurrence after resection of gallbladder cancer occurs most commonly in the liver or in the celiac or retropancreatic nodes. The prognosis for recurrent disease is very poor, and the main goal of follow-up is to provide palliative care. The most common problems are pruritus and cholangitis associated with obstructive jaundice, bowel obstruction secondary to carcinomatosis, and pain. Death occurs most commonly secondary to biliary sepsis or liver failure.

Cholangiocarcinoma

Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About half are located at the hepatic duct bifurcation (Klatskin tumors), with 40% occurring more distally and 10% being intrahepatic.⁸⁸ Surgical resection offers the only chance for cure, but unfortunately many patients have advanced disease at the time of diagnosis. Therefore, palliative procedures aimed to provide biliary drainage and prevent liver failure and cholangitis are often the only therapeutic possibilities available.

Incidence. The autopsy incidence of bile duct carcinoma is about 0.3%. The overall incidence of cholangiocarcinoma in the United States is about 1 per 100,000 people per year, with approximately 2500 new cases diagnosed annually. The disease has a slight male predominance and an average age of presentation between 50 and 70 years.⁸⁸

Etiology. Most cases of extrahepatic cholangiocarcinoma develop de novo with no identifiable risk factors. However, there is an increased risk of cholangiocarcinoma in patients with choledochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomoses, hepatitis B and C, cirrhosis, biliary tract infections with *Clonorchis* (liver flukes), and chronic typhoid carriers. Exposure to dietary nitrosamines, Thorotrast, or dioxin also puts patients at increased risk for cholangiocarcinoma.⁸⁸ Patients with primary sclerosing cholangitis have a 5% to 10% lifetime risk of developing cholangiocarcinoma with typical disease onset in their 40s. For this reason, these patients require regular screening.⁶⁷ Features common to most risk factors include biliary stasis, bile duct stones, and infection.

Pathology. Over 95% of bile duct cancers are ductal adenocarcinomas with the vast majority occurring in the extrahepatic biliary tree. Morphologically, they are divided into nodular (the most common type), scirrhous, diffusely infiltrating, or papillary. Anatomically, they are divided into distal, perihilar or intrahepatic tumors. Intrahepatic cholangiocarcinomas make up approximately 10% of cases and are typically treated like hepatocellular carcinoma, with hepatectomy when possible and transplant when unresectable. About half of all cholangiocarcinomas are located in the perihilar region with the remaining 40% occurring more distally in the common bile duct.

Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification (Fig. 32-31). Type I tumors are confined to the common hepatic duct, but type II tumors involve the bifurcation without involvement of the secondary intrahepatic ducts. Type IIIa and IIIb tumors extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors involve both the right and left secondary intrahepatic ducts.

Clinical Manifestations and Diagnosis. Painless jaundice is the most common initial presentation in patients with cholangiocarcinoma. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss may also be present. Cholangitis is the presenting symptom in about 10% of patients. Except for jaundice, physical examination is usually normal in patients with cholangiocarcinoma. Occasionally, asymptomatic patients are found to have cholangiocarcinoma while being evaluated for elevated liver function tests. Tumor markers, such as CA 125 and carcinoembryonic antigen (CEA), can be elevated in

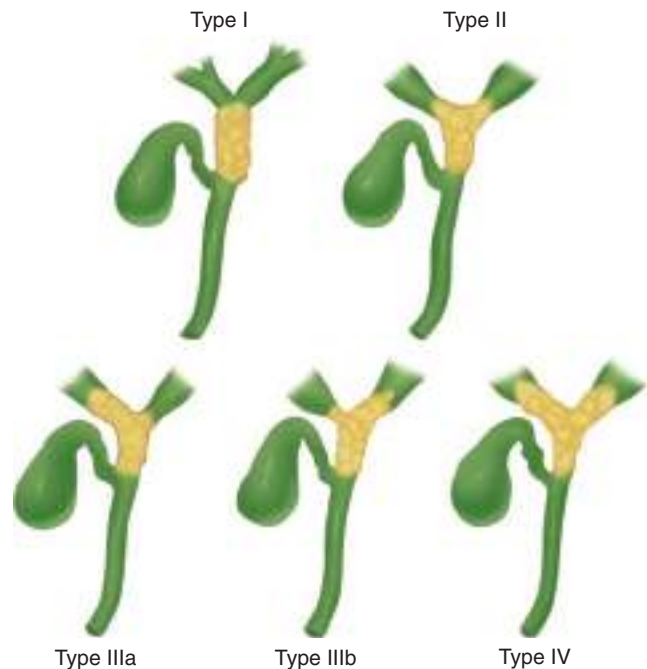

Figure 32-31. Bismuth-Corlette classification of perihilar bile duct tumors (Klatskin tumors).

cholangiocarcinoma but tend to be nonspecific because they also increase in other GI and gynecologic malignancies. The tumor marker most commonly used to aid the diagnosis of cholangiocarcinoma is CA 19-9, which has a sensitivity of 79% and specificity of 98% if the serum value is >129 U/mL.⁸⁹ However, mild elevations in CA 19-9 can also be seen in cholangitis, biliary obstruction, other GI and gynecologic neoplasms, and patients who lack the Lewis blood type antigen.⁹⁰

The initial workup for suspected cholangiocarcinoma includes abdominal imaging with ultrasound or CT scanning. Perihilar tumors will cause dilatation of the intrahepatic biliary tree, but a normal or collapsed gallbladder and extrahepatic bile ducts distal to the tumor. Distal bile duct cancer will lead to dilatation of the extra- and intrahepatic bile ducts as well as the gallbladder. Initial imaging is important to determine the level of obstruction and to rule out the presence of bile duct stones as the cause of the obstructive jaundice (Fig. 32-32). It is usually difficult to visualize the tumor itself on ultrasound, CT, or even MRCP, but any of these modalities can provide an outline of biliary anatomy, an estimate of the level of obstruction, evaluation of portal vein patency, and screening for nearby lymphadenopathy. Detailed evaluation of the biliary anatomy and tumor itself is best completed through cholangiography. ERCP is generally adequate, but in cases where the proximal extent of the tumor remains in question, PTC may be required to determine resectability.

Tissue diagnosis may be difficult to obtain. Current diagnostic techniques including fine-needle aspiration (percutaneous or endoscopic), and biliary brushings have been shown to have a low sensitivity in detecting malignancy, anywhere between 15% and 60%. Choledochoscopy with direct visualization and sampling of intraluminal masses may be able to improve diagnosis rates but is only available in specialized centers (see Fig. 32-10). Patients with potentially resectable disease should, therefore, be offered surgical exploration based on radiographic findings and clinical suspicion.⁹¹

A

B

Figure 32-32. **A.** An endoscopic retrograde cholangiogram in a patient with cancer of the common hepatic duct (*arrowheads*). The common bile duct is of normal size, as is the cystic duct (*arrow*), but the proximal biliary tree is dilated. The gallbladder is not visualized because of tumor obstructing its neck. **B.** An ultrasound from the same patient showing dilated ducts and tumor obstructing the common hepatic duct (*arrow*). The walls of the bile ducts adjacent to the obstruction are thickened by tumor infiltration (*arrowheads*).

Treatment. Surgical excision is the only potentially curative treatment for cholangiocarcinoma. In the past one to two decades, improvements in surgical techniques have resulted in lower mortality and better outcomes for patients undergoing aggressive surgical excision for cholangiocarcinoma.⁹²

Despite improvements in ultrasonography, CT scanning, and MRI, more than one-half of patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. Patients suspected of having resectable disease should first undergo diagnostic laparoscopy. Those who are found to have previously unidentified metastatic disease should undergo cholecystectomy and surgical bypass for biliary decompression.⁹³

For curative resection, the location and local extension of the tumor dictates the extent of the surgery required. Distal bile duct tumors are often resectable but may require pancreaticoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojejunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular involvement are candidates for local tumor excision with portal lymphadenectomy, cholecystectomy, common bile duct excision, and bilateral Roux-en-Y hepaticojejunostomies. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Frequently, resection of the adjacent caudate lobe is required because of direct extension into caudate biliary radicals or parenchyma.⁹¹ Type IV Klatskin tumors, those with more extensive involvement of both hepatic ducts and intrahepatic spread, are often considered unresectable or only treatable with liver transplantation.

The best outcomes in perihilar cholangiocarcinoma are seen in patients who undergo neoadjuvant chemoradiation

followed by liver transplantation. However, there are very strict inclusion criteria for transplantation, and few patients qualify.⁸⁸ Patients with primary sclerosing cholangitis who develop cholangiocarcinoma should be treated with liver transplant whenever possible.

Nonoperative biliary decompression can be performed for patients with unresectable disease on initial presentation. Endoscopic placement of expandable metal stents is often the preferred approach. For very proximal or intrahepatic tumors, percutaneous drainage catheters may be necessary to fully decompress the biliary tree (see Fig. 32-12). There is a significantly higher risk of cholangitis in patients with drainage catheters or stents compared to those with surgical bypasses. In addition, stent occlusion is not uncommon. Nevertheless, operative intervention is not warranted in patients with metastatic disease.⁹⁴

There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy has also not been shown to increase either quality of life or survival in resected patients. Patients with unresectable disease can be offered palliative chemotherapy, typically with gemcitabine and cisplatin, but the response rates are low (10–20%), and the survival benefit is marginal. The combination of radiation and chemotherapy may be more effective than either treatment alone for unresectable disease, but no data from randomized trials are available. Giving chemoradiation to these patients can be difficult because of the high incidence of cholangitis. External-beam radiation has not been shown to be an effective treatment for unresected disease. The use of interstitial (intraoperative) radiation, brachytherapy with iridium-192 via percutaneous or endoscopic stents, and combined interstitial and external-beam radiation for unresectable cholangiocarcinoma has been reported with some encouraging results. However, no randomized, prospective trials have been reported.⁹¹ Photodynamic therapy has been proposed as a palliative measure for patients with unresectable disease and

has been found to prolong survival and improve quality of life in patients with biliary stents.^{95,96}

Prognosis. Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Median survival in this population is between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10% and 30%, but for patients with negative margins, it may be as high as 40%. The operative mortality for perihilar cholangiocarcinoma is 6% to 8%. Patients with distal cholangiocarcinoma are more likely to have resectable disease and improved prognosis compared to perihilar cholangiocarcinoma. The overall 5-year survival rate for resectable distal disease is 30% to 50%, and the median survival is 32 to 38 months. Patients who receive liver transplantation for cholangiocarcinoma can experience 5-year disease free survival rates as high as 68%.

The greatest risk factors for recurrence after resection are the presence of positive margins and lymph node–positive tumors. Therapy for recurrent disease concentrates on palliation of symptoms and additional surgery is not recommended for patients with recurrent disease.

ANATOMY

The pancreas is perhaps the most unforgiving organ in the human body, leading most surgeons to avoid even palpating it unless necessary. Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Seemingly minor trauma to the pancreas can result in the release of pancreatic enzymes and cause life-threatening pancreatitis. Therefore, knowledge of the relationships of the pancreas to surrounding structures is critically important for all surgeons to ensure that pancreatic injury is avoided during abdominal surgery.

Gross Anatomy

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum (Fig. 33-1). In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20 cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the

retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents. Patients with pancreatic cancer without bile duct obstruction usually present after months of vague upper abdominal discomfort, or no antecedent symptoms at all. Due to its retroperitoneal location, pain associated with pancreatitis often is characterized as penetrating through to the back.

Regions of the Pancreas

Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The head of the pancreas is nestled in the C-loop of the duodenum and is posterior to the transverse mesocolon. Just posterior to the head of the pancreas lie the vena cava, the right renal artery, and both renal veins. The neck of the pancreas lies directly anterior to the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near

Key Points

- 1▶ Incomplete fusion of the dorsal and ventral pancreatic ducts results in pancreas divisum, but a variety of ductal anomalies can be seen. Magnetic resonance cholangiopancreatography as well as endoscopic retrograde cholangiopancreatography can identify these ductal anomalies, and clarification of the ductal pattern of the pancreas is important before attempts at interventions.
- 2▶ The “replaced right hepatic artery” occurs in 15% of patients and needs to be identified preoperatively to prevent inadvertent injury with resulting hepatic necrosis. Anomalous hepatic arterial anatomy can result in hepatic ischemia during dissection of the porta hepatis as well. “Thin cut” multidetector computed tomographic images are usually able to identify the relevant arterial and venous patterns around the pancreas.
- 3▶ Regardless of the etiology, the management of the early phase of acute pancreatitis is critical to achieve a successful outcome. Aggressive fluid resuscitation and early enteral feeding both reduce the risk of complications. It is no longer considered appropriate to “rest the pancreas” if the patient can tolerate enteral nutrients.
- 4▶ Surgical intervention in acute pancreatitis is reserved for patients with infected collections or infected necrosis only, or to relieve an impacted gallstone in the ampulla if endoscopic or radiologic treatments are unsuccessful. Infection is usually confirmed by a pattern of air in the retroperitoneum on computed tomographic scan or by documentation of bacteria on Gram’s stain or culture from fine-needle aspiration of a suspected infected fluid collection. Fine-needle aspiration of suspicious fluid collections should not be converted to percutaneous drainage unless infection is confirmed and the consensus decision has been made that percutaneous drainage is appropriate for the individual patient.
- 5▶ The appearance of chronic pancreatitis on computed tomographic scan varies dramatically, and multiple diagnostic studies are usually needed to establish the extent of disease. Calcific pancreatitis is not a marker of alcoholic pancreatitis alone, and it rarely indicates autoimmune pancreatitis. Endoscopic ultrasound provides a better assessment of the disease than computed tomography and is useful to disclose indolent or unsuspected cancer, which can occur in up to 10% of patients.
- 6▶ The nidus of inflammation in chronic pancreatitis due to any cause is the head of the gland. Therefore, treatment approaches that address the disease in the head have the best long-term results. The Whipple procedure, the Beger procedure, and the Frey procedure, with or without longitudinal duct drainage, are the best surgical options, as all three approaches remove all or most of the disease in the head of the gland. Although the limited pancreatic procedures (Beger/Frey) have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation. Level 1 studies confirm that the duodenum preserving options are associated with a lower immediate morbidity and mortality and therefore, in the absence of a mass or concerns about cancer, are better options than a Whipple procedure for chronic pancreatitis.
- 7▶ The precursor lesion that probably leads to most cases of ductular adenocarcinoma is the ductal epithelial hyperplasia/dysplasia process described by the pancreatic intraepithelial neoplasia classification system. Pancreatic intraepithelial neoplasia 2 and pancreatic intraepithelial neoplasia 3 lesions may be associated with other, nonspecific changes in pancreatic morphology seen on imaging studies, or they may only be seen histologically. Resection margins for pancreatic neoplasms should be examined for advanced pancreatic intraepithelial neoplasia stage patterns of ductal hyperplasia to ensure adequate resection status.
- 8▶ A low threshold for ordering a computed tomography scan with “pancreatic protocol” should be maintained for older adult patients with unexplained, persistent, although vague, abdominal pain. New-onset diabetes in an older adult patient, especially if combined with vague abdominal pain, should prompt a search for pancreatic cancer.
- 9▶ Intraductal papillary mucinous neoplasms are small macroscopic polypoid or plaque-like adenomas that develop in the main pancreatic duct or in side-branch ducts, and secrete mucin. They are often silent symptomatically but cause characteristic appearances of small cyst-like collections of mucus or diffuse dilatation of the main pancreatic duct with mucus. These premalignant lesions may be multifocal or single and can evolve into invasive adenocarcinoma in a similar pattern as with other adenomatous polypoid lesions of the gastrointestinal tract. They have been diagnosed with increasing frequency and account for more than one-third of pancreatic resections at some centers. Main-duct intraductal papillary mucinous neoplasms are an indication for resection; side-branch intraductal papillary mucinous neoplasms have a lower incidence of malignancy and are sometimes followed with serial imaging surveillance.

its junction with the portal vein. Sometimes, the inferior mesenteric vein joins the superior mesenteric vein or merges with the superior mesenteric portal venous junction to form a trifurcation (Fig. 33-2). The superior mesenteric artery lies parallel to and just to the left of the superior mesenteric vein. The uncinate process and the head of the pancreas wrap around the right side of the portal vein and end posteriorly near the space between the superior mesenteric vein and superior mesenteric artery. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal

and superior mesenteric veins during pancreatic resection, unless the tumor is invading the vein anteriorly. The common bile duct runs in a deep groove on the posterior aspect of the pancreatic head until it passes through the pancreatic parenchyma to join the main pancreatic duct at the ampulla of Vater. The body and tail of the pancreas lie just anterior to the splenic artery and vein. The vein runs in a groove on the back of the pancreas and is fed by multiple fragile venous branches from the pancreatic parenchyma. These branches must be divided to perform a spleen-sparing distal pancreatectomy. The splenic artery runs parallel and just superior to the vein along the posterior superior edge of the body and tail of the pancreas. The splenic artery often is

Figure 33-1. Pancreatic anatomy as seen on computed tomography. Knowledge of the relationship of the pancreas with surrounding structures is important to ensure that injury is avoided during abdominal surgery. IMV = inferior mesenteric vein; SMA = superior mesenteric artery; SMV = superior mesenteric vein.

Figure 33-2. Variations in portal venous anatomy. The superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein, but sometimes joins the superior mesenteric vein; or the three veins merge as a trifurcation to form the portal vein.

tortuous. The anterior surface of the body of the pancreas is covered by peritoneum. Once the gastrocolic omentum is divided, the body and tail of the pancreas can be seen along the floor of the lesser sac, just posterior to the stomach.

Pancreatic pseudocysts commonly develop in this area, and the posterior aspect of the stomach can form the anterior wall of the pseudocyst, allowing drainage into the stomach. The base of the transverse mesocolon attaches to the inferior margin of the body and tail of the pancreas. The transverse mesocolon often forms the inferior wall of pancreatic pseudocysts or inflammatory processes, allowing surgical drainage through the transverse mesocolon. The body of the pancreas is anterior to the aorta at the origin of the superior mesenteric artery. The neck of the pancreas is anterior to the vertebral body of L1 and L2, and blunt anteroposterior trauma can compress the neck of the pancreas against the spine, causing parenchymal and, sometimes, ductal injury. The neck divides the pancreas into approximately two equal halves. The small portion of the pancreas anterior to the left kidney is referred to as the *tail* and is nestled in the hilum of the spleen near the splenic flexure of the left colon. Awareness of these anatomic relationships is important to avoid injury to the pancreatic tail during left colectomy or splenectomy.

Pancreatic Duct Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud (Fig. 33-3). The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in

the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one-third of patients, the bile duct and pancreatic duct remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one-third, and in the remaining one-third, a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30% of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse.¹ This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as *pancreas divisum* (see Fig. 33-3). In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

The main pancreatic duct is usually only 2 to 3 mm in diameter and runs midway between the superior and inferior borders of the pancreas, usually closer to the posterior than to the anterior surface. Pressure inside the pancreatic duct is about twice that in the common bile duct, which is thought to prevent reflux of bile into the pancreatic duct. The main pancreatic duct joins with the common bile duct and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. The muscle fibers around the ampulla form the sphincter of Oddi, which controls the flow of pancreatic and biliary secretions into the duodenum. Contraction and relaxation of the sphincter is regulated by complex neural and hormonal factors. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2 cm proximal to the ampulla of Vater.

Figure 33-3. Embryology of pancreas and duct variations. The duct of Wirsung from the ventral bud connects to the bile duct, while the duct of Santorini from the larger dorsal bud connects to the duodenum. With gut rotation, the two ducts fuse in most cases such that the majority of the pancreas drains through the duct of Wirsung to the major papilla. The duct of Santorini can persist as a blind accessory duct or drain through the lesser papilla. In a minority of patients, the ducts remain separate, and the majority of the pancreas drains through the duct of Santorini, a condition referred to as *pancreas divisum*.

Figure 33-4. Arterial supply to the pancreas. Multiple arcades in the head and body of the pancreas provide a rich blood supply. The head of the pancreas cannot be resected without devascularizing the duodenum unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved.

Vascular and Lymphatic Anatomy

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (Fig. 33-4). The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The right gastric artery branches off the gastroduodenal artery just superior to the duodenum. The gastroduodenal artery also supplies the superior pancreaticoduodenal artery which divides into the anterior and superior pancreaticoduodenal arteries. These travel inferiorly within the pancreaticoduodenal groove giving off small branches to the duodenum and head of the pancreas. The superior pancreaticoduodenal arteries join the inferior pancreaticoduodenal arteries to complete the arcade. The inferior pancreaticoduodenal artery is a branch off the superior mesenteric artery. Therefore, it is impossible to resect the head of the pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. The inferior pancreaticoduodenal artery needs to be controlled when dissecting the head of the pancreas off the SMA during a Whipple procedure. The gastroduodenal artery travels inferiorly anterior to the neck of the pancreas and posterior to the duodenal bulb. A posterior ulcer in the duodenal bulb can erode into the gastroduodenal artery in this location. At the inferior border of the duodenum, the gastroduodenal artery then gives rise to the right gastroepiploic artery then can continue on to join the inferior pancreaticoduodenal artery.

Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15% to 20% of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a *replaced right hepatic artery*). It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the

replaced hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas and account for the rich blood supply of the organ.

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply (Fig. 33-5). The veins are usually superficial to the arteries within the parenchyma of the pancreas. There is an anterior and posterior venous arcade within the head of the pancreas. Typically, the superior vein drains directly into the portal vein just above the neck of the pancreas and is often a larger branch of the portal vein which is divided during the Whipple procedure. The posterior inferior arcade drains directly into the inferior mesenteric vein at the inferior border of the neck of the pancreas and this is also divided during a Whipple procedure. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein. Traction on the transverse colon during colectomy can tear these fragile veins, which then retract into the parenchyma of the pancreas, making control tedious. There also are numerous small venous branches coming from the pancreatic parenchyma directly into the lateral and posterior aspect of the portal vein. Venous return from the body and tail of the pancreas drains into the splenic vein.

The lymphatic drainage from the pancreas is diffuse and widespread (Fig. 33-6). The profuse network of lymphatic

Figure 33-5. Venous drainage from the pancreas. The venous drainage of the pancreas follows a pattern similar to the arterial supply, with the veins usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.

Figure 33-6. Lymphatic supply to the pancreas. The lymphatic drainage from the pancreas is diffuse and widespread, which explains the high incidence of lymph node metastases and local recurrence of pancreatic cancer. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas are often unresectable because they metastasize to these lymph nodes. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas. This diffuse lymphatic drainage contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. Lymph nodes can be palpated along the distal bile duct and posterior aspect of the head of the pancreas in the pancreaticoduodenal groove, where the mesenteric vein passes under the neck of the pancreas, along the inferior border of the body, at the celiac axis and along the hepatic artery ascending into the porta hepatis, and along the splenic artery and vein. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas often metastasize to these nodes and lymph nodes along the splenic vein and in the hilum of the spleen.

Neuroanatomy

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The acinar cells responsible for exocrine secretion, the islet cells responsible for endocrine secretion, and the islet vasculature are innervated by both systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion.² The pancreas is also innervated by neurons that secrete amines and peptides, such as somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. The exact role of these neurons in pancreatic physiology is uncertain, but they do appear to affect both exocrine and endocrine function. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, as well as acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia (Fig. 33-7). Interruption of these somatic fibers with a celiac plexus block can stop transmission of pain sensation.

HISTOLOGY AND PHYSIOLOGY

The exocrine pancreas accounts for about 85% of the pancreatic mass; 10% of the gland is accounted for by extracellular matrix, and 4% by blood vessels and the major ducts, whereas only 2% of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreas are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion. This complex system regulates the type of digestion, its rate, and the processing and distribution of absorbed nutrients. This coordination is facilitated by the physical approximation of the islets and the exocrine pancreas, the presence of specific islet hormone receptors on the plasma membranes of pancreatic acinar cells, and the existence of an islet-acinar portal blood system.

Although patients can live without a pancreas when insulin and digestive enzyme replacement are administered, the loss of this islet-acinar coordination leads to impairments in digestive function. Although only approximately 20% of the normal pancreas is required to prevent insufficiency, in many patients undergoing pancreatic resection, the remaining pancreas is not normal, and pancreatic endocrine and exocrine insufficiency can develop with removal of smaller portions of the gland.

Exocrine Pancreas

The pancreas secretes approximately 500 to 800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases, and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen

Figure 33-7. Innervation of the pancreas. The pancreas has a rich supply of afferent sensory fibers that travel superiorly to the celiac ganglia. Interruption of these somatic fibers with a celiac plexus block can interfere with transmission of pancreatic pain. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Figure 33-8. Acinar cell. Zymogen granules fuse with the apical membrane and release multiple enzymes to digest carbohydrates, proteins, and fat. (Reproduced with permission from Bloom W, Fawcett DW: *A Textbook of Histology*, 10th ed. Philadelphia, PA: Saunders; 1975.)

granules that fuse with the apical cell membrane (Fig. 33-8). Unlike the endocrine pancreas, where islet cells specialize in the secretion of one hormone type, individual acinar cells secrete all types of enzymes. However, the ratio of the different enzymes released is adjusted to the composition of digested food through nonparallel regulation of secretion.

Pancreatic amylase is secreted in its active form and completes the digestive process already begun by salivary amylase. Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrans. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. Gastric hydrolysis of protein yields peptides that enter the intestine and stimulate intestinal endocrine cells to release cholecystokinin (CCK)-releasing peptide, CCK, and secretin, which then stimulate the pancreas to secrete enzymes and bicarbonate into the intestine.

The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin, in turn, activates the other proteolytic enzymes. Trypsinogen activation within the pancreas is prevented by the presence of inhibitors that are also secreted by the acinar cells. A failure to express a normal trypsinogen inhibitor, pancreatic secretory trypsin inhibitor (PSTI), also known as serine protease inhibitor Kazal type 1 (SPINK1), is a cause of familial pancreatitis. Inhibition of trypsinogen activation ensures that the enzymes within the pancreas remain in an inactive precursor state and are activated only within the

duodenum. Trypsinogen is expressed in several isoforms, and a missense mutation on the cationic trypsinogen, or *PRSS1*, results in premature, intrapancreatic activation of trypsinogen. This accounts for about two-thirds of cases of hereditary pancreatitis. Chymotrypsinogen is activated to form chymotrypsin. Elastase, carboxypeptidase A and B, and phospholipase are also activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase is also secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme that becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids and, as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, where the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream (Table 33-1).

The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice. About 40 acinar cells are arranged into a spherical unit called an *acinus*. Centroacinar cells are located near the center of the acinus and are responsible for fluid and electrolyte secretion. These cells contain the enzyme carbonic anhydrase, which is needed for bicarbonate secretion. The amount of bicarbonate secreted varies with the pancreatic secretory rate, with greater concentrations of bicarbonate being secreted as the pancreatic secretory rate increases. Chloride secretion varies inversely with bicarbonate secretion such that the sum of these two remains constant. In contrast, sodium and potassium concentrations are kept constant throughout the spectrum of secretory rates³ (Fig. 33-9). The hormone secretin is released from cells in the duodenal mucosa in response to acidic chyme passing through the pylorus into the duodenum. Secretin is the major stimulant for bicarbonate secretion, which buffers the acidic fluid entering the duodenum from the stomach. CCK also stimulates bicarbonate secretion, but to a much lesser extent than secretin. CCK potentiates secretin-stimulated bicarbonate secretion. Gastrin and acetylcholine, both stimulants of gastric acid secretion, are also weak stimulants of pancreatic bicarbonate secretion.⁴ Truncal vagotomy produces a myriad of complex effects on the downstream digestive tract, but the sum effect on the exocrine pancreas is a reduction in bicarbonate and fluid secretion.⁵ The endocrine pancreas also influences the adjacent exocrine pancreatic secretions. Somatostatin, pancreatic polypeptide (PP), and glucagon are all thought to inhibit exocrine secretion.

The acinar cells release pancreatic enzymes from their zymogen granules into the lumen of the acinus, and these proteins combine with the water and bicarbonate secretions of the centroacinar cells. The pancreatic juice then travels into small intercalated ducts. Several small intercalated ducts join to form an interlobular duct. Cells in the interlobular ducts contribute fluid and electrolytes to adjust the final concentrations of the pancreatic fluid. Interlobular ducts then join to form about 20 secondary ducts that empty into the main pancreatic duct.

Destruction of the branching ductal tree from recurrent inflammation, scarring, and deposition of stones in chronic pancreatitis eventually contributes to destruction of the exocrine pancreas and exocrine pancreatic insufficiency.

Endocrine Pancreas

There are nearly 1 million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40 to 900 μm . Larger islets are located closer to the major arterioles and smaller islets are embedded more deeply in the parenchyma of the pancreas. Most islets contain 3000 to 4000 cells of five major types: alpha cells that secrete glucagon, beta-cells that

secrete insulin, delta cells that secrete somatostatin, epsilon cells that secrete ghrelin, and PP cells that secrete PP (Table 33-2).

Insulin is the best-studied pancreatic hormone. The discovery of insulin in 1920 by Frederick Banting, an orthopedic

Figure 33-9. Composition of pancreatic exocrine secretions. Greater concentrations of bicarbonate are secreted at higher secretory rates, and chloride secretion varies inversely with bicarbonate secretion. In contrast, sodium and potassium concentrations are independent of the secretory rate. Table 33-2

Pancreatic Islet Peptide Products

HORMONES	ISLET CELL	FUNCTIONS
Insulin	Beta	Decreases gluconeogenesis, glycogenolysis, fatty acid breakdown, and ketogenesis Increased glycogenesis, protein synthesis and glucose uptake
Glucagon	Alpha	Opposite effects of insulin; increases hepatic glycogenolysis and gluconeogenesis
Somatostatin	Delta	Inhibits secretion and action of all pancreatic and gut peptides, inhibits cell growth
Pancreatic Polypeptide	PP or F	Inhibits pancreatic exocrine secretion and facilitates hepatic action of insulin
Amylin (IAPP)	Beta	Counter-regulates insulin secretion and function
Pancreastatin	Beta	Decreases insulin and somatostatin secretion, increases glucagon secretion, decreases exocrine secretion
Ghrelin	Epsilon	Decreases insulin secretion and action
Peptide YY (PYY)	not known	Increases insulin secretion and beta cell growth

surgeon, and Charles Best, a medical student, was recognized with the awarding of the Nobel Prize in Physiology or Medicine. They produced diabetes in dogs by performing total pancreatectomy and then treated them with crude pancreatic extracts from dog and calf pancreata using techniques to prevent the breakdown of insulin by the proteolytic enzymes of the exocrine pancreas. Insulin was subsequently purified and found to be a 56-amino acid peptide with two chains, an alpha and a beta chain, joined by two disulfide bridges and a connecting peptide, or C-peptide. Proinsulin is made in the endoplasmic reticulum and then is transported to the Golgi complex, where it is packaged into granules and the C-peptide is cleaved off. There are two phases of insulin secretion. In the first phase, stored insulin is released. This phase lasts about 5 minutes after a glucose challenge. The second phase of insulin secretion is a longer, sustained release due to ongoing production of new insulin. beta-cell synthesis of insulin is regulated by plasma glucose levels, neural signals, and the paracrine influence of other islet cells. The diagnosis of diabetes is made by using oral and intravenous (IV) glucose tolerance tests. Oral glucose not only enters the bloodstream but also stimulates the release of enteric hormones such as gastric inhibitory peptide (also known as *glucose-dependent insulinotropic polypeptide* or *GIP*), glucagon-like peptide-1 (GLP-1), and CCK that augment the secretion of insulin and are therefore referred to as *incretins*. As a result, oral glucose is a more vigorous stimulus to insulin secretion than IV glucose. In the oral glucose tolerance test (OGTT), the patient is fasted overnight, and a basal glucose value is determined. Forty g/m² or 75 g of glucose is given orally over 10 minutes. Blood samples are taken every 30 minutes for 2 hours. Normal values and criteria for diabetes vary by age, but essentially all values should be <200 mg/dL, and the 120-minute value should be <140 mg/dL.

Insulin secretion by the beta-cell is also influenced by plasma levels of amino acids such as arginine, lysine, leucine, and free fatty acids. Glucagon, GIP, GLP-1, and CCK stimulate

insulin release, while somatostatin, amylin, and pancreastatin inhibit insulin release.⁶ Cholinergic fibers and alpha-sympathetic fibers stimulate insulin release, while beta-sympathetic fibers inhibit insulin secretion.

Insulin's gluoregulatory function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport into cells, thus lowering plasma glucose levels. Insulin also inhibits glycogenolysis, fatty acid breakdown, and ketone formation, and stimulates protein synthesis. There is a considerable amount of functional reserve in insulin secretory capacity. If the remaining portion of the pancreas is healthy, about 80% of the pancreas can be resected without the patient becoming diabetic.⁷ In patients with chronic pancreatitis, or other conditions in which much of the gland is diseased, resection of a smaller fraction of the pancreas can result in pancreatogenic, or type 3c diabetes (Table 33-3).

Insulin receptors are dimeric, tyrosine kinase-containing transmembrane proteins that are located on all cells. Insulin deficiency (seen in type 1 and type 3c diabetes) results in an overexpression or upregulation of insulin receptors, which causes an enhanced sensitivity to insulin in muscle and adipocytes (and therefore increases the risk of insulin-induced hypoglycemia). Type 2 diabetes is associated with a downregulation of insulin receptors and relative hyperinsulinemia, with resulting insulin resistance. Some forms of diabetes are associated with selected impairments of hepatic or peripheral insulin receptors, such as pancreatogenic or type 3c diabetes (T3cDM) or maturity-onset diabetes of the young (MODY).

Glucagon is a 29-amino-acid, single-chain peptide that promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Glucose is the primary regulator of glucagon secretion, as it is with insulin, but it has an inhibitory rather than stimulatory effect. Glucagon release is stimulated by hypoglycemia and by the amino acids arginine and alanine. GLP-1 inhibits glucagon secretion in vivo, and insulin and somatostatin inhibit glucagon

Table 33-3

Clinical and laboratory findings in types of diabetes mellitus

PARAMETER	TYPE 1	TYPE 2	TYPE 3C
	IDDM	NIDDM	Pancreatogenic
Ketoacidosis	Common	Rare	Rare
Hyperglycemia	Severe	Usually mild	Mild
Hypoglycemia	Common	Rare	Common
Peripheral insulin sensitivity	Normal or increased	Decreased	Increased
Hepatic insulin sensitivity	Normal	Normal or decreased	Decreased
Insulin levels	Low	High	Low
Glucagon levels	Normal or high	Normal or high	Low
PP levels	Normal or low (late)	High	Low
GIP levels	Normal or low	Normal or high	Low
GLP-1 levels	Normal	Normal or high	Normal or high
Typical age of onset	Childhood or adolescence	Adulthood	Any

Abbreviations: IDDM = insulin dependent diabetes mellitus; NIDDM = non-insulin-dependent diabetes mellitus; PP = pancreatic polypeptide; GIP = glucose-dependent insulinotropic polypeptide; GLP-1 = glucagon-like peptide 1.

secretion in a paracrine fashion within the islet. The same neural impulses that regulate insulin secretion also regulate glucagon secretion, so that the two hormones work together in a balance of actions to maintain glucose levels. Cholinergic and alpha-sympathetic fibers stimulate glucagon release, while beta-sympathetic fibers inhibit glucagon release.⁸ In pancreatogenic or type 3c diabetes, glucagon responsiveness to a fall in blood glucose is lost, thereby increasing the risk for hypoglycemia.

Although originally isolated from the hypothalamus, somatostatin is a peptide that is now known to have a wide anatomic distribution, not only in neurons but also in the pancreas, gut, and other tissues. It is a highly conserved peptide hormone, as it is found in lower vertebrates, and is now realized to be of fundamental importance in regulatory processes throughout the body. One gene encodes for a common precursor that is differentially processed to generate tissue-specific amounts of two bioactive products, somatostatin-14, and somatostatin-28. These peptides inhibit endocrine and exocrine secretion and affect neurotransmission, GI and biliary motility, intestinal absorption, vascular tone, and cell proliferation.

Five different somatostatin receptors (SSTRs) have been cloned and the biologic properties of each are different.⁹ The hexapeptide and octapeptide analogues such as octreotide bind only to SSTR2, SSTR3, and SSTR5. These analogues have a longer serum half-life, and their potent inhibitory effect has been used clinically to treat both endocrine and exocrine disorders. For example, octreotide has been shown to decrease fistula output and speed the time it takes for enteric and pancreatic fistulas to close.¹⁰

Endocrine release of somatostatin occurs during a meal. The major stimulant is probably intraluminal fat. Acidification of the gastric and duodenal mucosa also releases somatostatin in isolated perfused organ preparations. Acetylcholine from the cholinergic neurons inhibits somatostatin release.

Pancreatic polypeptide (PP) is a 36-amino-acid, straight-chain peptide discovered by Kimmel in 1968 during the process of insulin purification. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a weaker effect.¹¹ Hypoglycemia, whether or not it is insulin induced, strongly stimulates PP secretion through cholinergic stimulation.¹² Phenylalanine, tryptophan, and fatty acids in the duodenum stimulate PP release, probably by inducing CCK, GIP, and secretin release. Vagal stimulation of the pancreas is the most important regulator of PP secretion. In fact, vagotomy eliminates the rise in PP levels usually seen after a meal. This can be used as a test for the completeness of a surgical vagotomy or for the presence of diabetic autonomic neuropathy.

PP has been shown to inhibit choleresis (bile secretion), gallbladder contraction, and secretion by the exocrine pancreas. However, PP's most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. A deficiency in PP secretion due to proximal pancreatectomy, severe chronic pancreatitis, or cystic fibrosis, is associated with diminished hepatic insulin sensitivity due to reduced hepatic insulin receptor availability.¹³ This effect is reversed by PP administration.¹⁴

Recent studies have shown that a fifth islet peptide, ghrelin, is secreted from a distinct population of islet cells, called *epsilon cells*.^{15,16} Ghrelin also is present in the gastric fundus in large amounts and stimulates growth hormone secretion via growth hormone releasing hormone release from the pituitary. It is an orexigenic, or appetite-stimulating, peptide the plasma

levels of which are increased in obesity. Ghrelin has also been shown to block insulin effects on the liver, and inhibits the beta-cell response to incretin hormones and glucose.¹⁷ Therefore, ghrelin secretion from and within the islet may modulate the responses of other islet cells to nutrient and hormonal stimuli.

In addition to the five main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin, peptide YY (PYY), and pancreastatin, as well as neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is a 37-amino-acid polypeptide that is predominantly expressed by the pancreatic beta-cells, where it is stored along with insulin in secretory granules.¹⁸ The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release.^{19,20} In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.²¹ PYY is structurally related to PP and was initially found in hormone-secreting "L" cells of the small intestine, where it colocalizes with GLP-1. Recently, PYY has been localized to the islets²² where it appears to regulate insulin secretion through an autocrine mechanism.

Islet Distribution

The beta-cells are generally located in the central portion of each islet and make up about 70% of the total islet cell mass. The other cell types are located predominantly in the periphery. The delta cells are least plentiful, making up only 5%; the ζ -cells make up 10%, and the PP cells make up 15%.²³ In contrast to the acinar cells that secrete the full gamut of exocrine enzymes, the islet cells seem to specialize in the secretion of predominantly one hormone. However, individual islet cells can secrete multiple hormones. For example, the beta-cells secrete both insulin and amylin, which counter regulates the actions of insulin. In reality, more than 20 different hormones are secreted by the islets, and the exact functions of this milieu are very complex. There is diversity among the islets depending on their location within the pancreas. The beta and delta cells are evenly distributed throughout the pancreas, but islets in the head and uncinate process (ventral anlage) have a higher percentage of PP cells and fewer alpha cells, whereas islets in the body and tail (dorsal anlage) contain the majority of alpha cells and few PP cells. This is clinically significant because pancreatectomy removes 95% of the PP cells in the pancreas. This may partially explain the higher incidence of glucose intolerance after the Whipple procedure compared to a distal pancreatectomy with an equivalent amount of tissue resected. In addition, chronic pancreatitis, which disproportionately affects the pancreatic head, is associated with PP deficiency and pancreatogenic diabetes.²⁴ The relative preponderance of alpha cells in the body and tail of the pancreas explains the typical location of glucagonomas.

ACUTE PANCREATITIS

Definition, Incidence, and Epidemiology

Acute pancreatitis is an inflammatory disorder of the pancreas that is characterized by edema and, when severe, necrosis. It is a common and challenging disease that can develop local and systemic complications. As such, it ranges from a mild, self-limiting inflammation of the pancreas to severe and critical disease characterized by infected pancreatic necrosis, multiple

organ failure, and a high mortality.²⁵ The traditional view is that acute pancreatitis completely resolves with no morphological, functional, or symptomatic sequelae. But necrotizing pancreatitis can leave significant scarring, strictures, and impairment of exocrine and endocrine pancreatic function. The overall clinical outcome has improved over recent decades, even in the absence of specific treatments that target outcome-determining pathophysiology, probably because of a more standardized approach to diagnosis, monitoring, and management.

Acute pancreatitis is the most common inpatient principal gastrointestinal discharge diagnosis in the United States (274,119 in 2009), with an increasing incidence (30% since 2000) and is associated with the highest aggregate inpatient costs at 2.6 billion dollars per year.²⁶ The crude mortality rate of 1 per 100,000 population ranks it as the 14th most common overall and the 9th most common noncancer cause of gastrointestinal deaths. Worldwide, the incidence of acute pancreatitis ranges from 5 to 80 per 100,000 population, with the highest incidence recorded in Finland and the United States.²⁷ The incidence of acute pancreatitis also shows significant variation related to the prevalence of etiological factors and ethnicity. The annual incidence of acute pancreatitis in Native Americans is 4 per 100,000 population; in whites, it is 5.7; and in blacks it is 20.7.²⁸ Smoking is an independent risk factor for acute pancreatitis.²⁹

Etiology

Many factors are causally related to the onset of acute pancreatitis, but the mechanism is often poorly understood. The most common causes are gallstones and alcohol (Table 33-4), accounting for up to 80% of cases, but it is not uncommon to diagnose acute pancreatitis in the absence of these etiological factors (“idiopathic acute pancreatitis”), and it is important that a systematic approach is taken to the identification of other, less

common and potentially modifiable factors. The median age at index presentation of acute pancreatitis varies with etiology: with alcohol- and drug-induced pancreatitis presenting in the third or fourth decade compared with gallstone and trauma in the sixth decade. The gender difference is probably more related to etiology: in males alcohol is more often the cause while in females it is gallstones.

Gallstones

Evidence that passage of a gallstone is related to the onset of acute pancreatitis comes from the characteristic transient derangement of liver function tests and the high retrieval rate of gallstones from feces within 10 days of an attack of acute pancreatitis compared with those without acute pancreatitis (88% vs. 11%).³⁰ The mechanism by which small gallstones cause acute pancreatitis in migrating through to the duodenum is not clear. Opie made the seminal observation of a gallstone impacted in the sphincter of Oddi in two fatal cases of acute pancreatitis, which led to the “common channel” hypothesis. It was proposed that this allowed bile to reflux into the pancreatic duct, but this cannot be reliably reproduced in experimental models. Another proposal was that transient incompetence caused by the passage of a stone through the sphincter might allow duodenal fluid and bile to reflux into the pancreatic duct, but this is not supported by the failure of this to commonly occur after endoscopic sphincterotomy. A third possibility is that acute pancreatitis is due to the gallstone obstructing the pancreatic duct and leading to ductal hypertension. It has been postulated that this backpressure might lead to minor ductal disruption, extravasation of pancreatic juice into the less alkaline interstitium of the pancreas, and promotion of enzyme activation. When gallstones and other etiological factors cannot be identified, there is still the possibility of finding microlithiasis, seen as birefringent crystals, on bile microscopy.³¹ This occult microlithiasis is probably responsible for up to half of those with idiopathic acute pancreatitis.

Alcohol

Alcohol ingestion is associated with acute pancreatitis, and sustained alcohol ingestion is associated with recurrent acute pancreatitis and development of chronic pancreatitis in susceptible individuals who have been drinking for more than a decade. The type of alcohol consumed is less important than the amount consumed (typically 100–150 grams per day) and the pattern of drinking. It is common for patients with alcohol-associated acute pancreatitis to have a history of excess alcohol consumption prior to the first attack. There are several mechanisms by which ethanol causes acute pancreatitis by acting on the acinar and stellate cells.³² The acinar cell metabolizes ethanol by oxidative and nonoxidative pathways, and exhibits changes that predispose the cell to autodigestive injury, necroinflammation, and cell death. The stellate cells are activated on exposure to ethanol to a myofibroblast phenotype, stimulating synthesis of proinflammatory mediators and cytokines. Ethanol causes a brief secretory increase followed by inhibition. The secretory burst coupled with ethanol induced spasm of the sphincter of Oddi probably incites acute pancreatitis. Ethanol also induces ductal permeability, which allows prematurely activated enzymes to cause damage to the pancreatic parenchyma. Ethanol also increases the protein content of pancreatic juice and decreases bicarbonate levels and trypsin inhibitor concentration. The formation of protein plugs may also contribute by causing an obstructive element to pancreatic outflow, more often seen in chronic pancreatitis.

intra-acinar activation of zymogens has been demonstrated consistently in multiple animal models of acute pancreatitis and is considered a key precipitating event.^{37,38} The key role of trypsin activation in acute pancreatitis has gained additional support from recent studies showing that mice lacking trypsinogen-7 (the isoform of trypsinogen that is activated during acute pancreatitis in mice) have significantly less pancreatic injury during acute pancreatitis³⁹ and that intra-acinar expression of active trypsin causes pancreatitis in mice.⁴⁰ The role of trypsin activation in the pathophysiology of acute pancreatitis has also been suggested by clinical studies. Hereditary pancreatitis is associated with mutations that lead to elevated intracellular trypsin activation,⁴¹ and activation of trypsinogen causes clinical pancreatitis.⁴²

Significant progress has been made in understanding the mechanisms by which injurious stimuli lead to intra-acinar activation of trypsinogen and autodigestion of the gland (Figure 33-11). Under physiologic conditions, several protective mechanisms have evolved to prevent autodigestion of the pancreas by these enzymes. This includes synthesis of enzymes as inactive precursors, separation of the site of production, and activation of the enzymes and presence of trypsin inhibitors in the pancreas. It is thought that acute pancreatitis occurs when these protective mechanisms are overwhelmed with erroneously activated enzymes, causing injury. It has been shown that intra-acinar activation of trypsinogen goes hand-in-hand with inhibition of acinar secretion.^{43,44} Furthermore, with injurious stimuli the zymogens responsible for initiating the disease are not secreted outside, but colocalize with cytoplasmic vacuoles that contain lysosomal enzymes such as cathepsin B⁴⁵ that activate trypsinogen. Thus, inhibition of cathepsin B by pharmacological inhibitors⁴⁶ or by genetic deletion of cathepsin

B eliminates trypsin activation and decreases the severity of pancreatitis in animal models.⁴⁷ What leads to the colocalization of zymogens and lysosomal hydrolases is unclear, but injurious stimuli leading to sustained cytosolic calcium increase have been indicted. Blocking this calcium increase prevents colocalization and activation of trypsin, and it decreases injury due to pancreatitis.⁴⁸ Based on these data, pre-ERCP supplementation of magnesium, a natural antagonist of calcium, is currently being evaluated as a strategy to decrease post-ERCP pancreatitis.⁴⁹ Recent work has led to the novel hypothesis that the lysosomal hydrolase cathepsin B activates trypsinogen to trypsin within the colocalization vacuoles. Trypsin then permeabilizes these colocalization vacuoles causing the release of cathepsin B into the cytosol. Once in the cytosol, cathepsin B initiates apoptotic cell death by permeabilizing mitochondrial membranes, which allows cytochrome C to be released into the cytosol. This initiates the apoptotic cascade and results in the apoptotic death of the acinar cells⁵⁰ (see Figure 33-11).

Intrapancreatic Events

Although intra-acinar events initiate acute pancreatitis, events occurring subsequent to acinar cell injury determine the severity of pancreatitis. Activated neutrophils are attracted and activated in the pancreas releasing superoxide (the respiratory burst) and proteolytic enzymes (cathepsins, elastase, and collagenase) that cause further pancreatic injury. In addition, macrophages release cytokines (including tumor necrosis factor- α (TNF- α) and interleukins (IL-1, IL-2, IL-6, and IL-8) that mediate local and systemic inflammation.³⁸

These inflammatory mediators cause an increased pancreatic vascular permeability, leading to hemorrhage, edema, and

Figure 33-11. Schematic representation of the acinar cell events in acute pancreatitis. When acinar cells are pathologically stimulated, their lysosomal (L) and zymogen (Z) contents colocalize, and consequently trypsinogen is activated to trypsin by cathepsin B. Increased cytosolic calcium is required for colocalization. Once trypsin has permeabilized the contents of the cytosol, cathepsin B and other contents of these colocalized organelles are released. Once in the cytosol, cathepsin B activates apoptosis by causing cytochrome c to be released from the mitochondria. Activation of PKC results in a sudden activation of nuclear factor kappa beta (NF κ β), which in turn triggers the release of cytokines that attract inflammatory response cells that mediate local and systemic inflammation cascades.

Figure 33-12. Computed tomography scan showing well perfused interstitial edematous acute pancreatitis of the neck and tail of the pancreas with a confluent area of necrosis of the pancreatic body. The pancreas is surrounded by fluid, inflammation, and possible peripancreatic fat necrosis.

microthrombi. Fluid may collect in and around the pancreas. The failure of the pancreatic microcirculation, a feature of more severe acute pancreatitis, results in pancreatic hypoperfusion and necrosis. Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but with no recognizable necrosis, is termed interstitial edematous pancreatitis.²⁵ When necrosis is present, as evidenced by pancreatic hypoperfusion with contrast CT, it is termed necrotizing pancreatitis (Figure 33-12). The updated morphological definitions and the contrast enhanced CT criteria for the diagnosis of the local complications of acute pancreatitis are in the revised Atlanta statement⁵¹ and summarized in Table 33-5.⁵²

Systemic Events

An important aspect of the pathophysiology of acute pancreatitis is the mechanism by which events occurring in the pancreas induce systemic inflammation and multiorgan failure. The NFκB-dependent inflammatory pathway is an important mechanism (see Figure 33-11). Activation of NFκB parallels trypsin activation in acute pancreatitis but appears to be independent of it, as it occurs in trypsin knockout mice.³⁹ Sustained calcium increase, which leads to trypsinogen activation, is critical for NFκB activation since attenuation of cytosolic calcium abrogates NFκB activation.⁵³ Once activated, NFκB regulates synthesis of multiple cytokines and chemokines, leading to recruitment of various inflammatory cells that then magnify and

propagate systemic inflammation.⁵⁴ The infiltrating neutrophils can also further augment the pancreatic injury.^{55,56} Inhibition of many of these cytokines have led to reduced local and systemic injury in animal models of acute pancreatitis. But these results did not translate to clinical improvement.⁵⁷ New strategies are required to reduce the systemic inflammatory response.⁵⁸⁻⁶⁰

Organ failure can develop at any stage of acute pancreatitis, associated with an overwhelming proinflammatory response early, or later secondary to the development of infected local complications. The drivers of the systemic response are poorly understood, although factors include the elaboration of proinflammatory cytokines, and it appears that mesenteric lymph, bypassing the liver and containing these constituents, may contribute to the development of organ failure⁶¹ (see Figure 33-10). The development of pancreatic necrosis, the breakdown of the intestinal barrier, and the suppression of the immune response through the compensatory inflammatory response contribute to the development of infected pancreatic necrosis, the incidence of which peaks in the third to fourth week. This is usually associated with deterioration in the patient's condition and may be associated with the late development of the systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome/failure (MODS/F).

Organ failure is scored using the Marshall or Sequential Organ Failure Assessment (SOFA) systems (Table 33-6). The three organ systems most frequently involved are cardiovascular, respiratory, and renal. Multiple organ failure is defined as two or more organs registering two or more points on these scoring systems.⁵¹ Monitoring organ failure over time and in response to treatment is important in the care and timing of intervention in these patients.

Management of Acute Pancreatitis

General Considerations. The management of acute pancreatitis covers a wide spectrum of severity. All patients with suspected acute pancreatitis should be admitted to hospital. Those with mild acute pancreatitis usually remain in hospital for less than a week, while those with severe and critical acute pancreatitis may require many weeks or months of intensive treatment. The risk of mortality reflects this spectrum of severity. The risk is less than 1% for those with mild disease, increasing to around 10% for those with moderate disease, but for severe (20–40%) and critical (>50%) disease the mortality risk is much higher. The earlier identification of these high-risk categories and their transfer to specialized centers is an important priority of management.⁶²

The management of acute pancreatitis is multidisciplinary, and it is important that this is coordinated care plan is carefully supervised.⁶³ The essential requirements for the management

^aAdrenergic agents administered for at least 1 h (doses given in μg/kg per min). A score of 2 or more in any two systems indicates the presence of multiple organ failure.

Abbreviations: MAP = mean arterial pressure; Epi = epineptvine; Norepi = norepinephrine.

of acute pancreatitis are accurate diagnosis, appropriate triage, high-quality supportive care, and monitoring for and treatment of complications.⁶⁴

Diagnosis

The diagnosis of acute pancreatitis requires the patient to present with abdominal pain consistent with acute pancreatitis (acute onset of a severe constant epigastric pain that often radiates through to the mid back) and the elevation of serum amylase or lipase (>3 times upper limit of normal). Imaging (usually by contrast-enhanced CT scanning) is only required for the diagnosis of acute pancreatitis when these diagnostic criteria are not met.⁵¹ Because of the many causes of hyperamylasemia, it is important to use either the pancreatic isoenzyme of amylase or lipase.⁶³

The serum amylase concentration increases almost immediately with the onset of disease and peaks within several hours and remains elevated for 3 to 5 days.⁶⁴ There is no correlation between the extent of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase compared with that in a more severe form of the disease. It is important to note that hyperamylasemia can also occur in association with other diseases. For example, it can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intra-abdominal inflammatory conditions. In contrast, a patient with acute pancreatitis can have a normal serum amylase level, for several different reasons. In patients with hyperlipidemia, values might appear to be normal because of interference with chemical determination of serum amylase by lipids. In some cases, urinary clearance of pancreatic enzymes from the circulation increases during pancreatitis, meaning that urinary levels may be more sensitive than serum levels. For these reasons, it is recommended that amylase concentrations also be measured in the urine. Urinary amylase levels usually remain elevated

for several days after serum levels have returned to normal. In patients with severe pancreatitis associated with significant necrosis, the pancreas may not have the capacity to release large amounts of enzymes into the circulation. With more severe disease, there is also hemoconcentration from third space fluid loss, and this can affect the serum concentration of amylase.

The clinical signs of acute pancreatitis include abdominal tenderness, often with signs of peritonitis in the upper abdomen. Rarely, pancreatic fluid and bleeding from the pancreas into the retroperitoneum may result in a bruise-like discoloration around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign). Another rare sign is tetany as a result of hypocalcaemia. In addition to hemoconcentration, patients with acute pancreatitis often have azotemia with elevated blood urea nitrogen and creatinine levels, hyperglycemia, and hypoalbuminemia.

Pain Management

Pain is the cardinal symptom of acute pancreatitis, and its relief is a clinical priority. There is a lack of high-quality evidence to guide the choice of analgesic. Because of unpredictable absorption, analgesia should be administered intravenously, at least at the outset and before oral intake has been established. Those with mild pain can usually be managed with a nonsteroidal anti-inflammatory drugs (e.g., metamizole 2 g/8 h IV), while those with more severe pain are best managed with opioid analgesia (e.g., buprenorphine 0.3 mg/4 h IV). Administration of buprenorphine, pentazocine, procaine hydrochloride, and meperidine are all of value in controlling abdominal pain. Morphine is to be avoided because of its potential to cause sphincter of Oddi spasm.

Predicting Severity

Whereas classification relates to the present or past severity of acute pancreatitis, prediction is about the future and ultimate severity and outcome of the patient. Accurately predicting acute

Table 33-7

Ranson's prognostic signs of pancreatitis

Criteria for acute pancreatitis not due to gallstones	
At admission	During the initial 48 h
Age >55 y	Hematocrit fall >10 points
WBC >16,000/mm ³	BUN elevation >5 mg/dL
Blood glucose >200 mg/dL	Serum calcium <8 mg/dL
Serum LDH >350 IU/L	Arterial PO ₂ <60 mmHg
Serum AST >250 U/dL	Base deficit >4 mEq/L
	Estimated fluid sequestration >6 L
Criteria for acute gallstone pancreatitis	
At admission	During the initial 48 h
Age >70 y	Hematocrit fall >10 points
WBC >18,000/mm ³	BUN elevation >2 mg/dL
Blood glucose >220 mg/dL	Serum calcium <8 mg/dL
Serum LDH >400 IU/L	Base deficit >5 mEq/L
Serum AST >250 U/dL	Estimated fluid sequestration >4 L

Note: Fewer than three positive criteria predict mild, uncomplicated disease, whereas more than six positive criteria predict severe disease with a mortality risk of 50%.

Abbreviations: AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; PO₂ = partial pressure of oxygen; WBC = white blood cell count.

Data from Ranson JHC. Etiological and prognostic factors in human acute pancreatitis: a review. *Am J Gastroenterol.* 1982;77:633 and from Ranson JH, Rifkind KM, Roses DF, et al. Prognostic signs and the role of operative management in acute pancreatitis. *Surg Gynecol Obstet.* 1974;139:69.

pancreatitis severity is important in making triage decisions about whether a patient should be transferred to a tertiary hospital or an intensive care unit and in making decisions about fluid therapy and whether an ERCP is indicated, as well as other issues.⁶⁵ There is a very long history of attempts to find prognostic or predictive markers that accurately stratify the risk, with the most widely used being the Ranson's criteria (Table 33-7) or modified Glasgow criteria. Both use clinical and biochemical parameters scored over the first 48 hours of admission. When there are three or more positive criteria, the disease is considered "predicted severe." There are many other approaches to predicting severity. At 24 hours after admission an APACHE II score of 8 or more or a serum C-reactive protein level of >150 mg/dL has a similar accuracy in predicting severity as Ranson's criteria.⁶⁶ The more recently proposed Bedside Index for Severity of Acute Pancreatitis (BISAP) is calculated from blood urea nitrogen (> 25 mg/dL), impaired mental status (GCS <15), presence of systemic inflammatory response syndrome, age >60 years, and pleural effusion. Although it has the advantage of simplicity and can be performed within the first 24 hours of admission, it performed no better than other predictors.⁶⁷ The presence of SIRS also has prognostic significance.⁶⁸ There remains some controversy as to how important obesity is as a risk factor for severe and critical acute pancreatitis.⁶⁹ Another approach has been taken in seeking to predict those with the "harmless acute pancreatitis score"⁷⁰ using three factors that can be determined on admission: absence of

rebound tenderness or guarding, normal hematocrit, and normal serum creatinine. The accuracy of this approach appears to be over 90% and triages most patients away from intensive care.

Unfortunately, these and many other single and combined predictors of severity have an accuracy of around 70%.⁶⁶ This means that there is misclassification error of 30% that limits the value in predicting the severity of acute pancreatitis in individual patients. In the absence of any new biomarkers of pancreatitis severity, making better use of existing predictors through sequencing tests, combining tests, or using artificial neural network methodologies has shown some promise.⁷¹ Scoring systems should augment clinical judgment, but not replace it.⁶⁴ Over the first 2 to 3 days the clinician must be alert to patients with an elevated BUN or creatinine and/or persistent SIRS after adequate fluid resuscitation because these patients are at risk of developing severe acute pancreatitis.⁶⁴

Classification of Severity

Accurately classifying or staging acute pancreatitis severity is important for clinical decision-making, communication, and enrolment into trials. The wide spectrum of pancreatitis severity was not captured in the previous binary classifications (mild or severe). The key determinants of severity are local complications (absent, sterile, or infected) and systemic complications (absent, transient organ failure, persistent organ failure).^{25,72} Two classification systems have recently been proposed: the three grades (mild, moderately severe, and severe) of the Revised Atlanta Criteria (RAC)⁵¹ and the four categories (mild, moderate, severe, critical) of the Determinants Based Classification (DBC)⁷³ (Table 33-8). The DBC

Table 33-8

Definitions for the classification of acute pancreatitis severity according to Revised Atlanta Classification¹¹ and the Determinants Based Classification¹⁴. (Transient organ failure has a duration of <48 hours, persistent organ failure has duration of >48 hours.)

Determinant Based Classification (2012)	Revised Atlanta Classification (2013)
Mild	No local complication
No systemic complication	No local complication
No systemic complication	
Moderate	Sterile local complication and/or
Transient organ failure	Local or systemic complications without persistent organ failure or exacerbation of preexisting comorbidity
Severe	infected local complication or
Persistent organ failure	Persistent organ failure (single or multiple)
Critical	Infected local complication and
Persistent organ failure	-

Table 33-9

The Modified Determinant Based Classification (MDBC) (Acevedo) of acute pancreatitis severity compared with the Revised Atlanta Classification (RAC) and Determinants Based Classification (DBC). Note that the DBC has a narrower definition for local complications than RAC, leading to a slightly broader range of mild acute pancreatitis in this table.

RAC	Mild
(No OF, No LC)	Moderately severe
(TOF and/or LC)	Severe
(POF)	
DBC	Mild
(No OF, No LC)	Moderate
(TOF and/or SN)	Severe
(POF or IN)	Critical
(POF and IN)	
MDBC Excluded	Group 1
(TOF and/or SN)	Group 2
(IN without POF)	Group 3
(POF without IN)	Group 4
(POF and IN)	

Abbreviations: OF = organ failure; LC = local complication; TOF = transient organ failure; POF = persistent organ failure; SN = sterile necrosis; IN = infected necrosis.

was developed on the principle of casual inference, derived by meta-analysis, and refined by an international multidisciplinary process,⁷³ and both classifications have been independently validated, which suggests that they are broadly equivalent. More recently a prospective multicenter study has modified the DBC to address the ongoing issue that patients considered to have severe acute pancreatitis represent several subgroups with different morbidity, mortality, and intervention profiles⁷⁴ (Table 33-9).

The classification of patient severity is helpful in tracking the clinical trajectory of a patient, and it can be applied on a daily or more frequent basis. It can also be used in retrospect for audit purposes.

Determining Etiology

The history of alcohol ingestion must be ascertained and preferably confirmed with blood ethanol levels. Gallstones should be investigated by ultrasonography. A gallstone etiology is more likely in females over the age of 50 with an elevation of alkaline phosphatase (>300 iu/L), alanine transferase (>100 iu/L), and amylase (>4000 iu/L). In the absence of gallstones and alcohol, a systematic approach to the identification of another factor will include taking a history of drugs, trauma, ERCP, infection, and measuring serum triglycerides, calcium, and others (see Table 33-4).

Fluid Resuscitation

Fluid therapy to restore and maintain circulating blood volume is the most important intervention in the early management of

acute pancreatitis⁷⁵. However, a recent systematic review has shown that the evidence base for fluid therapy is scant,⁷⁶ and most recommendations are based on expert opinion.⁶⁴ It is not known which fluid to give, how aggressively to administer it, or what goal to use to guide and monitor the response to it. While there are proponents for vigorous fluid therapy (5–10 mL per kilogram per hour), especially in the first 24 hours, and for specific resuscitation goals,⁷⁷ it is probably best to resuscitate with a balanced crystalloid and aim to restore normal blood volume, blood pressure, and urine output. In one study, lactated Ringer's solution was superior to normal saline in reducing the systemic inflammatory response.⁷⁸ Caution needs to be exercised in those with cardiac and renal disease and in the elderly, where the risks of over-resuscitation are greater.

Nutritional Support

In contrast to analgesia and fluid therapy, there is a sound evidence base for nutritional support in acute pancreatitis. It is no longer acceptable to “rest the pancreas” by avoiding enteral nutrition, now the mainstay of nutritional support.⁷⁹ Parenteral nutrition is now known to be more expensive, riskier, and not more effective than enteral nutrition and should only be offered if the patient's calculated nutritional requirements cannot be achieved by the enteral route. Early initiation of enteral nutrition (within the first 24 hours of admission) is not superior to delaying an oral diet until 72 hours.⁸⁰ If this is not tolerated over 48 to 72 hours, then nasogastric tube feedings can be started and increased in step-wise fashion over 2 to 3 days.⁸¹ The tube can be advanced to the jejunum, by endoscopy or fluoroscopy, if there is evidence of feeding intolerance. A delay in commencing enteral nutrition may contribute to the development of intestinal ileus and feeding intolerance, but aggressive early enteral feeding, particularly before adequate resuscitation, may put the patient at risk of nonocclusive mesenteric ischemia. There is no evidence to support the use of elemental or immune-enhancing formulas over standard polymeric formulas.⁸² In predicted mild acute pancreatitis the recommencement of oral fluids and then food was delayed until resolution of abdominal pain and normalization of serum levels of amylase, but it appears safe to allow patients to resume intake ad libitum (i.e., patient-controlled nutrition). If after 3 to 5 days there is evidence of feeding intolerance, tube feeding should be commenced.

Cross-Sectional Imaging

It may be necessary to perform a CT scan to diagnose acute pancreatitis in patients who are severely ill or in those presenting with undifferentiated abdominal pain. But there is no advantage in using CT scanning to predict the severity of acute pancreatitis.^{51,63} The primary purpose of cross-sectional imaging is the diagnosis of local complications; in particular, the development and extent of pancreatic necrosis and the different collections (see Table 33-5). CT scanning is also important to guide the insertion of percutaneous drains, now assuming a greater role in the management of the local complications (discussed later). Magnetic resonance imaging (MRI) is superior to CT scanning in detecting any solid content within collections (Figure 33-13). And when a bleed is suspected, in association with a local complication, an arterial phase CT scan (CTa) is useful in detecting a pseudoaneurysm, active bleeding, and/or hematoma.

Figure 33-13. Corresponding computed tomography (CT) (A) and MR (B) images of a patient with a symptomatic pseudocyst. CT image reveals a well circumscribed homogenous collection (arrows) exerting mass effect on antrum of stomach. The T2-weighted MR image clearly distinguishes necrotic pancreas (black arrows) from fluid (white arrows). (Reproduced with permission from Bollen TL: *Imaging of acute pancreatitis: update of the revised Atlanta classification*, *Radiol Clin North Am.* 2012 May;50(3):429-445.)

Therapeutic Endoscopic Retrograde Cholangiopancreatography

Randomized trials have demonstrated that early ERCP (within 24 or 48 hours of admission) reduce complications, but not mortality, in patients with predicted severe gallstone associated acute pancreatitis. While the benefits of this invasive modality are clear (e.g., treatment of cholangitis and release of impacted stone), this can be offset by the risks of increasing the severity of pancreatitis, bleeding, cholangitis, and perforation. More recent evidence has suggested that early ERCP confers no benefit in the absence of concomitant cholangitis,⁸³ as the offending common duct stone usually passes before ERCP can be performed. This may be evidenced by improvement in the liver function tests over the first 2 to 3 days. If there is persistent cholestasis, an MRCP can be used to detect a common duct stone and can be used as a prerequisite for attempting an ERCP.⁸⁴ Persistent cholestasis without cholangitis may require an ERCP but not usually in the acute setting.

Antibiotics

Although the use of broad-spectrum antibiotics to treat established infection in acute pancreatitis is a well-established practice, there has been considerable controversy surrounding the use of prophylactic antibiotics.⁶³ The overuse of antibiotics has been associated with a documented rise in fungal infections and resistant organisms. Overall, it appears that the most recent and generally better designed studies do not support the use of prophylactic antibiotics to reduce the frequency of pancreatic infectious complications, surgical intervention, and death.⁸⁵

Managing Local Complications

Vigilance is required for the timely and accurate diagnosis of local complications. The decisions regarding how and when to

intervene are often difficult. While guided by the information gained by cross-sectional imaging, the decision to intervene is based on the clinical status and trajectory of the patient and the poor response to maximal intensive care support. This means close monitoring of the patient by serial examination, supplemented by regular measurement of inflammatory markers (e.g., C-reactive protein) and a pancreatic protocol CT scan if a local complication is suspected and intervention considered warranted. In practice, intervention is delayed in order to allow demarcation and to reduce the risk of bleeding, disseminated infection, and collateral damage to adjacent organs by an intervention (Figure 33-14). Appreciation of this has resulted in a notable trend toward delayed

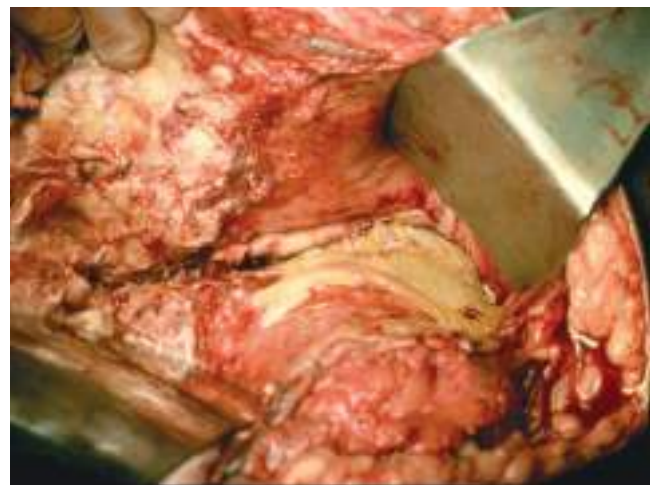

Figure 33-14. Operative view of infected acute pancreatitis. Peripancreatic infection, characterized by mucopurulent exudate, extends far beyond the boundaries of the pancreas in the retroperitoneum.

intervention, now uncommon before 3 to 4 weeks from the onset of symptoms. An important emerging approach is the increasing use of percutaneous catheter drainage in patients with suspected infected collections.⁸⁶ Fine-needle aspiration is now rarely used to confirm infection because the insertion of a needle at the time of planned drainage allows confirmation of the suspected infection. Preemptive drainage with one or more catheters often produces improvement or stabilization of the patient's overall clinical status.⁸⁷ In this way, drainage "buys time" and allows the lesion to become more walled off and safer to treat. Recent data suggests that primary percutaneous catheter drainage may be the only intervention required in a third to a half of patients and that this proportion might increase further if there were a policy of regular catheter exchange, upsizing, and irrigation.⁸⁷ A proportion of patients do, however, require further treatment when they fail to respond and there is a wide array of minimally invasive options to choose from⁸⁸ (Figure 33-15). These interventions can be classified on the basis of the method of visualization, route taken to the lesion, and the purpose of the intervention.⁸⁹ In practice, the approach taken will depend on local expertise and equipment as well as the location and type of the specific local complication. A large Dutch randomized trial has shown that open surgical techniques should only be considered in those who fail to respond to the step-up approach, that is, prior percutaneous drainage and minimally invasive intervention.⁹⁰ The exception is to be found in the rare situation where an abdominal compartment syndrome requires open decompression, but this is usually earlier than the optimal time to intervene for local complications. A recent landmark randomized trial has compared two minimally

invasive techniques, endoscopic transgastric drainage, and the videoscope-assisted retroperitoneal debridement through a flank incision (see Figure 33-15). The data shows that the former approach is superior, although the latter has a role when the walled-off necrosis is remote from the stomach or duodenum, as in the left flank.⁹¹

The management of an acute noninfected pseudocyst is usually conservative, as about half of these will resolve spontaneously. When symptoms of pain or the inability to eat persist or infection occurs, intervention is required. The indications for intervention are therefore no longer based on size and duration alone. Pseudocysts persist because of communication with the main pancreatic duct and/or distal ductal stenosis. Percutaneous drainage should be avoided in this situation because of the risk of external pancreatic fistula.⁹² EUS-guided internal drainage into stomach or duodenum or transpapillary stenting is the preferred approach.

Managing Organ Failure

The specific management of multiple organ failure is beyond the scope of this chapter. The early identification of organ dysfunction and failure is important because it is a key determinant of severity and outcome and to facilitate the timely transfer of the patient to an intensive care unit to optimize management, provide organ support and allow more intensive monitoring. The severity of organ failure can be scored (see Table 33-6). The responsiveness of organ failure to resuscitation over the first 48 hours is an important prognostic clue; those that respond have transient organ failure and have a better outlook than those who do not respond and have persistent organ failure.⁹³ Organ failure that develops later in the disease course is usually

Figure 33-15. Two minimally invasive interventions for local complications of acute pancreatitis: **A.** video-assisted retroperitoneal debridement and **B.** endoscopic transgastric necrosectomy. (Reproduced with permission from Bakker OJ, van Santvoort HC, van Brunschot S, et al: Endoscopic transgastric vs surgical necrosectomy for infected necrotizing pancreatitis: a randomized trial, *JAMA*. 2012 Mar 14; 307(10):1053-1061.)

secondary to infection of a local complication and should be managed accordingly (see Figure 33-9).

Cholecystectomy

While it is widely accepted that cholecystectomy is essential to prevent recurrent gallstone associated pancreatitis, the question relates to the timing of it. Index cholecystectomy, done in the same admission and prior to discharge, appears safe and can almost always be accomplished laparoscopically.⁹⁴ But index cholecystectomy is not suitable for all patients, particularly some who have had local pancreatic complications, which includes a large inflammatory mass that extends into the porta hepatis. These patients may require an interval cholecystectomy after resolution of the inflammatory process. If surgery is required for the management of local complications, then a cholecystectomy is often performed at that time.

Diabetes

Recent evidence indicates that prediabetes and diabetes are common after acute pancreatitis and occur in nearly 40% of patients

after hospital discharge.⁹⁵ The prevalence of newly diagnosed diabetes is much higher after acute pancreatitis (23%) than the prevalence of diabetes in the general population (4–9%). The risk of diabetes increases by at least twofold after 5 years as compared with 12 months. Interestingly, the severity of acute pancreatitis appears to have minimal effect on risk of diabetes.⁹⁵ The implication is that patients recovered from an attack of acute pancreatitis may need follow-up and screening for glucose intolerance.

The management of acute pancreatitis remains a formidable challenge (Table 33-10) due to the variety and severity of the many associated complications (Table 33-11), and continues to evolve. Although specific treatments for acute pancreatitis remain elusive, progress has been made in the management of pain, fluid resuscitation, antibiotic prophylaxis, enteral nutrition, therapeutic ERCP, and cholecystectomy. Progress has also been made in the intensive care management of systemic complications and in the development of less invasive interventions for the treatment of local complications, particularly infected pancreatic necrosis.

CHRONIC PANCREATITIS

Definition, Incidence, and Prevalence

Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Autopsy studies indicate that evidence of chronic inflammation, such as fibrosis, duct ectasia, and acinar atrophy is seen in up to 5% of the population,⁹⁶ although these data are difficult to interpret because many of these changes are also present in asymptomatic

elderly patients.⁹⁷ Population studies suggest a prevalence that ranges from 5 to 40 persons per 100,000 population, with considerable geographic variation.⁹⁸ Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively over the past 50 years.

Etiology

There are multiple etiologies of chronic pancreatitis, including genetic mutations, alcohol exposure, duct obstruction due to trauma, gallstones, and tumors, metabolic diseases such as hyperlipidemia and hyperparathyroidism, and auto-immune disease. In addition, nutritional causes include so-called tropical pancreatitis, which has been thought to result from ingestion of certain starches. A significant number of patients have no discernible cause of the disease despite extensive testing, and are said to have "idiopathic" chronic pancreatitis.

Genetic Causes

In 1952, Comfort and Steinberg reported a kindred of "hereditary chronic relapsing pancreatitis" after treating the proband, a 24-year-old woman, at the Mayo Clinic.⁹⁹ Subsequently, familial patterns of chronic, nonalcoholic pancreatitis have been described worldwide, and a familial pattern has emerged. Typically, patients first present in childhood or adolescence with abdominal pain and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms due to pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence, in some series, of 40%, but the age of onset for carcinoma is typically >50 years old.¹⁰⁰ The disorder is characterized by an autosomal dominant pattern of inheritance, with 80% penetrance and variable expression. The incidence is equal in both sexes.

Whitcomb and colleagues,¹⁰¹ and separately LeBodic and associates,¹⁰² performed gene-linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg-to-His substitution at position ¹¹⁷ of the cationic trypsinogen gene, or *PRSSI*, one of the primary sites for proteolysis of trypsin. This gain-of-function mutation results in an excess production of trypsinogen, which results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas.¹⁰³ The position ¹¹⁷ mutation of *PRSSI* and an additional mutation, now known collectively as the R122H and N291 mutations of *PRSSI*, account for about two-thirds of cases of hereditary pancreatitis. Masson and associates described a gain-of-function mutation in the anionic trypsinogen gene, *PRSS2*, that is also present in some cases.¹⁰⁴

Similarly, SPINK1, an inflammation-induced trypsin inhibitor secreted in acinar cells, has been found to have a role in hereditary pancreatitis. SPINK1 specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Witt and colleagues investigated⁹⁶ unrelated children with chronic pancreatitis in Germany and found a variety of SPINK1 mutations in 23% of the patients.¹⁰⁵ Several studies have now confirmed an association of loss-of-function SPINK1 mutations with familial and idiopathic forms of chronic pancreatitis, as well as so-called tropical pancreatitis.^{106,107} SPINK1 mutations

are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4% in France¹⁰⁸ to 25.8% in the United States.¹⁰⁹ Thus, hereditary pancreatitis results from one or more mutational defects that incapacitate an auto-protective process that normally prevents proteolysis within the pancreas.

Cystic fibrosis, originally termed cystic fibrosis of the pancreas, results from a variety of mutations of the cystic fibrosis transmembrane receptor (CFTR). The CFTR is present in pancreatic duct cells and controls the amount of chloride and bicarbonate secreted into the normally alkaline pancreatic juice. The CFTR gene contains over 4300 nucleotides, divided into 24 exons, which encode a 1480-amino acid protein. Over 1000 polymorphisms have been reported, and many are common. The CFTR mutation associated with the classic pulmonary disease, F508, is rarely observed in chronic pancreatitis. But other CFTR mutations have been noted to be associated with chronic idiopathic pancreatitis, auto-immune pancreatitis, and pancreas divisum, in which the pulmonary, intestinal, and cutaneous manifestations of the disease are silent.¹¹⁰

Many studies have been undertaken to determine whether specific genetic abnormalities are associated with alcoholic chronic pancreatitis and which might confer susceptibility to the disease.¹⁰⁵ In 2012, a landmark study by Whitcomb and associates demonstrated a likely genetic cause of the predisposition to alcohol-induced chronic pancreatitis in men.¹¹¹ In a genome-wide association study of more than 2000 patients, these researchers discovered that a common DNA variant on the X chromosome is present in 26% of men without pancreatitis, but jumps to nearly 50% of men diagnosed with alcoholic pancreatitis. The variant involves the *claudin 2* (*CLDN2*) gene, which encodes a tight junction protein normally present in ductal cells. In cases of chronic pancreatitis, the *CLDN2* protein is abnormally expressed in acinar cells and may alter the secretory dynamics of enzyme release. The abnormality does not appear to cause pancreatitis, but if pancreatitis occurs for any reason in a person with the *CLDN2* variant, it is more likely that the person will develop chronic pancreatitis; the risk is increased even further among alcohol users. Only 10% of women have the X chromosome-linked variant on both X chromosomes, and most women with the *CLDN2* variant on one X chromosome appear to be protected from alcoholic chronic pancreatitis by the other X chromosome, if it is normal. Men, with only one X chromosome, have no protection if they inherit a *CLDN2* mutation. This helps to explain the high prevalence of alcoholic chronic pancreatitis among men, although the mechanism remains unclear. This study does not demonstrate a genetic cause for all cases of alcohol-related chronic pancreatitis, but it shows that a genetic element contributes to many patients with the disease (Fig. 33-16).

Alcohol

In 1878, Friedreich proposed that “a general chronic interstitial pancreatitis may result from excessive alcoholism (drunkard’s pancreas).”¹¹² Since that observation, numerous studies have shown that a causal relationship exists between alcohol and chronic pancreatitis, but the prevalence of alcohol as the etiology of the disease in Western countries ranges widely, from 38% to 94%¹¹³ (Fig. 33-17).

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis.¹¹⁴ The risk of disease is present in patients with even a low or occasional exposure to alcohol (1 to 20 g/d), perhaps due to the *CLDN2* gene

Figure 33-16. Schematic model of genetic causes of chronic pancreatitis. A pancreatic acinus is portrayed showing the pathway for digestive enzymes (zymogens) to be secreted by the acinar cell into the ductal system where water, sodium, and bicarbonate are secreted by the duct and centroacinar (CA) cells. Mutations in at least five genes have been identified as risk factors for chronic pancreatitis: gain-of function mutations in the cationic trypsinogen genes (*PRSS1*, *PRSS2*) cause hereditary pancreatitis. Cationic and anionic trypsinogen are normally active in the duodenum by entero-kinase (EK). Premature activation of the trypsin in the acinar cell leads to zymogen activation, local cellular injury, and inflammation. Mutations of the trypsin inhibitors *SPINK1* or chymotrypsin C (*CTRC*), or of the calcium sensing receptor *CASR*, result in premature activation of trypsinogen. Mutations in the cystic fibrosis transmembrane receptor *CFTR* results in trypsinogen stasis within the ducts due to insufficient secretion by duct cells. A mutation in *claudin-2* (*CLDN2*) results in abnormal expression in acinar cells, instead of its normal location between duct cells, and is associated with the accelerated development of chronic pancreatitis in alcohol abusers. (Modified with permission from Solomon S, Whitcomb DC: *Genetics of pancreatitis: an update for clinicians and genetic counselors*, *Curr Gastroenterol Rep*. 2012 Apr;14(2):112-711.)

mutation described previously, so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related and highest in heavy (>150 g/d, or about 11 1 oz shots, or 12 beers per day) drinkers, the prevalence of chronic pancreatitis among confirmed alcohol abusers is only 5% to 15%.¹¹⁵ However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 to 40 years, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.¹¹⁶

In their 1946 classic study, Comfort, Gambrill, and Baggenstoss proposed that chronic pancreatitis was the result of multiple episodes of acute inflammation, with residual and

Figure 33-17. Etiologies of chronic pancreatitis. (Reproduced with permission from Whitcomb DC: *Going MAD: development of a “matrix academic division” to facilitate translating research to personalized medicine*, Acad Med. 2011 Nov;86(11):1353-1359.)

progressively increasing chronic inflammation.¹¹⁷ Subsequently, Kondo and associates showed that other, additional factors were necessary for repeated exposure to alcohol to cause chronic pancreatitis.¹¹⁸ Regardless of the requirement for other predisposing or facilitative factors, the concept that multiple episodes (or a prolonged course) of pancreatic injury ultimately leads to chronic disease is widely accepted as the pathophysiologic sequence¹¹⁹ (Fig. 33-18).

Although direct alcohol exposure to the pancreatic ductal system, or elevated levels of alcohol in the bloodstream, has been shown to alter the integrity and function of pancreatic ducts and acini directly,¹²⁰ most investigators believe that alcohol metabolites such as acetaldehyde, combined with oxidant injury, result in local parenchymal injury that is preferentially targeted to the pancreas in predisposed individuals. Repeated or severe episodes of toxin-induced injury activate a cascade of cytokines, which, in turn, induces pancreatic stellate cells (PSCs) to produce collagen and cause fibrosis (Fig. 33-19).

Figure 33-18. “Multiple hit” theory of the etiology of chronic pancreatitis. Multiple episodes of acute pancreatitis cause progressively more organized inflammatory changes that ultimately result in chronic inflammation and scarring. (Reproduced with permission from Apte MV, Wilson JS: *Alcohol-induced pancreatic injury*, Best Pract Res Clin Gastroenterol. 2003 Aug;17(4):593-612.)

A high-protein, low-bicarbonate, low-volume secretory output is seen after chronic alcohol exposure, which may contribute to the precipitation of proteins in secondary ducts in the early stages of chronic pancreatitis.¹²¹ Calcium is complexed to protein plugs in small ductules, secondary ducts, and, eventually, in the main ductal system, which causes ductal cell injury and obstruction of the secretory system, which further promotes an inflammatory response.

Cigarette smoking has been strongly associated with chronic pancreatitis,¹²² but until recently it was unclear whether this was a causative risk factor. Studies have now shown that smoking actually accelerates the development of alcoholic pancreatitis,¹²³ and the risk of cancer in chronic pancreatitis is increased significantly by smoking. In hereditary pancreatitis, smoking has been found to lower the age of onset of carcinoma by about 20 years.¹²⁴ Smoking therefore appears to be an independent risk factor for the late complications of alcoholic pancreatitis, if not an early cofactor for the development of fibrosis.

Hyperparathyroidism

Hypercalcemia is a known cause of pancreatic hypersecretion,¹²⁵ and chronic hypercalcemia caused by untreated hyperparathyroidism is associated with chronic calcific pancreatitis.¹²⁶ Hypercalcemia is also a stimulant for pancreatic calcium secretion, which contributes to calculus formation and obstructive pancreatopathy. The treatment is correction of the hyperparathyroidism and assessment of any additional endocrinopathies.

Hyperlipidemia

In addition to the risk of acute pancreatitis, hyperlipidemia and hypertriglyceridemia predispose women to chronic pancreatitis when they receive estrogen replacement therapy.¹²⁷ Fasting triglyceride levels <300 mg/dL are below the threshold for this to occur, and the mechanism of estrogen potentiation of hyperlipidemia-induced chronic pancreatitis is unknown. It is assumed that chronic changes occur after repeated subclinical episodes of acute inflammation. Aggressive therapy of hyperlipidemia is therefore important in peri- or postmenopausal patients who are candidates for estrogen therapy.

Classification

A major impediment to a better understanding of the etiology, frequency, and severity of chronic pancreatitis has been the difficulty with which investigators and clinicians have struggled to identify a useful classification system. Multiple classification systems have been proposed. The TIGAR-O scheme categorizes chronic pancreatitis according to risk factors and etiologies, such as (a) toxic-metabolic, (b) idiopathic, (c) genetic, (d) autoimmune, (e) recurrent and severe acute pancreatitis, or (f) obstructive.¹²⁸ A recent classification system based on histopathology as well as etiology was delineated by Singer and Chari.¹²⁹

Chronic Calcific (Lithogenic) Pancreatitis

This type is the largest subgroup in the classification scheme proposed by Singer and Chari and includes patients with calcific pancreatitis of most etiologies. Although the majority of patients with calcific pancreatitis have a history of alcohol abuse, stone formation and parenchymal calcification can develop in a variety of etiologic subgroups; hereditary pancreatitis and tropical pancreatitis are particularly noteworthy for the formation of stone disease. The clinician should therefore avoid the assumption that calcific pancreatitis confirms the diagnosis of alcohol abuse.

Figure 33-19. The sentinel acute pancreatitis event (SAPE) hypothesis for the development of chronic pancreatitis. A critical episode of acute pancreatitis activates cytokine-induced transformation of pancreatic stellate cells, which results in collagen production and fibrosis. ETOH = ethyl alcohol. (Adapted with permission from Schneider A, Whitcomb DC: *Hereditary pancreatitis: a model for inflammatory diseases of the pancreas*, Best Pract Res Clin Gastroenterol. 2002 Jun;16(3):347-363.)

Chronic Obstructive Pancreatitis

This refers to chronic inflammatory changes that are caused by the compression or occlusion of the proximal ductal system by tumor, gallstone, posttraumatic scar, or inadequate duct caliber

(as in pancreas divisum). Obstruction of the main pancreatic duct by inflammatory (posttraumatic) or neoplastic processes can result in diffuse fibrosis, dilated main and secondary pancreatic ducts, and acinar atrophy. The patient may have little in

Figure 33-20. Pancreas divisum. Normal pancreatic duct anatomy and the variations of partial or complete pancreas divisum are shown. (Reproduced with permission from Beger HG: *The pancreas: an integrated textbook of basic science, medicine, and surgery*. London: Blackwell-Science; 1998.)

the way of pain symptoms or may present with signs of exocrine insufficiency. Intraductal stone formation is rare, and both functional and structural abnormalities may improve when the obstructive process is relieved or removed. Trauma to the pancreas frequently results in duct injury and leakage, which may result in pseudocyst formation as well as local scar formation. Inadequately treated pancreatic trauma may result in persistent inflammatory changes in the distal gland.¹³⁰

Pancreas divisum represents a special case of obstructive pancreatitis. It is the most common congenital anomaly involving the pancreas and occurs in up to 10% of children. It is thought to predispose the pancreas to recurrent acute pancreatitis and chronic pancreatitis, due to functional obstruction of a diminutive duct of Santorini that fails to communicate with Wirsung's duct (Fig. 33-20). However, the classic picture of obstructive pancreatopathy with a dilated dorsal duct is unusual in pancreas divisum, so a decompressive operation or a lesser papilla sphincteroplasty is frequently not feasible or unsuccessful. Endoscopic stenting through the lesser papilla may result in temporary relief of symptoms, and this response would increase the possibility that a permanent surgical or endoscopic intervention will be successful. Although some authors emphasize the pathologic implications of pancreas divisum,¹³¹ others express skepticism that it represents a true risk to pancreatic secretory capacity or contributes to the development of chronic pancreatitis.^{132,133} A recent French study reveals that pancreas divisum is equally prevalent among patients with idiopathic chronic pancreatitis and normal controls (7%), and is minimally increased in patients with *PRSS1* and *SPINK1* mutations. It is accompanied by *CFTR* mutations in 47% of patients, however, suggesting that the presence of pancreas divisum together with mutational events may increase the susceptibility to pancreatitis.¹³⁴

Chronic Inflammatory Pancreatitis

Chronic inflammatory pancreatitis is characterized by diffuse fibrosis and a loss of acinar elements with a predominant mononuclear cell infiltration throughout the gland.

A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies.¹³⁵ This type, referred to as *autoimmune pancreatitis* (AIP), is associated with a variety of illnesses with suspected or proven autoimmune etiology, such as Sjögren's syndrome, rheumatoid arthritis, and type 1 diabetes mellitus. AIP has been characterized as either type I, with accompanying systemic or multiorgan dysfunction, or type II, which is restricted to the pancreas.

Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen in both types of AIP, along with symptoms of obstructive jaundice. Increased levels of serum β -globulin or immunoglobulin G4 are also present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression.¹³⁶ *CFTR* mutations that result in dislocation of the transmembrane protein have been found in AIP, and steroid therapy results in a normalization of the *CFTR* localization and a resumption of normal chloride and bicarbonate secretion.¹³⁷ The differential diagnosis includes lymphoma, plasmacytoma ("pseudotumor" of the pancreas) and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids is usually undertaken, especially when clinical and laboratory findings, such as an elevation in IgG4 levels, support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.¹³⁸

Tropical (Nutritional) Pancreatitis

Chronic pancreatitis is highly prevalent among adolescents and young adults in Indonesia, southern India, and tropical Africa. Abdominal pain develops in adolescence, followed by the development of a brittle form of pancreatogenic diabetes. Parenchymal and intraductal calcifications are seen, and the pancreatic duct stones may be quite large.¹³⁹ Many of the patients appear malnourished, some present with extreme emaciation, and a characteristic cyanotic coloration of the lips may be seen.¹⁴⁰ In addition to protein-caloric malnutrition, toxic products of some indigenous foodstuffs have also been thought to contribute to the disease. Because of the geographic concentration of this early-onset form of chronic pancreatitis, it has been termed *tropical pancreatitis*, although the exact etiology remains unclear.

Clinically, tropical pancreatitis presents much like hereditary pancreatitis, and a familial pattern among cases is not unusual. *SPINK1* mutations have been documented in 20% to 55% of patients with tropical pancreatitis, and *CFTR* mutations have been reported as well.^{106,107} The accelerated deterioration of endocrine and exocrine function, the chronic pain due to obstructive disease, and the recurrence of symptoms despite decompressive procedures characterize the course of disease. As immigrants from the tropical regions increasingly find their way to all parts of the world, an awareness of this severe form of chronic pancreatitis is helpful for those who treat patients with pancreatic disease.

Asymptomatic Pancreatic Fibrosis

Pancreatic fibrosis is seen in some asymptomatic elderly patients, in tropical populations, or in asymptomatic alcohol users. There is diffuse perilobar fibrosis and a loss of acinar cell mass, but there is not a main ductular component. In addition, the presence of fibrosis and decreased exocrine function in patients with diabetes has raised the question of whether long-standing diabetes is a cause of chronic pancreatitis.¹⁴¹ Patients with this entity are usually asymptomatic in terms of typical pancreatic pain, and a recent histopathologic study of patients with typical chronic pancreatitis and “diabetic exocrine pancreatopathy” reveals significant differences in morphology, including a virtual absence of duct distortion or obstruction (Fig. 33-21).¹⁴²

It remains unknown whether this form of chronic inflammation precedes or contributes to the roughly twofold increase in the risk of pancreatic cancer in patients with long-standing diabetes.

Idiopathic Pancreatitis

When a definable cause for chronic pancreatitis is lacking, the term *idiopathic* is used to categorize the illness. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis but who may represent individuals with spontaneous gene mutations encoding regulatory proteins in the pancreas. A variable percentage of *SPINK1* and *CFTR* mutations have been described in various studies. In addition, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found.¹⁴³ However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that, as methods of biliary stone detection have improved, many elderly “idiopathic” pancreatitis patients are found to have biliary tract disease.¹⁴⁴

An increasing number of mutations of the *SPINK1* and *CFTR* genes have been identified in association with various forms of chronic pancreatitis. However, the role of genetic analysis in the management of these patients remains unclear, as guidelines have yet to be developed to allow physicians to use the data consistently. Although the clinical management of patients who harbor a minor *CFTR* mutation and chronic pancreatitis, for example, is still dictated by the clinical manifestations of the pancreatitis, recent data suggest that the etiology of chronic pancreatitis, rather than the morphology, may determine the response to surgical treatment.¹⁴⁵

A shortcoming of these clinical classification systems is the lack of histologic criteria of chronic inflammation due to the usual absence of a biopsy specimen. The differentiation of recurrent acute pancreatitis from chronic pancreatitis with exacerbations of pain can be difficult to establish and is not facilitated by the current system. Similarly, cystic fibrosis is known to cause fibrosis and acinar dysfunction but is not included in the classification despite increasing evidence for its possible role in idiopathic chronic pancreatitis.¹⁴⁶ Therefore, further refinements in the classification system for chronic pancreatitis

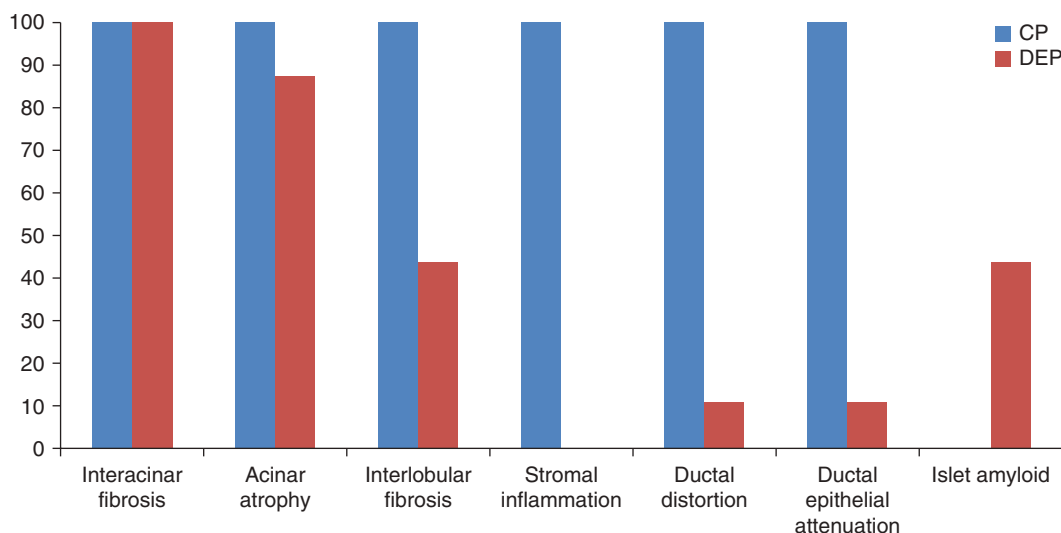

Figure 33-21. Comparative frequencies of key histopathologic features of chronic pancreatitis (CP n = 7) and diabetic exocrine pancreatopathy (DEP n = 9) (Reproduced with permission from Majumder S, Zhang L, Philip N, et al. Exocrine Pancreatopathy (EP) Associated With Diabetes Mellitus (DM) Is Histologically Distinct From Chronic Pancreatitis (CP): An International Multi-Reader Blinded Study, *Gastroenterol* 2016 April;150(4) Suppl 1: S191 (abstr).)

Figure 33-22. Histology of early chronic pancreatitis. are needed to allow a better prediction of its clinical course and a more accurate diagnosis of a likely etiologic agent.

Pathology

Histology. In early chronic pancreatitis, the histologic changes are unevenly distributed and are characterized by induration, nodular scarring, and lobular regions of fibrosis (Fig. 33-22). As the disease progresses, there is a loss of normal lobulation, with thicker sheets of fibrosis surrounding a reduced acinar cell mass and dilatation of ductular structures (Fig. 33-23). The ductular epithelium is usually atypical and may display features of dysplasia, as evidenced by cuboidal cells with hyperplastic features, accompanied by areas of mononuclear cell infiltrates or patchy areas of necrosis. Cystic changes may be seen, but areas of relatively intact acinar elements and normal-appearing islets persist. In severe chronic pancreatitis, there is considerable replacement of acinar tissue by broad, coalescing areas of fibrosis, and the islet size and number are reduced (Fig. 33-24). Small arteries appear thickened, and neural trunks become prominent.¹⁴⁷

Figure 33-23. Gross appearance of chronic pancreatitis. Areas of fibrosis and scarring are seen adjacent to other areas within the gland in which the lobar architecture is grossly preserved. A dilated pancreatic duct indicates the presence of downstream obstruction in this specimen removed from a patient with chronic pancreatitis. (Used with permission from Rhonda Yantiss, Weill Cornell Medical College.)

Figure 33-24. Histology of severe chronic pancreatitis. High-power microscopic (40x) histologic appearance of advanced chronic pancreatitis shows extensive sheets of fibrosis and loss of acinar tissue, with preservation of islet tissue in scattered areas. (Used with permission from Rhonda Yantiss, Weill Cornell Medical College.)

Tropical pancreatitis and hereditary pancreatitis are histologically indistinguishable from chronic alcoholic pancreatitis. In obstructive chronic pancreatitis, calculi are absent, although peri-acinar fibrosis and dilated ductular structures are prominent. In pancreatic lobular fibrosis seen in elderly subjects, small ducts are dilated, sometimes with small calculi trapped within. Hypertrophy of ductular epithelia is thought to cause this small-duct disease, which is accompanied by perilobular fibrosis.¹⁴⁸

Fibrosis. A common feature of all forms of chronic pancreatitis is the perilobular fibrosis that forms surrounding individual acini, then propagates to surround small lobules, and eventually coalesces to replace larger areas of acinar tissue. The pathogenesis of this process involves the activation of pancreatic stellate cells (PSCs) that are found adjacent to acini and small arteries.¹⁴⁹ The extended cytoplasmic processes of PSCs encircle the acini but appear quiescent in the normal gland, where they contain lipid vacuoles and cytoskeletal proteins. In response to pancreatic injury, the PSCs become activated and proliferate (similarly to hepatic stellate cells), lose their lipid vesicles, and transform into myofibroblast-like cells. These cells respond to proliferative factors such as transforming growth factor α , platelet-derived growth factor, and proinflammatory cytokines that synthesize and secrete type I and III collagen and fibronectin. Studies indicate that vitamin A metabolites, similar to those present in quiescent PSCs, can inhibit the collagen production of activated cultured PSCs.¹⁵⁰ This raises the possibility that early intervention may be possible to interrupt or prevent the fibrosis resulting from ongoing activation of PSCs.

The overall pathogenic sequence proposed by Schneider and Whitcomb¹⁵¹ whereby alcohol induces acute pancreatitis and, with ongoing exposure, promotes the development of chronic fibrosis, is summarized in Fig. 33-19. PSCs surrounding the acinus are activated in acute pancreatitis but may be inactivated by anti-inflammatory cytokines and, in the absence of further injury, may revert to a quiescent state. The role of proinflammatory macrophages, cytokines, and PSCs in models of acute and chronic pancreatitis represents an important area of current research.

Stone Formation. Pancreatic stones are composed largely of calcium carbonate crystals trapped in a matrix of fibrillar and other material. The fibrillar center of most stones contains no

calcium but rather a mixture of other metals. This suggests that stones form from an initial noncalcified protein precipitate, which serves as a focus for layered calcium carbonate precipitation. The same low molecular weight protein is present in stones and protein plugs and was initially named *pancreatic stone protein*, or PSP.¹⁵² PSP was found to be a potent inhibitor of calcium carbonate crystal growth and has subsequently been renamed *lithostathine*.¹⁵³ Independently, a 15-kDa fibrillar protein isolated from the pancreas was named *pancreatic thread protein*, and it has been shown to be homologous with lithostathine. Finally, a protein product of the *reg* gene, so named because it is expressed in association with regenerating islets in models of pancreatic injury, was isolated and called *reg protein* and was subsequently found to be homologous with lithostathine.¹⁵⁴ The PSP/pancreatic thread protein/*reg*/lithostathine gene encodes for a 166-amino acid product that undergoes posttranslational modification to produce isoforms present in pancreatic juice. The protein is expressed in all rodents and mammals, both in the pancreas as well as in brain tissue, where it is found in particularly high concentrations in pyramidal neurons in Alzheimer's disease and Down syndrome. It is also found in the renal tubules, which is consistent with its biologic action of preventing calcium carbonate precipitation.

Calcium and bicarbonate ions are normally present in pancreatic juice in high concentrations, and the solubility product of calcium carbonate is greatly exceeded under normal conditions. Microcrystals of calcium carbonate can be seen in normal pancreatic juice but are usually clinically silent. Lithostathine is a potent inhibitor of calcium carbonate crystal formation, at a concentration of only 0.1 $\mu\text{mol/L}$. However, lithostathine concentrations in normal pancreatic juice are in the range of 20 to 25 $\mu\text{mol/L}$, so a constant suppression of calcium carbonate crystal formation is present in the normal pancreas.

In alcoholics and in patients with alcoholic chronic pancreatitis, lithostathine expression and secretion are dramatically inhibited¹⁵⁵ (Fig. 33-25). In addition, elevated levels of precipitated lithostathine in the duct fluid in chronic pancreatitis patients suggests that the availability of the protein may be

further reduced by the action of increased proteases and other proteins present in the duct fluid of alcoholic patients. Increased pancreatic juice protein levels in alcoholic men are reversible by abstinence from alcohol,¹⁵⁶ so the availability and effectiveness of lithostathine may be restored in patients with early-stage disease by timely intervention. Nevertheless, calcific stone formation represents an advanced stage of disease, which can further promote injury or symptoms due to mechanical damage to duct epithelium or obstruction of the ductular network.

Duct Distortion. Although calcific stone disease is normally a marker for an advanced stage of disease, parenchymal and ductular calcifications do not always correlate with symptoms. Obstructing main duct stones are commonly observed and are thought to be an indication for endoscopic or surgical removal. The ball-valve effect of a stone in a secreting system produces inevitable episodes of duct obstruction, usually accompanied by pain. But some patients with complete duct obstruction have prolonged periods of painlessness. Ductular hypertension has been documented in patients with proximal stenosis of the main pancreatic duct, and prolonged ductular distention after secretin administration is taken as a sign of ductular obstruction.¹⁵⁷ Although calculus disease and duct enlargement appear together as late stages of chronic pancreatitis, controversy persists over whether they are associated, are independent events, or are causally related.

Radiology. Radiologic imaging of chronic pancreatitis assists in four areas: (a) diagnosis, (b) the evaluation of severity of disease, (c) detection of complications, and (d) assistance in determining treatment options.¹⁵⁸ With the advent of cross-sectional imaging techniques such as CT and MRI, the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms or trauma, and the extension of ultrasonic imaging to include endoscopic ultrasound (EUS) and laparoscopic US have resulted in the highest-resolution images that are capable of detecting very small (<1 cm) abnormalities in the pancreas. EUS is now frequently used as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually used (Table 33-12).

Ultrasonography is frequently used as an initial imaging method in patients with abdominal symptoms, and changes consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes, and a heterogeneous texture are seen in chronic pancreatitis (Fig. 33-26). The sensitivity of transabdominal ultrasonography ranges from 48% to 96%, and it is operator dependent.¹⁵⁹ However, the contour, texture, and ductal pattern are usually quite discernible, and it is a reliable method for periodic reexamination to determine the efficacy of treatment.

EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent than transabdominal ultrasonography, EUS provides not only imaging capability but also adds the capacity to obtain cytologic and chemical samples of tissue and fluid aspirated with linear array monitoring (Fig. 33-27). EUS images obtained through a high-frequency (7.5- to 12.5-mHz) transducer are able to evaluate subtle changes in 2- to 3-mm

Figure 33-25. Lithostathine levels in chronic calcific pancreatitis (CCP) patients, patients with alcohol abuse (Alc.), patients with other pancreatic disease (OPD), and controls. Table 33-12

Cambridge classification of pancreatic morphology in chronic pancreatitis

CLASSIFICATION	ERCP FINDINGS	CT AND US FINDINGS
Normal	No abnormal SBDs	Normal gland size, shape; homogeneous parenchyma
Equivocal	MPD normal	One of the following: less than three abnormal SBDs; MPD 2–4 mm; gland enlarged more than two times normal size; heterogeneous parenchyma
Mild	MPD normal	Two or more of the following: less than three abnormal SBDs; MPD 2–4 mm; slight gland enlargement; heterogeneous parenchyma
Moderate	MPD changes	Small cysts <10 mm; MPD irregularity
	SBD changes	Focal acute pancreatitis; increased echogenicity of MPD walls; gland-contour irregularity
Severe	Any of the above changes plus one or more of the following: cysts <10 mm; intraductal filling defects; calculi; MPD obstruction or stricture; severe MPD irregularity; contiguous organ invasion	—

Abbreviations: CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; MPD = main pancreatic duct; SBD = side-branch duct; US = ultrasound.

structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucus, cystic lesions, and subtle ductular abnormalities are recognizable by EUS (Table 33-13). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive than ERCP in the detection of mild disease.¹⁶⁰

CT scanning has affected the diagnosis of pancreatic disease more broadly than any other method. With the advent of

faster helical CT scanning and CT angiography, visualization of the nature, extent, location, and relative relationships of pancreatic structures and lesions is possible with great clarity. Duct dilatation, calculous disease, cystic changes, inflammatory events, and anomalies are all detectable with a resolution of 3 to 4 mm (Fig. 33-28). CT scanning has a false-negative rate of <10% for chronic pancreatitis, but early or mild chronic disease may go undetected by CT imaging. The earliest changes are dilatation of secondary ducts and heterogeneous parenchymal changes, which are detectable by EUS and ERCP. Another drawback of CT scanning is its lower sensitivity for detecting small neoplasms, which are seen with increased frequency in chronic pancreatitis and may be invisible to all modalities except EUS.

An MRI, in both the cross-sectional mode and the coronally oriented heavily weighted T2 or high spin ratio imaging

Table 33-13

Endoscopic ultrasound features of chronic pancreatitis

ENDOSCOPIC ULTRASOUND FEATURE	IMPLICATION
Ductal changes	
Duct size >3 mm	Ductal dilation
Tortuous pancreatic duct	Ductal irregularity
Intraductal echogenic foci	Stones or calcification
Echogenic duct wall	Ductal fibrosis
Side-branch ectasia	Periductal fibrosis
Parenchymal changes	
Inhomogeneous echo pattern	Edema
Reduced echogenic foci (1–3 mm)	Edema
Enhanced echogenic foci	Calcifications
Prominent interlobular septae	Fibrosis
Lobular outer gland margin	Fibrosis, glandular atrophy
Large, echo-poor cavities (>5 mm)	Pseudocyst

(MRCP) that can disclose fluid-filled ducts and cystic lesions, has added greatly to the imaging options for chronic pancreatitis (Fig. 33-29). The resolution of cross-sectional MRI scanning is now approaching that of CT scanning, although the availability of MRI scanners and the complexity of the images produced have limited their large-scale use for routine imaging of the pancreas. MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities that correlates closely with the contrast-filled ducts imaged by ERCP.¹⁶¹ The advantages of MRCP include its noninvasive methodology and

Figure 33-28. Computed tomographic imaging of chronic pancreatitis. A dilated pancreatic duct is seen, with evidence of intraductal stones and parenchymal calcification. Figure 33-29. Coronal T2-weighted magnetic resonance image showing evidence of chronic pancreatitis, including a pancreatic duct dilatation and side-branch clubbing. (Used with permission from Mellena Bridges, MD, Mayo Clinic Jacksonville, Department of Radiology.)

its ability to image obstructed ducts that are not opacified by ERCP injection. It is therefore a useful screening study to detect duct abnormalities and to confirm the need for interventional procedures. Oral, IV, and intraductal contrast are unnecessary for MRCP, and its lack of ionizing radiation makes this the safest method to image the ductal system in high-risk patients.

For the diagnosis and staging of chronic pancreatitis, ERCP is considered to be the gold standard. It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers, such as biopsy or brushing for cytology, or the use of stents to relieve obstruction or drain a pseudocyst (Fig. 33-30).

Figure 33-30. Pancreatic duct stenting. At endoscopic retrograde cholangiopancreatography, a stent is placed in the proximal pancreatic duct to relieve obstruction and reduce symptoms of pain. Pancreatic duct stents are left in place for only a limited time to avoid further inflammation.

Unfortunately, ERCP also carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients.¹⁶¹ Patients at increased risk include those with sphincter of Oddi dysfunction and those with a previous history of post-ERCP pancreatitis. Post-ERCP pancreatitis occurs after uncomplicated procedures, as well as after those that require prolonged manipulation. Severe pancreatitis and deaths have occurred after ERCP. It should be reserved for patients in whom the diagnosis is unclear despite the use of other imaging methods, or in whom a diagnostic or therapeutic maneuver is specifically indicated.

Presentation, Natural History, and Complications

Presenting Signs and Symptoms. Pain is the most common symptom of chronic pancreatitis. It is usually midepigastic in location but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally, it is perceived in the lower midabdomen but is frequently described as penetrating through to the back (Fig. 33-31). The pain is typically steady and boring, but not colicky. It persists for hours or days and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence hours later.

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Pain from chronic pancreatitis has been ascribed to multiple etiologies. Ductal hypertension, due to strictures or stones, may predispose to pain that is initiated or exacerbated by eating. Chronic pain without exacerbation may be related to parenchymal disease or retroperitoneal inflammation with persistent neural involvement. Acute exacerbations of pain in the setting of chronic pain may be due to acute increases in duct pressure or recurrent episodes of acute inflammation in the setting of chronic parenchymal disease. Nealon and Matin have described these various pain syndromes as being predictive of

the response to various surgical procedures.¹⁶² Pain that is found in association with ductal hypertension is most readily relieved by pancreatic duct decompression, through endoscopic stenting or surgical decompression.

The surgical relief of pain due to obstructive pancreatopathy may be dependent on the degree of underlying fibrosis and the etiology of the disease rather than the presence of ductal obstruction, per se, according to a recent studies from Johns Hopkins. Cooper et al studied 35 patients with chronic pain associated with evidence of duct obstruction who were treated with local resection of the pancreatic head and longitudinal pancreaticojejunostomy (LR-LPJ), or Frey procedure.¹⁶³ The degree of pain resolution after surgery was compared to the degree of underlying parenchymal fibrosis. After a follow-up that averaged 22 months, patients with more than 80% fibrosis had 100% pain relief, whereas only 60% patients with less than 10% fibrosis experienced substantial or complete pain relief. Subsequently, this group studied 60 patients who had undergone either the Frey procedure or the Whipple procedure for refractory pain due to chronic pancreatitis.¹⁴⁵ In addition to histopathologic findings, they also analyzed the etiology of the disease. Of patients with “toxic” etiologies of acquired disease (i.e., a history of alcohol or tobacco abuse), 89% experienced prolonged pain relief, whereas only 39% of those with hereditary or idiopathic disease achieved this result. Further, these results were independent of the degree of pancreatic fibrosis. These findings suggest that the etiology of the disease may be the most important predictor of the benefit of a resectional or hybrid procedure, and that patients with idiopathic or hereditary disease might be considered for an alternative approach, such as total pancreatectomy with islet auto-transplantation (see following section).

The pain of chronic pancreatitis may decrease or disappear completely over a period of years, as symptoms of exocrine and endocrine deficiency become apparent.¹⁶⁴ This is referred to as *burned out pancreatitis* and correlates with the progression of disease from a mild or moderate stage to severe destruction of the pancreas. Although this evolution of painful to nonpainful disease is sometimes used as a justification to avoid intervention in painful chronic pancreatitis, noninterventional approaches to the treatment of chronic pancreatitis are inevitably accompanied by the development of narcotic addiction, inability to work, and the sequelae of chronic illness.

Although increased ductal pressure, and therefore parenchymal pressure, has been thought to be the cause of pain in chronic obstructive pancreatitis, the role of chronic inflammation per se, and the development of actual nerve damage in the diseased gland, are also thought to contribute to pain.¹⁶⁵ Chronic inflammation results in the infiltration of tissue by macrophages, which secrete prostaglandins and other nociceptive agents that cause chronic stimulation of afferent neural fibers. Inflammatory damage to the perineurial layers surrounding the unmyelinated pancreatic nerves and a focal infiltration of inflammatory cells around nerves suggest that neural fibers are a target for the cellular response to inflammation in the pancreas.¹⁶⁶

Strategies to relieve pain are therefore based on three approaches: (a) reducing secretion and/or decompress the secretory compartment, (b) resecting the focus of chronic inflammatory change, or (c) interrupting the transmission of afferent neural impulses through neural ablative procedures. A trial of antisecretory therapy or endoscopic duct drainage may select those patients who will benefit preferentially from a decompressive procedure.

Patients with chronic pain due to chronic pancreatitis are often treated for years with escalating doses of narcotics, which imposes the additional problem of opioid dependency on this population. Further, it is now apparent that the pain pattern of many patients may be described as being either “visceral pain,” caused by inflammation in and around the pancreas, or “central sensitization of pain,” which is a syndrome of increased pain perception and sensitivity caused by the prolonged presence of pain¹⁶⁷ (Fig. 33-32). Recent studies have suggested a method to differentiate these pain processes and further suggest that drugs that decrease or ameliorate the central sensitization of pain, such as pregabalin and tramadol, may be especially useful in chronic pancreatitis patients.¹⁶⁸ These methods of differential diagnosis of pain syndromes now appear to offer the means by which it is possible to further identify and predict which patients will benefit from a surgical approach to chronic pancreatitis.¹⁶⁹

Malabsorption and Weight Loss. When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop¹⁷⁰ (Fig. 33-33). Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an “oil slick” on the water’s surface. In severe steatorrhea, an orange,

Figure 33-33. Relationship of lipase output to fat malabsorption. Excess fecal fat appears when the pancreatic lipase output falls below 10% of normal secretory values. (Data from DiMaggio EP, Go VL, Summerskill WH. *Relations between pancreatic enzyme outputs and malabsorption in severe pancreatic insufficiency*, N Engl J Med. 1973 Apr 19;288(16):813-815.)

oily stool is often reported. As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients may describe a good appetite despite weight loss or diminished food intake due to abdominal pain.

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Lipase deficiency tends to manifest itself before trypsin deficiency, so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency.¹⁷¹ As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption.¹⁷² Pancreatic exocrine insufficiency is frequently asymptomatic, however, and pancreatic exocrine function is difficult to measure, so a diagnosis of chronic pancreatitis is sufficient to justify a trial of pancreatic enzyme supplements. Each meal should be followed by 90,000 United States Pharmacopeia units of lipase, and the metabolic and symptomatic status of the patients should be followed.¹⁷³

Pancreatogenic Diabetes. The islets comprise only 2% of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue. Islets are typically smaller than normal and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients. In a study of 500 patients with predominantly alcoholic chronic pancreatitis, diabetes developed in 83% within 25 years of the clinical onset of chronic pancreatitis, and more than half of the diabetic patients required insulin treatment.¹⁷⁴ Ketoacidosis and diabetic nephropathy are relatively uncommon in pancreatogenic diabetes (see Table 33-3), but retinopathy and neuropathy are seen to occur with a similar frequency as in type 1 and type 2 diabetes.¹⁷⁵

Pancreatogenic diabetes is most common in cases of chronic pancreatitis, and it is often seen after surgical resection for benign or malignant disease^{176,177} (Fig. 33-34). Distal

pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is usually worse after subtotal or total pancreatectomy. Pancreatogenic, or type 3c diabetes (T3cDM), is seen in cystic fibrosis, in association with pancreatic cancer, and in cases of severe hemochromatosis.¹⁷⁸

The etiology and pathophysiology of pancreatogenic diabetes is distinct from that of either autoimmune (type 1) or obesity-related (type 2) diabetes. In type 3c diabetes, the loss of functioning pancreatic tissue by disease or surgical removal results in a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. In addition, there is a paradoxical combination of enhanced peripheral sensitivity to insulin and decreased hepatic sensitivity to insulin.^{178,179} As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (due to unoppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (due to enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia). This form of diabetes is referred to as *brittle* diabetes and requires special attention.

PP deficiency correlates with the severity of chronic pancreatitis, and impairments in the hepatic action of insulin are reversed in PP-deficient chronic pancreatitis patients by administration of PP.¹⁸⁰ In addition, a study of type 1 and type 3c diabetic patients treated with insulin pump therapy revealed that the addition of a continuous subcutaneous infusion of PP reduced the insulin requirements needed for glycemic control.¹⁸¹ Studies are currently underway to identify a clinically suitable PP analog or PP receptor agonist.

Laboratory Studies. The diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies (Table 33-14). The direct measurement of pancreatic enzymes (e.g., lipase and amylase) by blood test is highly sensitive and fairly specific in acute pancreatitis but is seldom helpful in the diagnosis of chronic pancreatitis. The pancreatic endocrine product that correlates most strongly with chronic pancreatitis is the PP response to a test meal (Fig. 33-35). Severe chronic pancreatitis is associated with a blunted or absent PP response to feeding but, as with many other tests, a normal PP response does not rule out the presence of early disease.¹⁴

The measurement of pancreatic exocrine secretion requires aspiration of pancreatic juice from the duodenum after nutrient (Lundh test meal) or hormonal (CCK or secretin) stimulation.^{182,183} Direct aspiration of pancreatic juice by endoscopic cannulation of the duct is performed in some centers, but it is not risk free, comfortable for the patient, or more sensitive than luminal intubation methods.¹⁸⁴

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds that are altered (“digested”) by pancreatic exocrine products and can be quantified by serum or urine measurements. A commonly used indirect test is the bentiromide test, in which *N*-benzoyl-L-tyrosyl-p-aminobenzoic acid is ingested by the subject, and the urinary excretion of the proteolytic metabolite p-aminobenzoic

Figure 33-35. Pancreatic polypeptide (PP) response to a test meal. Immunoreactive PP (IR-PP) responses in control subjects (NL, n = 6) and patients with severe chronic pancreatitis (CP) accompanied by PP deficiency (CP, n = 5) are shown. A test meal was administered at 0 minutes. Means \pm standard error of the mean are shown. (Reproduced with permission from Brunicaudi FC, Chaiken RL, Ryan AS, et al. Pancreatic polypeptide administration improves abnormal glucose metabolism in patients with chronic pancreatitis, *J Clin Endocrinol Metab.* 1996 Oct;81(10):3566-3572.)

acid (PABA) is measured.¹⁸⁵ Although the sensitivity of the test is as high as 100% in patients with severe chronic pancreatitis, it identifies only 40% to 50% of patients with mild disease, and reduced PABA excretion is found in patients with a variety of other GI, hepatic, and renal diseases. The quantification of stool fat has also been used as a measure of pancreatic lipase secretion, either through the direct measurement of total fecal fat levels while the subject consumes a diet of known fat content, or by the measurement of exhaled ¹⁴CO₂ after ingestion of [¹⁴C]-triolein or [¹⁴C]-olein. This so-called triolein breath test is less cumbersome than intubation methods and avoids the necessity of stool collections and analysis, but it also has a high false-negative rate.¹⁸⁶

Fecal levels of chymotrypsin¹⁸⁷ and elastase¹⁸⁸ have been proposed as simpler, less expensive tests of exocrine function and correlate well with loss of pancreatic function. As with other test methods, however, these tests lose their sensitivity in patients with mild to moderate chronic pancreatitis and may be more sensitive for other causes of pancreatic dysfunction, including cystic fibrosis. Fecal elastase C1 measurements have become widespread in their use, and levels above 200 μ g/g are considered normal, whereas levels below 100 μ g/g are indicative of pancreatic exocrine insufficiency.¹⁸⁹ The sensitivity and specificity of fecal elastase C1 measurements fall short of those needed for definitive diagnosis of pancreatic exocrine insufficiency, however.¹⁹⁰

Radiologic imaging has become the principal method of diagnosis of chronic pancreatitis, with the codification of classification systems that correlate with proven disease. ERCP has been considered the most sensitive radiologic test for the diagnosis of chronic pancreatitis, with specific ERCP findings that are highly correlative with the degree or stage of chronic disease¹⁹¹ (Table 33-15). CT scanning is sensitive for the diagnosis of chronic pancreatitis when calcification, duct dilatation, or cystic disease is present, but it is not accurate in the absence of these findings. CT is helpful as a screening study to guide interventional therapy or other diagnostic modalities,¹⁵⁸ although EUS has become the preferred method for the diagnosis of pancreatic disease and offers the advantage of very-high-resolution images of the pancreatic parenchyma, the main and secondary ductal systems, cystic lesions, and calcific changes.

Table 33-15

Cambridge classification of chronic pancreatitis by endoscopic retrograde cholangiopancreatography

GRADE	MAIN PANCREATIC DUCT	SIDE BRANCHES
Normal	Normal	Normal
Suggestive	Normal	<3 Abnormal
Mild	Normal	\geq 3 Abnormal
Moderate	Abnormal	>3 Abnormal
Severe	Abnormal plus at least one of the following: large cavity, duct obstruction, dilation or duct irregularity, intraductal filling defects	

Reproduced with permission from Axon AT, Classen M, Cotton PB, et al: *Pancreatography in chronic pancreatitis: international definitions*, *Gut.* 1984 Oct;25(10):1107-1112.

EUS findings may be inconclusive in mild or “minimal change” pancreatitis, however, and improved criteria for an EUS-based diagnosis are still a work in progress.¹⁹² Most importantly, EUS is highly reliable in ruling out pancreatic carcinoma when CT findings are normal or equivocal.

Prognosis and Natural History. The prognosis for patients with chronic pancreatitis is dependent on the etiology of the disease, the development of complications, and on the age and socioeconomic status of the patient. The influence of treatment is less evident in long-term studies, although the general absence of randomized, prospective trials clouds the issue of whether specific forms of therapy alter the long-term outlook for patients with the disease.

Several studies have demonstrated that, although symptoms of pain decrease over time in about half of the patients, this decline is also accompanied by a progression of exocrine and endocrine insufficiency.¹⁹³ In general, the likelihood of eventual pain relief is dependent upon the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60% of alcoholic patients who successfully discontinued drinking, but in only 26% who did not.¹⁹⁴

The long-term survival of patients with chronic pancreatitis is less than for patients without pancreatitis. In an international multicenter study of >2000 patients, Lowenfels and colleagues found that the 10- and 20-year survival rates for patients with chronic pancreatitis were 70% and 45%, respectively, compared to 93% and 65% for patients without pancreatitis.¹⁹⁵ The mortality risk was found to be 1.6-fold higher in patients who continued to abuse alcohol, compared to those who did not. Continued alcohol abuse has a similar effect on the response to surgical treatment (Fig. 33-36), and results in a twofold increase in mortality over a 10- to 14-year follow-up period.¹⁹⁵

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined here and in Table 33-16, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma.¹⁹⁶ There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient (Fig. 33-37). The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5% to 6%,¹⁹⁶ which is at

Table 33-16

least 10-fold greater than that of patients of similar age seen in a hospital setting. In patients with chronic pancreatitis accompanied by diabetes, the risk of carcinoma has been found to be increased 12- to 33-fold compared to healthy, comparably aged controls.^{197,198} In patients with advanced chronic pancreatitis referred for surgical therapy, indolent, undiagnosed carcinoma can be seen in as many as 10% of patients.¹⁹⁹

The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially cryptic, and the diagnosis of early-stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS seem logical in order to detect the development

Figure 33-36. Effect of alcohol use on survival after surgical procedures. The cumulative survival of patients with chronic pancreatitis following pancreaticoduodenectomy or distal pancreatectomy is shown for nonalcoholic and alcoholic patients. (Reproduced with permission from Frey CF, Child CG, Fry W. Pancreatectomy for chronic pancreatitis, *Ann Surg*. 1976 Oct;184(4):403-413.)

(Reproduced with permission from Lowenfels AB, Maisonneuve P, Cavallini G, et al. *Pancreatitis and the risk of pancreatic cancer. International Pancreatitis Study Group, N Engl J Med. 1993 May 20;328(20):1433-1437.*)

of carcinoma in the patient with chronic pancreatitis, although no evidence exists to indicate that this alters the outcome of patients who develop pancreatic cancer. Surgical procedures, particularly drainage procedures performed for presumed chronic pancreatitis, should always include biopsy of the tissue to exclude the diagnosis of malignancy.

Complications

Pseudocyst. A chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis is referred to as a *pseudocyst*. Pseudocysts occur in up to 10% of patients with acute pancreatitis, and in 20% to 38% of patients with chronic pancreatitis, and thus, they comprise the most common complication of chronic pancreatitis.²⁰⁰⁻²⁰² The identification and treatment of pseudocysts requires definition of the various forms of pancreatic fluid collections that occur (Table 33-17). In chronic pancreatitis, a pancreatic duct leak with extravasation of pancreatic juice results in a peripancreatic fluid collection (PPFC). Over a period of 3 to 4 weeks, the PPFC is sealed by an inflammatory reaction that leads to development of a wall of acute granulation tissue without much fibrosis. This is referred to as an *acute pseudocyst*. Acute pseudocysts may resolve spontaneously in up to 50% of cases, over a course of 6 weeks or longer.²⁰³ Pseudocysts >6 cm resolve less frequently than smaller ones but may regress over a period of weeks to months. Pseudocysts are multiple in 17% of patients,²⁰² or they may be multiloculated. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments (Fig. 33-38).

Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis.²⁰⁴ They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms (Fig. 33-39). They also can perforate and cause peritonitis or intraperitoneal bleeding.²⁰⁵

Table 33-17

Definitions of pancreatic fluid collections

TERM	DEFINITION
Peripancreatic fluid collection	A collection of enzyme-rich pancreatic juice that occurs early in the course of acute pancreatitis, or that forms after a pancreatic duct leak; located in or near the pancreas; it lacks a well-organized wall of granulation or fibrous tissue
Early pancreatic (sterile) necrosis	A focal or diffuse area of nonviable pancreatic parenchyma, typically occupying >30% of the gland and containing liquefied debris and fluid
Late pancreatic (sterile) necrosis	An organized collection of sterile necrotic debris and fluid with a well-defined margin or wall within the normal domain of the pancreas
Acute pseudocyst	A collection of pancreatic juice enclosed within a perimeter of early granulation tissue, usually as a consequence of acute pancreatitis that has occurred within the preceding 3–4 wk
Chronic pseudocyst	A collection of pancreatic fluid surrounded by a wall of normal granulation and fibrous tissue, usually persisting for >6 wk
Pancreatic abscess	Any of the above in which gross purulence (pus) is present, with bacterial or fungal organisms documented to be present

Modified with permission from Baron TH, Harewood GC, Morgan DE, et al. *Outcome differences after endoscopic drainage of pancreatic necrosis, acute pancreatic pseudocysts, and chronic pancreatic pseudocysts, Gastrointest Endosc. 2002 Jul;56(1):7-17.*

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly and may resolve spontaneously or persist without complication.^{201,203} Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology

Figure 33-38. Extensive pseudocyst disease. A computed tomographic scan in a patient with alcoholic chronic pancreatitis demonstrates multiloculated pseudocyst disease.

Figure 33-39. Pseudoaneurysm of the gastroduodenal artery. A pseudocyst can erode into an adjacent artery, which results in contained hemorrhage otherwise known as a *pseudoaneurysm*. A contrast-injected computed tomographic scan reveals active bleeding (area marked **B**) into a pseudocyst (arrows) as a result of this process. (Reproduced with permission from Balthazar EJ: *CT diagnosis and staging of acute pancreatitis*, Radiol Clin North Am. 1989 Jan;27(1):19-37.)

of the lesion, including a cystic neoplasm.²⁰⁵ Although pseudocysts comprise roughly two-thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true pancreatic cystic neoplasm or a pseudocyst.

The timing and method of treatment requires careful consideration. Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst that appears to be fluid filled on CT scan, and a failure to document true adherence with an adjacent portion of the stomach before attempting transgastric internal drainage.

If the pseudocyst has failed to resolve with conservative therapy and symptoms persist, internal drainage is usually preferred to external drainage to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80% of cases,²⁰⁶ so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either endoscopic methods (transgastric or transduodenal puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy (Fig. 33-40), a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically²⁰⁷ (Fig. 33-41), laparoscopically,²⁰⁸ or by a combined laparoscopic-endoscopic method.²⁰⁹

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time

Figure 33-40. Cystogastrostomy drainage of a retrogastric pancreatic pseudocyst. A larger opening is made through the common wall of a retrogastric pseudocyst, and a portion of the pseudocyst wall is submitted for histologic confirmation of the diagnosis. of ERCP may be directed into a pseudocyst through the ductal communication itself (Fig. 33-42), or they can be left across the area of suspected duct leakage to facilitate decompression and cyst drainage, analogous to the use of common bile duct stents in the setting of a cystic duct leak.²⁰⁶ In a surgical series of patients with chronic pancreatitis, ductal dilatation, and a coexisting pseudocyst, Nealon and Walser showed that duct drainage alone, without a separate cystoenteric anastomosis, was as successful as a combined drainage procedure.⁹² Furthermore, the “duct drainage only” group enjoyed a shorter hospital stay and fewer complications than the group who underwent a separate cystoenterostomy. These observations suggest that transductal drainage may be a safe and effective approach to the management of pseudocystic disease.

The complications of endoscopic drainage of pseudocysts often require surgical intervention. Bleeding from the cystoenterostomy and inoculation of a pseudocyst with failure of resolution and persistence of infection may require surgical treatment. Bleeding risks may be lessened by the routine use of EUS in the selection of the site for transluminal stent placement.²¹⁰ Endoscopic treatment of pseudocysts requires

large-bore catheters or multiple stents and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death.^{211,212} The most experienced therapeutic endoscopists report a complication rate of 17% to 19% for the treatment of sterile pseudocysts, and deaths as a result of endoscopic therapy have occurred.²¹² Therefore, the use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate and is limited to specialized centers.

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct or of the pseudocyst itself should be considered when distal resection is being contemplated.

Pancreatic Ascites. When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as *internal pancreatic fistulae*, both complications are seen more often in patients with chronic pancreatitis rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14% of patients, and 18% have a pancreatic pleural effusion alone.²¹³

Patients demonstrate the general demographics of chronic pancreatitis and usually present with a subacute or recent history of progressive abdominal swelling despite weight loss. Pain and nausea are rarely present. The abdominal CT scan discloses ascites and the presence of chronic pancreatitis or a partially collapsed pseudocyst (Fig. 33-43). Paracentesis or thoracentesis reveals noninfected fluid with a protein level >25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have

Figure 33-43. Pancreatic ascites. Computed tomographic scan of a patient with a ruptured pancreatic pseudocyst resulting in intra-peritoneal pancreatic fluid. (Reproduced with permission from Cameron JL, Cameron AM: *Current Surgical Therapy*, 11th ed. Philadelphia, PA: Elsevier; 2014.)

coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients.^{214,215} Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula.²¹⁴ Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage²¹⁵ (Fig. 33-44). If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

Pancreatic-Enteric Fistula. The erosion of a pancreatic pseudocyst into an adjacent hollow viscus can result in a pancreatic-enteric fistula. The most common site of communication is the transverse colon or splenic flexure. The fistula usually presents with evidence of GI or colonic bleeding and sepsis. If the fistula communicates with the stomach or duodenum, it may close spontaneously or persist as a pancreatic-enteric fistula. When the fistula involves the colon, operative correction is usually required.²¹⁵

Head-of-Pancreas Mass. In up to 30% of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas.²¹⁶ The clinical presentation includes severe pain and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct (Table 33-18). Mutations and polymorphisms of *p53* have been found in these patients, and a focus of ductular carcinoma was found in 3.7% of patients with pancreatic head enlargement in one series.²¹⁷ It was concluded that an accelerated transformation from hyperplasia to dysplasia exists in patients with pancreatic head enlargement, although the etiology for this process remains unclear.

Splenic and Portal Vein Thrombosis. Vascular complications of chronic pancreatitis are fortunately infrequent because they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 4% to 8% of cases.²¹⁸ Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as *left-sided* or *sinistral portal hypertension*. Although bleeding complications are infrequent, the mortality risk of bleeding is >20%. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

Treatment

Medical Therapy. The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and the selective use of antisecretory therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

Analgesia. Oral analgesics are prescribed as needed, alone or with analgesia-enhancing agents such as gabapentin.¹⁶⁸ Adequate pain control usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics.

Table 33-19

Pancreatic enzyme preparations

PRODUCT	FORMULATION	MANUFACTURER	LIPASE CONTENT (USP)/PILL OR CAPSULE
Zenpep	Enteric-coated porcine	Aptalis	3000, 5000, 10,000, 15,000, 20,000
Creon	Enteric-coated porcine	Abbott	3000, 6000, 12,000, 24,000
Pancreaze	Enteric-coated porcine	Ortho-McNeil-Janssen	4200, 10,500, 16,800, 21,000
Pertzye	Enteric-coated porcine mixed with bicarbonate granules	Digestive Care	8000, 16,000
Ultresa	Enteric-coated porcine	Aptalis	13,800, 20,700, 23,000
Viokace	Tablet non-enteric-coated porcine	Aptalis	10,440, 20,880

Note: USP = United States Pharmacopeia, the standard for lipase content in the United States. An average meal requires roughly 90,000 USP units of lipase for fat digestion. Enzyme therapy of exocrine deficiency typically begins with a dose of 50,000 USP units per meal with subsequent adjustment. Reproduced with permission from Forsmark CE: Management of chronic pancreatitis, *Gastroenterology*. 2013 Jun;144(6):1282-1291.

It is essential for patients to abstain from alcohol. In addition to removing the causative agent, alcohol abstinence results in pain reduction or relief in 60% to 75% of patients with chronic pancreatitis.²¹⁹ Despite this benefit, roughly half of alcoholic chronic pancreatitis patients continue to abuse alcohol.

Enzyme Therapy. Pancreatic enzyme administration serves to reverse the effects of pancreatic exocrine insufficiency. Adequate pancreatic enzyme replacement reverses the exocrine insufficiency seen in most patients, and it prevents secondary complications such as metabolic bone disease due to inadequate absorption of the fat-soluble vitamins A, D, E, and K. In addition, pancreatic enzyme replacement may reduce or alleviate the pain experienced by patients. The choice of enzyme supplement and the dose should be selected based on whether malabsorption or pain (or both) are the indications for therapy²²⁰ (Table 33-19). Conventional (nonenteric-coated) enzyme preparations are partially degraded by gastric acid but are available within the duodenal and jejunal regions to bind to CCK-releasing peptide and downregulate the release of CCK. This theoretically reduces the enteric signal for pancreatic exocrine secretion, which reduces the pressure within a partially or completely obstructed pancreatic duct.²²¹ Enteric-coated preparations result in little to no pain relief, presumably due to their reduced bioavailability in the proximal gut. Due to the loss of pancreatic enzymes by acid hydrolysis and proteolysis, relatively large doses are required to achieve effective levels of enzyme within the proximal small bowel. Enteric-coated preparations are protected from acid degradation but are presumably not released in the critical proximal gut in sufficient quantity to inhibit the stimulus for endogenous pancreatic enzyme secretion. Nonalcoholic patients may experience more effective pain relief than alcoholic patients, but it is recommended that all patients with chronic pancreatitis pain begin a trial of nonenteric-coated enzyme supplements together with an acid-suppressive medication for 1 month. If pain relief is achieved, therapy is continued. If enzyme therapy fails, further investigation of the pancreatic ductal system by ERCP guides the therapy based on specific anatomical findings (Fig. 33-45).

Antisecretory Therapy. Somatostatin administration has been shown to inhibit pancreatic exocrine secretion and CCK

release.²²² The somatostatin analogue octreotide acetate has therefore been investigated for pain relief in patients with chronic pancreatitis. In a double-blind, prospective, randomized 4-week trial, 65% of patients who received 200 µg of octreotide acetate subcutaneously three times daily reported pain relief, compared with 35% of placebo-treated subjects.²²³ Patients who had the best results were patients with chronic abdominal pain, suggestive of obstructive pancreatopathy. However, in another trial that used a 3-day duration of treatment, no significant pain relief was observed.²²⁴ Anecdotal reports suggest that severe pain exacerbations in chronic pancreatitis can benefit from a combination of octreotide therapy and TPN, and a pilot study of the effectiveness of the sustained-release form of octreotide suggested that it was as effective as three-times-per-day administration of the short-acting form of the drug.²²⁵

Neurolytic Therapy. Celiac plexus neurolysis with alcohol injection has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, the use of radiologically or endoscopically guided celiac plexus blockade in chronic pancreatitis has been disappointing. Due to the risk of alcohol injury and the need for repeated injections, celiac plexus blockade in chronic pancreatitis has used short-acting analgesics or other drugs rather than 50% alcohol. A trial of EUS-guided celiac plexus blockade revealed successful pain relief in 55% of patients, but the benefit lasted beyond 6 months in only 10% of patients.²²⁶ The procedure therefore appears safe, but the effect is short lived in those patients who obtain pain relief.

Endoscopic Management. The techniques of endoscopic treatment of pancreatic duct obstruction, stone disease, pseudocyst formation, pancreatic duct leak, and for the diagnosis and management of associated pancreatic tumors have expanded greatly over the past 20 years. Newer endoscopes with expanded therapeutic capabilities have been introduced, and the role of EUS and EUS-guided needle and catheter insertion has expanded the ability of the therapeutic endoscopist in the diagnosis and treatment of chronic pancreatitis and its complications.²²⁷

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stents can induce an inflammatory response within the

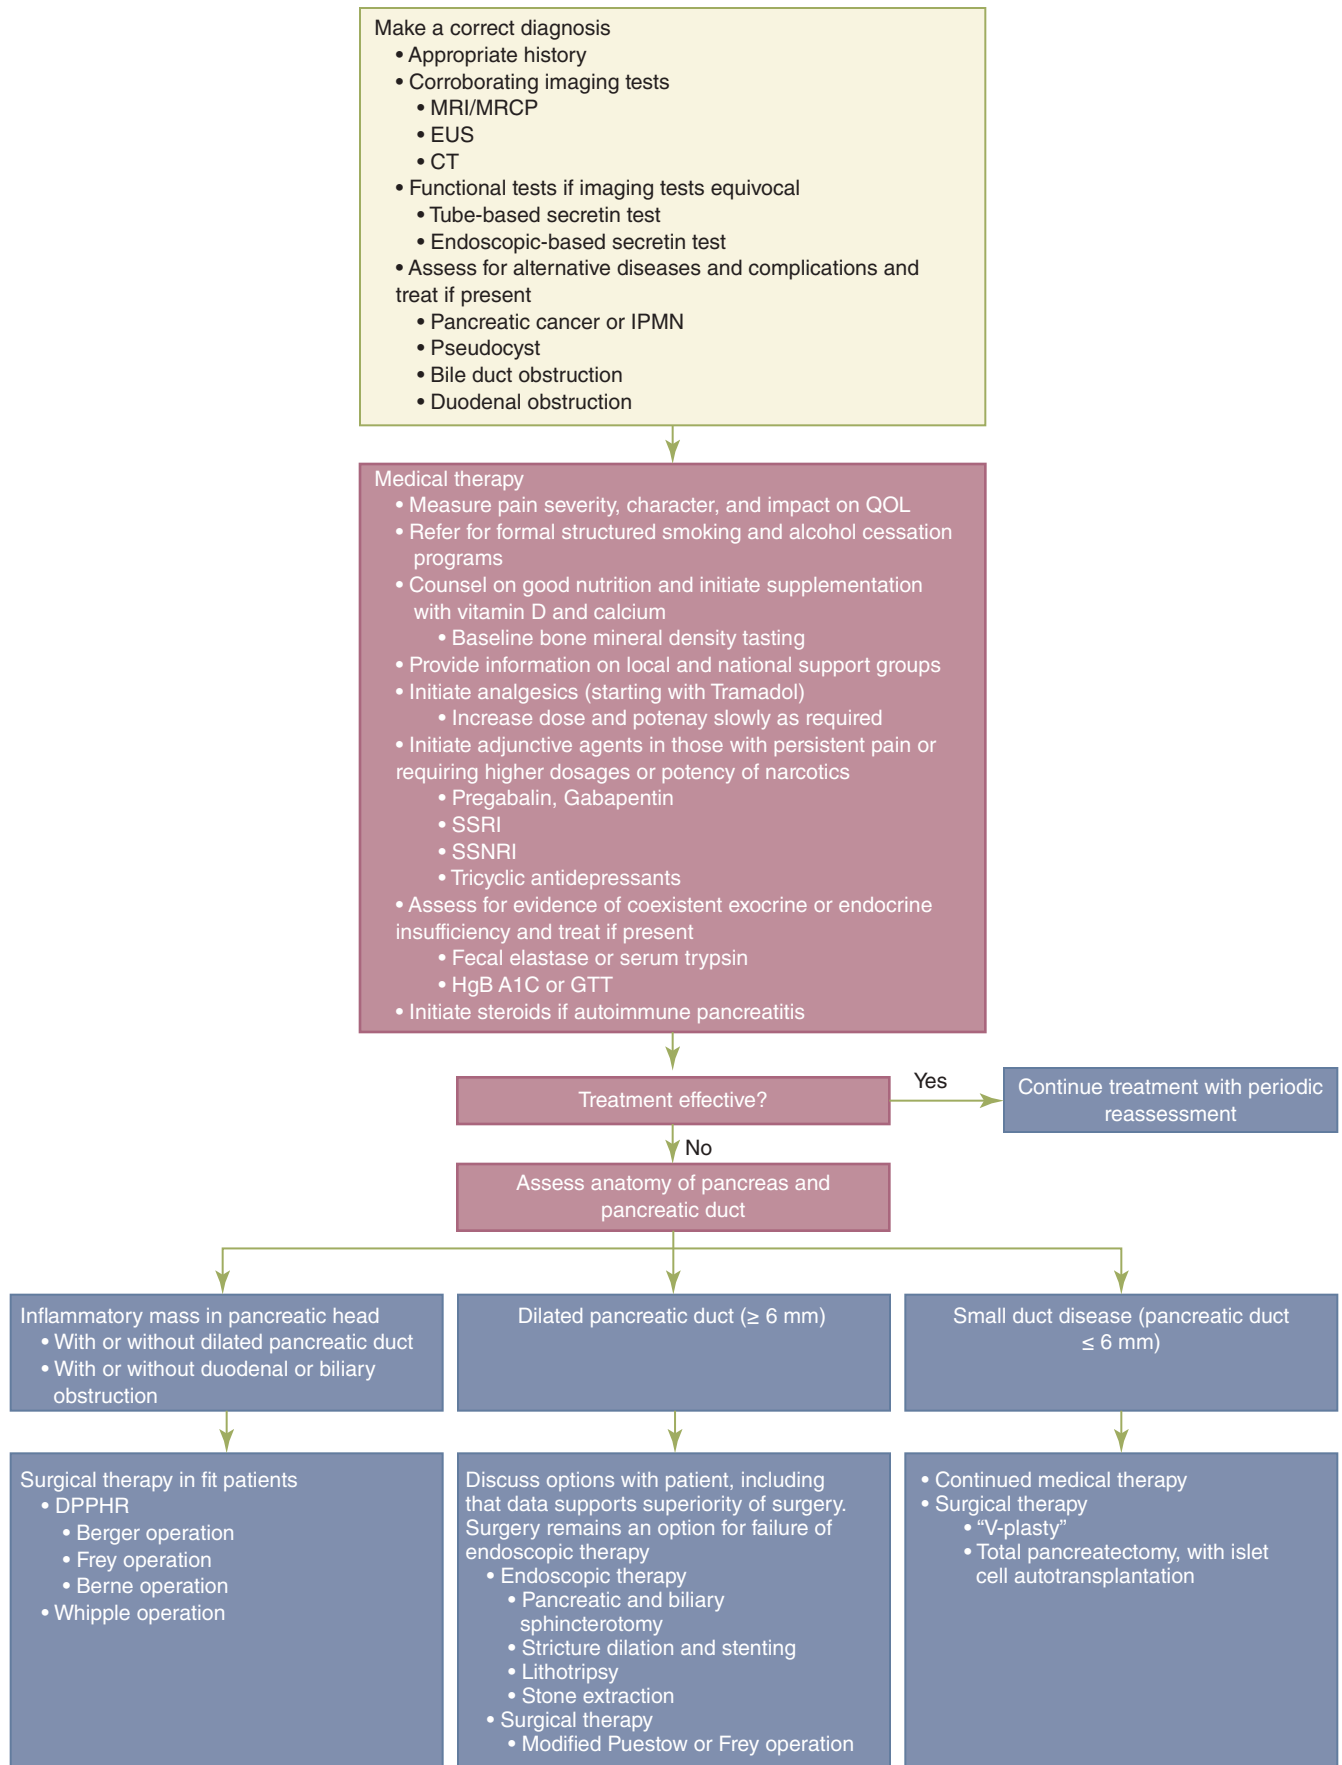

Figure 33-45. Management algorithm for chronic pancreatitis. IPMN = intraductal papillary mucinous neoplasm; QOL = quality of life; SSRI = selective serotonin reuptake inhibitor; SSNRI = selective serotonin-norepinephrine reuptake inhibitor; GTT = glucose tolerance test. (Reproduced with permission from Forsmark CE: Management of chronic pancreatitis, *Gastroenterology*. 2013 Jun;144(6):1282-1291.)

duct, so prolonged stenting is usually avoided. Patients with sphincter of Oddi dyskinesia are at high risk for developing post-ERCP pancreatitis after biliary sphincterotomy, and the prophylactic placement of a pancreatic duct stent or the administration of rectal indomethacin reduces the amylase level and development of pancreatitis after biliary sphincterotomy.^{33,228} Pancreatic duct leaks are seen in 37% of patients with acute pancreatitis, and pancreatic duct stenting appears to facilitate the resolution of the leak.²²⁹ Similarly, pancreatic duct stenting has been used to treat postsurgical pancreatic duct leaks and posttraumatic leaks.²²⁹⁻²³¹

Pancreas divisum (see Fig. 33-3) is thought to cause pain and chronic pancreatitis due to functional or mechanical obstruction of the dorsal duct draining exclusively, or predominantly, through the lesser papilla. A study from Marseille reported good long-term results in 24 patients after minor papilla sphincterotomy and dorsal duct stenting.²³² The number of patients with chronic pain decreased from 83% before stenting to 29% after stenting, but pancreatitis or recurrent papillary stenosis occurred in 38%. Patients that responded best were those with intermittent pain, and this subset may be preferentially treated with endoscopic therapy. Patients with recurrent pain and a dilated dorsal duct may be candidates for internal drainage of the obstructed duct with either an extended Puestow procedure or a Frey procedure (see later in this section).

Idiopathic pancreatitis patients have been treated with endoscopic stenting, pancreatic duct sphincterotomy, and endoscopic stone removal with good results. In a prospective randomized trial, 53% of idiopathic recurrent pancreatitis patients in the control group experienced continued episodes of pancreatitis, although only 11% of the treated patients had continued symptoms.²³³

Extracorporeal shock wave lithotripsy (ESWL) has been used for pancreatic duct stones, together with endoscopic stenting and stone removal.²³⁴ A single ESWL session was used in 35 patients with pancreatic duct stones, together with 86 ERCP sessions to complete the stone removal process. After 2.4 years, 80% of patients had significant relief of symptoms (Fig. 33-46). Also, endoscopic intraductal lithotripsy can now be performed in some specialized centers. However, due to the tendency for recurrent stone formation, the use of ESWL or endoscopic lithotripsy for long-term management of calcific pancreatitis remains uncertain.

Surgical Therapy

Indications and History The traditional approach to surgical treatment of chronic pancreatitis and its complications has maintained that surgery should be considered only when the medical therapy of symptoms has failed. Nealon and Thompson published a landmark study in 1993, however, that showed that the progression of chronic obstructive pancreatitis could be delayed or prevented by pancreatic duct decompression.²³⁵ No other therapy has been shown to prevent the progression of chronic pancreatitis, and this study demonstrated the role of surgery in the early management of the disease (Table 33-20). Small-duct disease or “minimal change chronic pancreatitis” are causes for uncertainty over the choice of operation, however. Major resections have a high complication rate, both early and late, in chronic alcoholic pancreatitis, and lesser procedures often result in symptomatic recurrence. Therefore, the choice of operation and the timing of surgery are based on each patient’s pancreatic anatomy, the likelihood (or lack thereof) that further

(Reproduced with permission from Kozarek RA, Brandabur JJ, Ball TJ, et al. *Clinical outcomes in patients who undergo extracorporeal shock wave lithotripsy for chronic calcific pancreatitis*. *Gastrointest Endosc.* 2002 Oct;56(4):496-500.)

Table 33-20

Effect of surgical drainage on progression of chronic pancreatitis

TREATMENT GROUP	24-MONTH EVALUATION
Operated (n = 47)	Mild to moderate 48 (87%); severe 6 (13%)
Nonoperated (n = 36)	Mild to moderate 8 (22%); severe 28 (78%)

Eighty-three patients with chronic pancreatitis were evaluated by exocrine, endocrine, nutritional, and endoscopic retrograde cholangiopancreatography studies, and all had mild to moderate disease and dilated pancreatic ducts. A Puestow-type duct decompression procedure was performed in 47 patients, and all subjects were restaged by the same methods 24 months later.

Reproduced with permission from Nealon WH, Thompson JC. Progressive loss of pancreatic function in chronic pancreatitis is delayed by main pancreatic duct decompression. A longitudinal prospective analysis of the modified puestow procedure. *Ann Surg.* 1993 May;217(5):458-466.

medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes to establish a bond of trust and commitment between the patient and the surgeon.

Historically, the surgery for chronic pancreatitis before the second half of the 20th century was a true demonstration of trial and error.²³⁶ Obtaining good surgical outcomes before the availability of CT scans and ERCP was either the result of serendipity or due to the skill and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochootomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreatostomy just above her navel.²³⁷ He later described the operation as having been a success for the next 30 years of the patient's life, during which the patient managed the care of the drainage tube without apparent problems.²³⁸

With the demonstration in 1942 by Priestley that total pancreatectomy was technically feasible,²³⁹ and the report in 1946 by Whipple that proximal pancreatic resection was beneficial in (three) patients with chronic pancreatitis,²⁴⁰ the option of surgical resection as treatment for chronic pancreatitis was established. By the mid 1950s, however, growing disappointment with the high risk of resection and the lack of long-term benefit overshadowed the surgical treatment of chronic pancreatitis. The choice of resection vs. drainage was largely based on surgeon preference until the 1970s, when the widespread adoption of ERCP and CT scans provided the ability to preoperatively diagnose obstructive and sclerotic disease, and this resulted in the rational selection of operative procedures. During this period, the major drawbacks to surgical therapy remained the recurrence of symptoms despite surgery, the corresponding development of an inflammatory (or malignant) mass in the

Figure 33-47. Head-of-pancreas mass after Puestow procedure. The computed tomographic appearance of an inflammatory mass occupying the head of the pancreas, which developed 2 years after Puestow decompression of the body and tail of pancreas.

undrained pancreatic head (Fig. 33-47), or the high morbidity and mortality of major resectional procedures that predisposed patients to a cascade of metabolic problems.²⁴¹

Sphincteroplasty The sphincter of Oddi and the pancreatic duct sphincter serve as gatekeepers for the passage of pancreatic juice into the duodenum (Fig. 33-48). Stenosis of either sphincter (sclerosing papillitis), due to scarring from pancreatitis or from the passage of gallstones, may result in obstruction of the pancreatic duct and chronic pain.²⁴² As gallstone pancreatitis became a popular diagnosis in the 1940s and 1950s, attention was focused on the ampullary region as a possible cause of chronic symptoms, and surgical sphincteroplasty was advocated. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent)

Figure 33-48. Schematic diagram of the ampullary, biliary, and pancreatic duct sphincters. The point of merger of the bile duct and pancreatic duct is highly variable, and a true sphincter of the pancreatic duct may be poorly developed. Figure 33-49. Operative sphincteroplasty of the biliary and pancreatic duct. The ampullary and bile duct sphincters are divided, as is the pancreatic duct sphincter, with suture apposition of the mucosal edges of the incision.

sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct may offer significant relief for the rare patient with a focal obstruction and inflammation isolated to this region (Fig. 33-49).

Drainage Procedures After the early reports of success with pancreatostomy for the relief of symptoms of chronic pancreatitis,²³⁸ Cattell described pancreaticojejunostomy for relief of pain in unresectable pancreatic carcinoma.²⁴³ Shortly thereafter, Duval²⁴⁴ and, separately, Zollinger and associates²⁴⁵ described the caudal Roux-en-Y pancreaticojejunostomy for the treatment of chronic pancreatitis in 1954 (Fig. 33-50). The so-called Duval procedure was used for decades by some surgeons, but it almost invariably failed due to restenosis and segmental obstruction of the pancreas due to progressive scarring. In 1958, Puestow and Gillesby described these segmental narrowings and dilatations of the ductal system as a “chain of lakes,” and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum²⁴⁶ (Fig. 33-51). Four of Puestow and Gillesby’s 21 initial cases were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure²⁴⁷ (Fig. 33-52).

Successful pain relief after the Puestow-type decompression procedure has been reported in 75% to 85% of patients for the first few years after surgery, but pain recurs in >20% of patients after 5 years due to progressive disease even in patients who are abstinent from alcohol.¹⁶⁴

Figure 33-50. Duval’s caudal pancreaticojejunostomy. (Reproduced with permission from Greenlee HB: *The role of surgery for chronic pancreatitis and its complications*, Surg Annu. 1983;15:283-305.)

With the advent of therapeutic endoscopy and techniques for transluminal stone removal and lithotripsy, multiple series have reported the successful endoscopic treatment of pancreatic duct calculi, although the long-term outcomes of these efforts has been uneven.²⁴⁸⁻²⁵¹ Endoscopic removal of pancreatic duct stones is usually coupled to prolonged pancreatic duct stenting,

Figure 33-51. Puestow and Gillesby’s longitudinal pancreaticojejunostomy. Originally described as an invaginating anastomosis that drained the entire body and tail, the anastomosis was created after amputating the tail of the gland and opening the duct along the long axis of the gland. (Reproduced with permission from Greenlee HB: *The role of surgery for chronic pancreatitis and its complications*, Surg Annu. 1983;15:283-305.)

Figure 33-52. Longitudinal doctotomy in obstructing calcific pancreatitis. A longitudinal pancreaticotomy typically discloses segmental stenosis of the pancreatic duct and the presence of intraductal calculi in a patient with chronic calcific pancreatitis (A). Following mobilization of a Roux limb of jejunum, a longitudinal pancreaticojejunostomy is performed to permit extensive drainage of the pancreatic duct system (B). This technique, described by Partington and Rochelle, is the typical method used for the Puestow procedure.

which carries the risk of further inflammation.^{252,253} Despite the risk of perioperative complications, the surgical management of pancreatic duct stones and stenosis has been shown to be superior to endoscopic treatment in randomized clinical trials in which the long, side-to-side technique of pancreaticojejunostomy is used.²⁵⁴⁻²⁵⁶

Resectional Procedures

Distal Pancreatectomy For patients with focal inflammatory changes localized to the body and tail, or in whom no significant ductal dilatation exists, the technique of partial (40–80%) distal pancreatectomy has been advocated (Fig. 33-53). Although distal pancreatectomy is less morbid than more extensive resectional procedures, the operation leaves untreated a major portion of the gland, and is therefore associated with a significant risk of

Figure 33-53. Distal (spleen-sparing) pancreatectomy. A distal pancreatectomy for chronic pancreatitis is usually performed with en bloc splenectomy, using either an open or laparoscopic technique. In the presence of minimal inflammation, a spleen-sparing version can be performed, as shown here.

symptomatic recurrence. It has been a more popular operation in British centers, where its success seems to be greater, perhaps due to the lower incidence of alcoholic chronic pancreatitis.²⁵⁷ However, long-term outcomes reveal good pain relief in only 60% of patients, with completion pancreatectomy required for pain relief in 13% of patients.

Laparoscopic distal pancreatectomy has been shown to be feasible for the removal of focal lesions of the distal pancreas,²⁵⁸ but it is more difficult in the setting of chronic pancreatitis.

Ninety-Five Percent Distal Pancreatectomy In 1965, Fry and Child proposed the more radical 95% distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct.²⁴¹ The operation was found to be associated with pain relief in 60% to 77% of patients long term, but it is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition. Although the operation was the first attempt to resect the pancreatic head while preserving the duodenum and distal bile duct, the extensive degree of metabolic complications led to its failure as viable treatment for the symptoms of pancreatic sclerosis.

Proximal Pancreatectomy In 1946, Whipple reported a series of five patients treated with either pancreaticoduodenectomy or total pancreatectomy for symptomatic chronic pancreatitis, with one operative death.²⁴⁰ Subsequently, proximal pancreatectomy or pancreaticoduodenectomy, with or without pylorus preservation (Fig. 33-54), has been widely used for the treatment of chronic pancreatitis.²⁵⁹ In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple

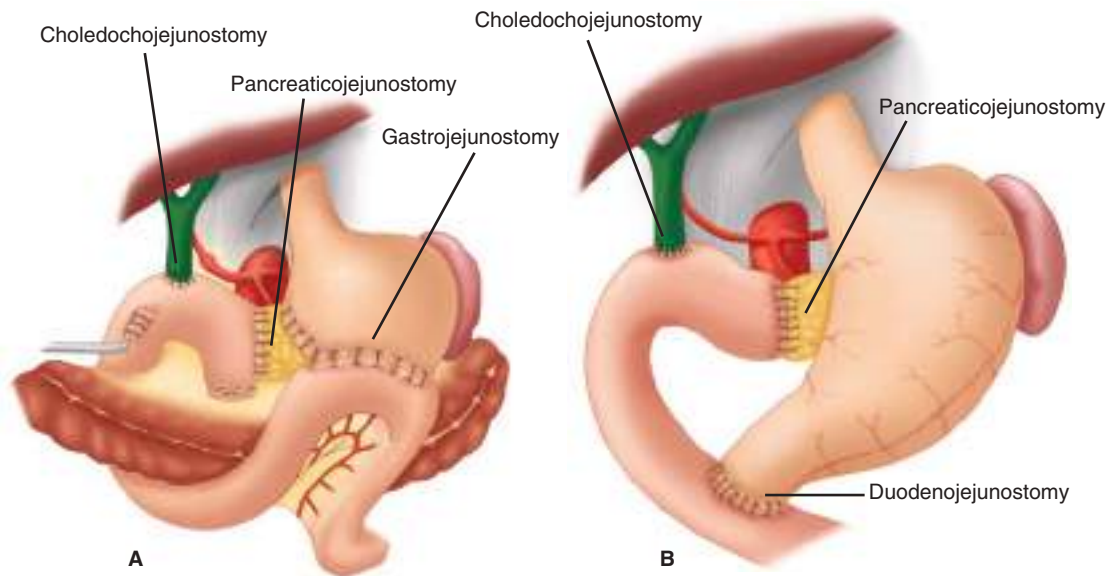

Figure 33-54. The pancreaticoduodenectomy (Whipple procedure) can be performed either with the standard technique, which includes distal gastrectomy (A), or with preservation of the pylorus (B). The pylorus-sparing version of the procedure is used most commonly. (Reproduced from Wu GY, Aziz K, Whalen GF: *An Internist's Illustrated Guide to Gastrointestinal Surgery*. Totowa: Humana Press; 2003.)

procedure, pain relief 4 to 6 years after operation was found in 71% to 89% of patients. However, mortality ranged from 1.5% to 3%, and major complications occurred in 25% to 38% of patients at the Johns Hopkins Hospital,²⁶⁰ the Mayo Clinic,²⁶¹ and the Massachusetts General Hospital.²⁶² In follow-up, 25% to 48% of patients developed diabetes, and about the same percentage required exocrine therapy. Advocates of the Whipple procedure as treatment for chronic pancreatitis suggest that the high rate of symptomatic relief outweighs the metabolic consequences and the mortality risk of the procedure, but increasingly this approach is being reserved for those patients with suspected occult malignancy.

Total Pancreatectomy Priestley and associates first described successful total pancreatectomy in 1944 in a patient with hyperinsulinism,²³⁹ and two of Whipple's original five cases of chronic pancreatitis reported in 1946 were treated with total pancreatectomy.²⁴⁰ Subsequently, surgeons who used total pancreatectomy found that the operation produces no better pain relief for their patients than pancreaticoduodenectomy (about 80–85%). Moreover, the metabolic consequences of total pancreatectomy in the absence of islet cell transplantation can be profound and life-threatening. The patients have a “brittle” form of diabetes in which avoidance of hyper- and hypoglycemia is problematic.²⁶³ In addition, lethal episodes of hypoglycemia are common in severe pancreatic diabetes. These are due to hypoglycemic unresponsiveness, due to the absence of pancreatic glucagon, and to hypoglycemia unawareness, despite an ongoing need to treat with exogenous insulin.¹⁷⁷ In a series of >100 patients treated with total pancreatectomy, Gall and colleagues showed that half of all the late deaths after this operation were due to (iatrogenic) hypoglycemia.²⁶⁴ Despite newer forms of insulin, insulin delivery systems, and continuous blood glucose monitoring systems, severe pancreatogenic diabetes remains an adverse outcome, as complete prevention of the physiologic consequences of total pancreatectomy remains an unfulfilled goal. Even with the growing acceptance of islet auto-transplantation as an adjunct to the procedure (see later in

this section), total pancreatectomy itself is now used only rarely for the treatment of refractory chronic pancreatitis.

Hybrid Procedures In 1980, Beger and associates described the Duodenum-preserving Pancreatic Head Resection or DPPHR²⁶⁵ (Fig. 33-55), and they published long-term results with DPPHR for the treatment of chronic pancreatitis in 1985²⁶⁶ and again in 1999.²⁶⁷ In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was reportedly maintained in 91%, mortality was <1%, and diabetes developed in 21%, with 11% demonstrating a reversal of their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial of 40 patients with chronic pancreatitis.²⁶⁸ The mortality was reportedly zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94% of DPPHR patients, but in only 67% of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but they actually improved in the DPPHR patients.

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses (Fig. 33-56), and it carries a similar complication risk as the Whipple procedure due to the risk of pancreatic leakage and intra-abdominal fluid collections.

In 1987, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ), which included excavation of the pancreatic head, including the ductal structures in continuity with a long dochootomy of the dorsal duct²⁶⁹ (Fig. 33-57). The Frey procedure provides thorough decompression of the pancreatic head as well as the body and tail of the gland, and a long-term follow-up suggested that improved outcomes are associated with this more extensive decompressive procedure. Frey and Amikura reported their results in 50 patients followed for >7 years, and they found complete or substantial pain relief in 87% of patients. There was no operative mortality, but 22% of patients developed postoperative complications.²⁷⁰

Figure 33-55. The duodenum-preserving pancreatic head resection described by Beger and colleagues. **A.** The completed resection after transection of the pancreatic neck, and subtotal removal of the pancreatic head, with preservation of the distal common bile duct and duodenum. **B.** Completion of the reconstruction with anastomosis to the distal pancreas and to the proximal pancreatic rim by the same Roux limb of jejunum. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Key steps in the performance of the LR-LPJ include preservation of the pancreatic neck as well as the capsule of the posterior pancreatic head. In the pancreaticoduodenectomy and the DPPHR, the pancreatic neck is freed up from the portal and superior mesenteric vein confluence and divided. In the LR-LPJ, the neck of the pancreas is preserved intact as are the body and tail of the pancreas. Not having to divide the pancreatic neck, as in the pancreaticoduodenectomy or DPPHR, reduces the risk of the operation because it avoids intraoperative problems with the venous structures lying posterior to the gland. To reduce the risk of penetrating the posterior capsule of the head, Frey recommended in his 1994 report that the posterior limit of resection be the back wall of the opened duct of Wirsung and duct to the uncinata (Fig. 33-58).

Subsequent to Frey's own modification of the technique, other surgeons have described modifications of the extent or technique of the LR-LPJ. Andersen and Topazian advocated

Figure 33-56. Intraoperative view of the Beger procedure. The gastroduodenal artery is encircled by a vessel loop. Just below, the intrapancreatic portion of the common bile duct is exposed as it courses toward the ampulla. A rim of well-vascularized pancreatic tissue remains in the duodenal C-loop. Preservation of the posterior branch of the gastroduodenal artery is essential to preserve viability of these structures.

performing the LR-LPJ as it was originally described, in which the entirety of the ducts are excised from the head (Fig. 33-59), and described the use of the ultrasonic aspirator and dissector for this purpose.²⁷¹ This device permits precise removal of the ducts and adjacent tissue with good visualization and without complications. There is little pancreatic tissue behind these ducts, and the pancreatic capsule is continuously palpated as the dissection proceeds to ensure a safe margin of resection. The intrapancreatic portion of the common bile duct is usually exposed, and avoiding injury to it is enhanced by the ultrasonic aspirator. The majority of the parenchyma of the uncinata process is spared, and the excavation of the pancreatic head is made contiguous with a generous dochtotomy of the dorsal duct. Whether merely unroofing as opposed to removal of the proximal ducts contributes to better pain relief is not known and awaits a randomized trial to compare the two versions of the LR-LPJ. Izbicki and colleagues at the University of Hamburg also recommend a more extensive excavation of the pancreatic head, and they use a technique that they refer to as the *Hamburg modification* of the LR-LPJ²⁷² (Fig. 33-60). This wider excavation of the pancreatic head is created in continuity with the dorsal dochtotomy, and it is followed by a single, side-to-side pancreaticojejunostomy.

In 2001, Ho and Frey subsequently described merely excavating the core of the pancreatic head and draining the excavation with a Roux-en-Y pancreaticojejunostomy, but without any effort to include the dorsal duct^{273,274} (Fig. 33-61). In 2003,

Figure 33-57. Frey procedure. The local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ) provides complete decompression of the entire pancreatic ductal system. Reconstruction is performed with a side-to-side Roux-en-Y pancreaticojejunostomy. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Figure 33-58. Operative view of excavated head of the pancreas during the Frey procedure. The main pancreatic duct is opened widely down to the level of the ampulla, and the head of the pancreas is excavated in a conical fashion so as to allow complete decompression of the chronically obstructed and inflamed pancreatic ducts. Figure 33-59. Complete excavation of the pancreatic head and distal pancreaticochotomy. A true excavation and removal of the proximal ductal system is combined with a distal pancreaticochotomy. Reconstruction is performed with a single side-to-side Roux-en-Y pancreaticojejunostomy. (Reproduced with permission from Andersen DK, Topazian MD. *Pancreatic head excavation: a variation on the theme of duodenum-preserving pancreatic head resection*, Arch Surg. 2004 Apr;139(4):375-379.)

Figure 33-60. The Hamburg modification of the local resection of the pancreatic head with longitudinal pancreaticojejunostomy. (Reproduced with permission from Shackelford RT, Yeo CJ, Peters JH: *Shackelford's Surgery of the Alimentary Tract*. New York, NY: Saunders/Elsevier; 2007.)

Farkas and colleagues described a similar excavation of the central portion of the pancreatic head without any effort to include the duct of the body in the lateral pancreaticojejunostomy,²⁷⁵ and they reported excellent results with what they termed an *organ-preserving pancreatic head resection* (OPPHR) in a randomized comparison to the pylorus-preserving pancreaticoduodenectomy (PPPD).²⁷⁶

This approach was advocated by Gloor and associates in Bern as an alternative to the DPPHR procedure in patients with portal hypertension²⁷⁷ and was described as the *Berne modification of the DPPHR* (Fig. 33-62). Königer and colleagues in Heidelberg subsequently published a randomized, controlled trial of the “Berne” version of the excavation method compared to the “classic” Beger procedure.²⁷⁸ Operative times and length of stay were shorter in the group undergoing excavation of the pancreatic head, while long-term outcomes and quality-of-life scores were identical over 2 years postoperatively.

The common element of these variations on the theme of LR-LPJ remains the excavation or “coring out” of the central portion of the pancreatic head. It remains uncertain, however, whether and to what degree the doctotomy needs to be extended

6▶ into the body and tail. The logical conclusion of all of these efforts is that the head of the pancreas is the nidus of the chronic inflammatory process in chronic pancreatitis and that removal of the central portion of the head of the gland is the key to the successful resolution of pain in the long term.

Complications Initial and long-term results of the LR-LPJ demonstrate pain relief that is equivalent to that of pancreaticoduodenectomy and the DPPHR.^{279,280} The observed mortality rate has been virtually zero, and therefore, less than with the Whipple procedure. Major complications were less with the LR-LPJ (16%) than with pancreaticoduodenectomy (40%) or DPPHR (25%) in one single-site series, and the incidence of new postoperative diabetes after LR-LPJ was 8% with an average follow-up of 3 years.¹⁹⁹

Figure 33-61. Excavation of pancreatic head without longitudinal pancreaticojejunostomy.

Comparisons of the Three Operative Procedures: Pancreaticoduodenectomy (Whipple procedure), DPPHR (Beger procedure), and LR-LPJ (Frey procedure). There has been considerable interest to apply evidence-based methods to the study of the three operations currently advocated for the treatment of chronic pancreatitis. The best studies, or level 1 data by the Strength of Recommendation Taxonomy, are prospective, randomized controlled trials comparing two or more operations from a single or multi-institutional study. Retrospective, cohort-based studies are regarded as level 2 data by the Strength of Recommendation Taxonomy criteria.

To date, ten published level 1 studies^{268,276,278-285} and three level 2 studies^{199,286,287} have examined various comparisons between these three operations. In the level 1 study of Klempa and colleagues²⁸¹ and that of Buchler et al,²⁸⁸ DPPHR patients had a shorter hospital stay, greater weight gain, less postoperative diabetes, and exocrine dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. Similar results were observed in a

Figure 33-62. The Berne modification of the local resection of the pancreatic head with longitudinal pancreaticojejunostomy.

recent level 2 retrospective study of 123 patients²⁸⁷ and in the level 1 study by Keck et al.²⁸⁷

In a level 1 study of 61 patients randomized to PPPD or LR-LPJ, Izbicki and colleagues found a lower postoperative complication rate associated with the Frey procedure (19%) compared to the PPPD group (53%), and better global quality-of-life scores (71% vs. 43%, respectively).²⁷⁹ Both operations were equally effective in controlling pain over a 2-year follow-up. Similar results were seen in the study by Farkas and associates²⁷⁶ who employed a similar method of excavation of the pancreatic head that their group described as an *organ-preserving pancreatic head resection* (OPPHR) and found that OPPHR was associated with a shorter operating time, less postoperative morbidity, shorter hospital stay, and better quality of life than PPPD. The superior outcomes of the Frey procedure were found to be durable in a 15-year follow-up study by Bachmann et al²⁸⁵ who found that survival and function were superior after the Frey procedure.

Late Morbidity and Mortality In 2005, Izbicki's group reported on a level 1 study of 74 patients randomized to the DPPHR or LR-LPJ who were then followed for an average of 8.5 years.²⁸⁶ There were no significant differences between the groups with regard to global quality of life, pain scores, late mortality, and exocrine or endocrine insufficiency. The level 1 study by Königer, which compared the classic DPPHR with excavation of the pancreatic head, showed identical outcomes at 2 years after an initial reduction in morbidity associated with the excavation procedure.²⁷⁸ These results were echoed in the level 2 study by Aspelund and associates, which demonstrated fewer complications with both the DPPHR and LR-LPJ procedures compared to pancreaticoduodenectomy, a lower incidence

of new diabetes (8%) for both DPPHR and LR-LPJ compared to the Whipple procedure (25%), but no significant differences in outcomes or pain relief between DPPHR and LR-LPJ.¹⁹⁹ Finally, level 2 data support the efficacy of both DPPHR and LR-LPJ in patients with dilated as well as nondilated ducts.^{286,289,290}

Long-term exocrine and/or endocrine insufficiency in chronic pancreatitis patients treated surgically is a product of the surgical intervention as well as the progression of the underlying disease. Although the short-term (3-year) incidence of new diabetes after operation appears less with the LR-LPJ and DPPHR than with the PPPD, the late incidence of diabetes appears similar in all groups. After an average of 7 years of follow-up after LR-LPJ or PPPD, survival, pain relief, and pancreatic function were similar in both groups. The rate of diabetes was slightly lower after LR-LPJ (61%) than after PPPD (65%), but these had both more than doubled from their preoperative status.²⁷⁵⁻²⁸¹ Therefore, although the limited pancreatic procedures of DPPHR and LR-LPJ have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation.

The level 1 studies confirm that the duodenum preserving options are associated with a lower immediate morbidity and mortality and therefore, in the absence of a mass or concerns about cancer, are better options than a Whipple procedure for chronic pancreatitis. The choice of LR-LPJ, DPPHR, or OPPHR depends largely on surgeon experience, and the LR-LPJ is most common in the United States.

Total Pancreatectomy With Islet Auto-Transplantation Islet cell transplantation for the treatment of diabetes is an attractive adjunct to pancreatic surgery in the treatment of benign pancreatic disease. Despite the difficulties in recovering islets from a chronically inflamed gland, Najarian and associates demonstrated the utility of autotransplantation of islets in patients with chronic pancreatitis in 1980.²⁹¹ Subsequently, through refinements in the methods of harvesting and gland preservation, and through standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, the success of total pancreatectomy combined with islet autotransplantation has steadily increased to achieve insulin independence in the majority of patients treated in recent series.^{292,293} Although 2 to 3 million islets are required for successful engraftment in an allogeneic recipient, the auto-transplant recipient can usually achieve long-term, insulin-independent status after engraftment of only 300,000 to 400,000 islets (about one-third to one-half of the number of islets in the normal pancreas).²⁹⁴

The ability to recover a sufficient quantity of islets from a sclerotic gland is dependent on the degree of fibrotic disease present, so the selection of patients as candidates for autologous islet transplantation is important. The impressive improvement in quality of life measures and pain relief seen after total pancreatectomy with islet auto-transplantation (TP-IAT) indicate that it is a highly successful form of therapy for some patients (Fig. 33-63).²⁹⁵ The outcomes of TP-IAT are significantly better in pediatric patients than in adults, largely due to the prevalence of hereditary and idiopathic causes of chronic pancreatitis in pediatric patients.²⁹⁶ These studies suggest that further definition is needed regarding criteria for considering TP-IAT vs. hybrid or resectional procedures for patients with persistent symptoms. With the emerging evidence that hybrid procedures seem to offer better outcomes in patients with toxic etiologies of chronic pancreatitis, and that TP-IAT appears to

Effect	Num DF	Den DF	F statistic	P value
Age	1	528	0.26	0.608
Time	13	4299	268.29	<0.001
Age x Time	12	4299	4.84	<0.001

Figure 33-63. Prevalence of narcotic use after total pancreatectomy with islet auto-transplantation (TP-IAT) in adult and pediatric patients. (Reproduced with permission from Chinnakotla S, Beilman GJ, Dunn TB, et al. *Factors Predicting Outcomes After a Total Pancreatectomy and Islet Autotransplantation Lessons Learned From Over 500 Cases*, Ann Surg. 2015 Oct;262(4):610-622.)

preferentially benefit patients with hereditary and idiopathic forms of the disease, the importance of the careful definition of the etiology of chronic pancreatitis, including genetic testing, is steadily increasing.

PANCREATIC NEOPLASMS

Neoplasms of the Endocrine Pancreas

Neoplasms of the endocrine pancreas are relatively uncommon but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. The cells of the endocrine pancreas, or islet cells, originate from neural crest cells, also referred to as *amine precursor uptake and decarboxylation cells*. Multiple endocrine neoplasia (MEN) syndromes occur when these cells cause tumors in multiple sites. The MEN1 syndrome involves pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Although most pancreatic endocrine tumors are nonfunctional, some are functional, secreting peptide products that produce interesting clinical presentations. Neoplasms of the endocrine pancreas that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the

disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures. Unresectable disease in the liver is often addressed with chemoembolization.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a multidetector CT scan with four phases of contrast and fine cuts through the pancreas and liver. Neuroendocrine tumors of the pancreas often enhance with contrast. EUS can be superior to CT in localizing these tumors, which can produce dramatic symptoms despite their small (<1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors (SSTRs) that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning (Fig. 33-64). The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

Insulinoma

Insulinomas are the most common functional pancreatic endocrine neoplasms and present with a typical clinical

Figure 33-64. Radioactive octreotide scan demonstrating pancreatic endocrine tumor in the body of the pancreas (*arrow*).

syndrome known as Whipple's triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level <50 mg/dL, and relief of symptoms with the administration of glucose. Patients can present with a profound syncopal episode or less severe symptoms that are averted by frequent eating. Common symptoms include palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone a personality change.

Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. Serum insulin levels are elevated. C-peptide levels should also be elevated and rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents because excess endogenous insulin production leads to excess C-peptide. The diagnosis can be clinched with a monitored fast in which blood is sampled every 4 to 6 hours for glucose and insulin levels until the patient becomes symptomatic. However, this can be dangerous and must be done with close supervision.

Insulinomas are usually localized with CT scanning and EUS. Technical advances in EUS have led to preoperative identification of $>90\%$ of insulinomas.²⁹⁷ Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas.²⁹⁸ Unlike most endocrine pancreatic tumors, the majority (90%) of insulinomas are benign

and solitary, and only 10% are malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (>2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative US is useful to determine the tumor's relation to the main pancreatic duct and guides intraoperative decision making. Approximately 90% of insulinomas are sporadic, and 10% are associated with the MEN1 syndrome. Insulinomas associated with the MEN1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

Noninsulinoma Hyperinsulinemia Hypoglycemia Syndrome

A syndrome of noninsulinoma pancreatogenous hypoglycemia was described by Service et al in 1999.²⁹⁹ The syndrome is associated with beta-cell hypertrophy, islet hyperplasia and increased beta-cell mass. When these findings are accompanied by ectopic islet tissue, multilobulated islets, and ductuloinsular complexes, the definition of nesideoblastosis is met. Nesideoblastosis accompanied by hyperinsulinism was previously considered a disease of neonates, where subtotal or total pancreatectomy was required to correct potentially fatal neonatal hyperinsulinism. However, dozens of cases of nesideoblastosis associated with hyperinsulinism have now been reported in patients 2 to 5 years after Roux-en-Y gastric bypass for obesity.³⁰⁰ Many of these patients have undergone partial or total pancreatectomy to prevent potentially fatal hypoglycemia. The illness in former bariatric surgery patients appears to result from an idiosyncratically-prolonged hypersecretion of the incretin hormones GIP and GLP-1 after the gastric bypass. GLP-1 is a potent stimulant of the expression of the transcription factor PDX-1, which normally regulates beta-cell development and growth. The correct treatment of this condition to prevent episodes of hypoglycemia is conversion of the gastric bypass to a form of bariatric procedure that restores normal intestinal flow of nutrients, such as the gastric sleeve, or the addition of a restriction element such as an adjustable gastric band. Pancreatic resection without conversion of the Roux-en-Y gastric bypass is not appropriate because this allows the abnormal enteroinsular relationship to continue and hyperinsulinemia persists or recurs after partial pancreatectomy.

Gastrinoma

Zollinger-Ellison syndrome (ZES) is caused by a *gastrinoma*, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. Although most of the ulcers are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. At the time of diagnosis, 21% of patients with gastrinoma have diarrhea.

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is >1000 pg/mL. Gastrin levels can be elevated under conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

Figure 33-65. Passaro's triangle. The typical location of a gastrinoma is described by this anatomic region, including the head of the pancreas, duodenum, and the lymphatic bed posterior and superior to the duodenum, as originally described by E. Passaro. (Reproduced with permission from Stable BE, Morrow DJ, Passaro E: *The gastrinoma triangle: operative implications*, Am J Surg. 1984 Jan;147(1):25-31.)

In 70% to 90% of patients, the primary gastrinoma is found in Passaro's triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas (Fig. 33-65). However, because gastrinomas can be found almost anywhere, whole-body imaging is required. The test of choice is SSTR (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85% of gastrinomas and detecting tumors <1 cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. EUS is another modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, where gastrinomas are usually <1 cm in size. A combination of octreotide scan and EUS detects >90% of gastrinomas.

It is important to rule out MEN1 syndrome by checking serum calcium levels before surgery because resection of the gastrinoma(s) in these patients rarely results in normalization of serum gastrin concentrations or a prolongation of survival. Only one-fourth of gastrinomas occur in association with the MEN1 syndrome. One-half of patients with gastrinomas will have solitary tumors while the remainder will have multiple gastrinomas. Multiple tumors are more common in patients with MEN1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the forearm.

Approximately 50% of gastrinomas metastasize to lymph nodes or the liver and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in Passaro's triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary

gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debulking or incomplete removal of multiple hepatic metastases is probably not helpful, especially in the setting of MEN1. The application of new modalities such as radiofrequency ablation seems reasonable, but data to support this approach are limited.³⁰¹ Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. In patients found to have inoperable disease, chemotherapy with streptozocin, doxorubicin, and 5-fluorouracil (5-FU) is used. Other approaches such as somatostatin analogues, interferon, and chemoembolization also have been used in gastrinoma with some success.

Unfortunately, a biochemical cure is achieved in only about one-third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80%, while the 5-year survival rate for patients with liver metastases is 20% to 50%. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often they have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro's triangle, have the worst prognosis.

Vasoactive Intestinal Peptide-Secreting Tumor

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting VIP. The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The *vasoactive intestinal peptide-secreting tumor (VIPoma) syndrome* is also called *WDHA syndrome* due to the presence of watery diarrhea, hypokalemia, and achlorhydria. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic and single measurements might be normal and misleading. A CT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogues are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogues. Hepatic artery embolization also has been reported as a potentially beneficial treatment.³⁰²

Glucagonoma

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on

the lower abdomen, perineum, perioral area, and feet. Patients also complain of an enlarged, sensitive tongue. The diagnosis is confirmed by measuring serum glucagon levels, which are usually >500 pg/mL. Glucagon is a catabolic hormone, and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

Somatostatinoma

Because somatostatin inhibits pancreatic and biliary secretions, patients with a somatostatinoma present with gallstones due to bile stasis, diabetes due to inhibition of insulin secretion, and steatorrhea due to inhibition of pancreatic exocrine secretion and bile secretion. Most somatostatinomas originate in the proximal pancreas or the pancreatoduodenal groove, with the ampulla and periampullary area as the most common site (60%). The most common presentations are abdominal pain (25%), jaundice (25%), and cholelithiasis (19%).³⁰³ This rare type of pancreatic endocrine tumor is diagnosed by confirming elevated serum somatostatin levels, which are usually >10 ng/mL. Although most reported cases of somatostatinoma involve metastatic disease, an attempt at complete excision of the tumor and cholecystectomy is warranted in fit patients.

Nonfunctioning Pancreatic Endocrine Tumors

Although some pancreatic endocrine neoplasms secrete one or more hormones and are associated with interesting characteristic clinical syndromes, most are not associated with elevated serum hormone levels that cause symptoms. Pancreatic endocrine tumors are considered functional if they are associated with a clinical syndrome and nonfunctioning if not associated with clinical symptoms. The majority of pancreatic endocrine tumors (PET), also called pancreatic neuroendocrine tumors (pNET), are malignant because they have the potential for uncontrolled

growth and metastasis. Immunohistochemical markers such as synaptophysin, chromogranin A (CgA), and neuron-specific enolase can be helpful in the diagnosis, but the gross histology is not a reliable predictor of biologic behavior. CgA is used by some as a serum marker to monitor patients for disease recurrence or response to treatment, but the test performs poorly for this purpose. Patients often present similar to patients with pancreatic adenocarcinoma with vague pain or weight loss, but pNETs are increasingly discovered incidentally when imaging is performed for another reason. The tumor frequently enhances with arterial contrast (Fig. 33-66). Sometimes a cystic component is seen due to central necrosis. Octreoscan (somatostatin receptor scintigraphy) can be helpful to stage the disease. Surgical resection is typically recommended in fit patients in the absence of metastatic disease. For patients with tumors in the body and tail of the pancreas, this typically includes splenectomy. Enucleation and splenic preservation, although tempting in small tumors, fails to remove regional lymph nodes.

With advances in imaging, small indolent pNETs are being discovered with increasing frequency, and some surgeons are considering observation in these cases.³⁰⁴ There are several arguments in favor of observation of small (<2 cm) nonfunctional pNETs, particularly in MEN-1 patients. Pancreatic resection has significant morbidity and mortality. In the setting of MEN-1, resection is rarely curative, and most patients require reoperation. Also, the survival of these patients, even with metastatic disease, is generally excellent at least compared to pancreatic ductal adenocarcinoma. However, the 5-year survival with metastatic pNET is only 16% and radical surgery with curative intent is the standard of care, particularly in sporadic cases that are fit surgical candidates where the primary tumor can be completely excised.

Adjuvant treatment after resection is withheld in the absence of radiographically demonstrable metastatic disease even if CgA levels remain elevated. Although these tumors have a slow growth pattern compared to pancreatic ductal adenocarcinoma, many patients with pNETs will die of their disease even after an apparent complete resection, making surveillance after complete resection important. CT scan and or octreotide scan is recommended annually for 5 years after resection.

Figure 33-66. Pancreatic neuroendocrine tumor (PNET) demonstrating enhancement during arterial phase of computed tomography scan. Pancreatic head PNET seen in (left) sagittal, (middle) coronal, and (right) lateral views of the abdomen.

Incomplete resection (debulking) for locally advanced or metastatic pNETs of the pancreas is controversial because of the favorable survival duration of patients without surgery. However, in carefully selected fit patients with a pNET in the head of the pancreas and minimal disease in the liver, a pancreaticoduodenectomy with wedge resection of the liver metastasis might be appropriate because this avoids the morbidity of gastrointestinal hemorrhage and biliary and gastric outlet obstruction before death from the metastatic disease. The role of cytoreductive surgery in metastatic pNET is controversial, but consensus guidelines agree that aggressive resection of the primary tumor, regional lymph nodes, and liver/distant metastases should be pursued if greater than 90% of the tumor burden can be resected, which is the case in only about 10% of patients with metastatic disease.

Treatment of metastatic pancreatic neuroendocrine cancer requires a multidisciplinary approach often including a combination of cytoreductive surgery when appropriate, directed therapy for the treatment of liver metastases when possible, and systemic medical therapy. Local ablative therapies include radiofrequency ablation (RFA), cryotherapy, microwave coagulation, and ethanol injection, although RFA is the most popular and widely studied. These therapies can be performed percutaneously or during surgery via laparotomy or laparoscopy, can be repeated, and have been shown to complement resection of the primary tumor and amenable liver metastases; making palliative surgery possible for patients that would otherwise not meet criteria. This approach often improves symptoms and 5-year survival is improved to 48%.³⁰⁵

Transarterial chemoembolization (TACE) can be employed as palliative therapy in patients with liver metastases not amenable to surgical resection and/or ablation. It relies on the principle that metastatic tumor cells derive the majority of their oxygen supply from the hepatic artery as opposed to hepatocytes, which receive oxygen primarily from the portal vein. Performed via angiography, embolization may be performed alone (bland embolization) or in combination with chemotherapeutic agents (chemoembolization). Radioembolization, the selective distribution of radioactive yttrium-90 microspheres into the peritumoral vasculature via branches of the hepatic artery, is another alternative.

Somatostatin analogs can inhibit release of hormones from functional pNETs and reduce diarrhea in patients with VIPomas, glucagonomas, and somatostatinomas, and it can also help the rash of glucagonomas. Somatostatin analogs such as octreotide (Sandostatin LAR Depot), lanreotide (Somatuline Depot), and a new analog pasireotide (Sifnifor LAR) are also used to slow the growth of some functional and nonfunctional pNETs. Disease seen on an octreotide scan has somatostatin receptors and would be expected to respond. Patients with unresectable disease are often treated with somatostatin analogs first before targeted therapy and cytotoxic chemotherapy are utilized because the side effects are minimal.

Some targeted drugs can be helpful in treating advanced pNETs that progress despite somatostatin analogs. Sunitinib (Sutent) attacks new blood vessel growth and other targets that help cancer cells grow. Everolimus (Afinitor) works by blocking a cell protein known as mammalian target of rapamycin (mTOR) and the VEGF pathway, which normally helps cells grow and divide. These targeted agents induce stabilization much more frequently than response, but they tend to carry fewer side effects than traditional cytotoxic chemotherapy. Cytotoxic

chemotherapy for pNETs is usually reserved for large tumors or quickly growing tumors that are causing symptoms, or tumors that progressed despite somatostatin analogs and targeted therapy. Platinum-based chemotherapy does, however, remain the standard of care for high-grade (poorly differentiated) pNET, yielding high response rates but typically short-lived benefit. The newer cytotoxic combination of capecitabine and temozolomide has shown activity in well-differentiated pNET.³⁰⁶

Neoplasms of the Exocrine Pancreas

Epidemiology and Risk Factors. It is estimated that in 2017, 53,670 Americans will be diagnosed with pancreatic cancer and 43,090 will die from the disease. Overall, pancreatic cancer has the worst prognosis of all malignancies with a 5-year survival rate of only 7.2%.³⁰⁷ The incidence of pancreatic cancer continues to increase, perhaps related to the increased incidence of risk factors such as obesity and diabetes, and as a result, it is predicted that pancreatic cancer will become the leading cause of cancer deaths in the United States by 2050. Pancreatic cancer recently surpassed breast cancer and is now the third leading cause of cancer death behind lung and colorectal cancer. Despite its ubiquity, this disease is extremely difficult to treat, and its exact cause is unknown. However, epidemiologic studies linking various environmental and host factors provide some clues. Recent discoveries using modern molecular biologic techniques have also improved our understanding of the causes of pancreatic cancer. The etiology of pancreatic cancer likely involves a complex interaction of genetic and environmental factors. These factors will become more fully understood as DNA sequencing is used to screen populations at risk for developing pancreatic cancer.

Pancreatic cancer is more common in older adults with most patients being 75 to 84 years old. Pancreatic cancer is more common in African Americans and slightly more common in men than women. The risk of developing pancreatic cancer is two to three times higher if a parent or sibling had the disease. Another risk factor that is consistently linked to pancreatic cancer is cigarette smoking. Smoking increases the risk of developing pancreatic cancer by at least twofold due to the carcinogens in cigarette smoke.³⁰⁸ Coffee and alcohol consumption have been investigated as possible risk factors, but the data are inconsistent. As in other GI cancers, diets high in fat and low in fiber, fruits, and vegetables are thought to be associated with an increased risk of pancreatic cancer.

Diabetes has been known to be associated with pancreatic cancer for many years. In fact, glucose intolerance is present in 80% of patients with pancreatic cancer, and approximately 20% have overt diabetes, a much greater incidence than would be expected to occur by chance. Preexisting type 2 diabetes increases the risk for development of pancreatic cancer by about twofold.³⁰⁹ The new onset of diabetes also can be an early manifestation of otherwise occult pancreatic cancer. Thus, the new onset of diabetes, or a sudden increase in insulin requirement in an older adult patient with preexisting diabetes, should provoke concern for the presence of pancreatic cancer.

Recent epidemiologic studies have confirmed the fact that patients with chronic pancreatitis, especially familial pancreatitis, have an increased risk of developing pancreatic cancer.^{124,196-198} Large, retrospective cohort studies of patients with pancreatitis have revealed up to a 20-fold increase in risk for pancreatic cancer. This increased risk seems to be independent of the type of pancreatitis, a finding consistent with the fact that most studies have shown little effect of alcohol ingestion per se

on the risk of pancreatic carcinoma. The mechanisms involved in carcinogenesis in patients with preexisting pancreatitis are unknown. However, the mutated *K-ras* oncogene, which is present in most cases of pancreatic cancer, has been detected in the ductal epithelium of some patients with chronic pancreatitis.

Genetics of Pancreatic Cancer. Pancreatic carcinogenesis probably involves multiple mutations that are inherited and acquired throughout aging. The *K-ras* oncogene is currently thought to be the most commonly mutated gene in pancreatic cancer, with approximately 90% of tumors having a mutation.³¹⁰ This prevalent mutation is present in precursor lesions and is therefore thought to occur early and be essential to pancreatic cancer development. *K-ras* mutations can be detected in DNA from serum, stool, pancreatic juice, and tissue aspirates of patients with pancreatic cancer, suggesting that the presence of this mutation or others may provide the basis for diagnostic testing in select individuals. The *HER2/neu* oncogene, homologous to the epidermal growth factor receptor (EGFr), is overexpressed in pancreatic cancers.³¹⁰ This receptor is involved in signal transduction pathways that lead to cellular proliferation. Multiple tumor-suppressor genes are deleted and/or mutated in pancreatic cancer, including *p53*, *p16*, and *DPC4* (*Smad 4*), and in a minority of cases, *BRCA2*.³¹¹ Most pancreatic cancers have three or more of the aforementioned mutations.

The genetic landscape of pancreatic adenocarcinoma has recently been investigated using exome capture technology combined with the SOLiD or Illumina next generation sequencing platforms and copy number analysis. Detailed analysis of 99 tumors reaffirmed the importance of the already known mutations such as *KRAS*, *TP53*, *CDKN2A*, *SMAD4*, *MLL3*, *TGFBR2*, *ARID1A*, and *SF3B1* in pancreatic cancer and identified eight novel significantly mutated genes involved in chromatin modification (*EPC1* and *ARID2*), DNA damage repair (*ATM*) and other mechanisms (*ZIM2*, *MAP2K4*, *NALCN*, *SLC16A4*, and *MAGEA6*). Pathway-based analysis of recurrently altered genes also revealed the involvement of axon-guidance genes, particularly *SLIT/ROBO* signaling, in pancreatic carcinogenesis.³¹² Rapid and sensitive sequencing techniques will hopefully lead to better diagnostic and therapeutic approaches for pancreatic cancer.

It is estimated that up to 10% of pancreatic cancers occur as a result of an inherited genetic predisposition. A family history of pancreatic cancer in a first-degree relative increases the risk of pancreatic cancer by about twofold. Rare familial cancer syndromes that are associated with an increased risk of pancreatic cancer include *BRCA2*, the familial atypical multiple mole–melanoma syndrome, hereditary pancreatitis, familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer, Peutz-Jeghers syndrome, and ataxia-telangiectasia.³¹¹

Pathology. Pancreatic cancer probably arises through a stepwise progression of cellular changes, just as colon cancer progresses by stages from hyperplastic polyp to invasive cancer. Systematic histologic evaluation of areas surrounding pancreatic cancers has revealed the presence of precursor lesions that have been named *pancreatic intraepithelial neoplasia* (Fig. 33-67). Three stages of pancreatic intraepithelial neoplasia have been defined. These lesions demonstrate the same oncogene mutations and loss of tumor-suppressor genes found in invasive cancers, the frequency of these abnormalities increasing with progressive cellular atypia and architectural disarray.³¹³ The ability to detect these precursor

lesions in humans at a stage where the cancer can still be prevented or cured is an important goal of current pancreatic cancer research.

About two-thirds of pancreatic adenocarcinomas arise within the head or uncinate process of the pancreas; 15% are in the body, and 10% are in the tail, with the remaining tumors demonstrating diffuse involvement of the gland. Tumors in the pancreatic body and tail are generally larger at the time of diagnosis, and therefore, less commonly resectable. Tumors in the head of the pancreas are typically diagnosed earlier because they cause obstructive jaundice. Ampullary carcinomas, carcinomas of the distal bile duct, and periampullary duodenal adenocarcinomas present in a similar fashion to pancreatic head cancer but have a slightly better prognosis, probably because early obstruction of the bile duct and jaundice leads to the diagnosis.

In addition to ductal adenocarcinoma, which makes up about 75% of nonendocrine cancers of the pancreas, there are a variety of less common types of pancreatic cancer. Adenosquamous carcinoma is a variant that has both glandular and squamous differentiation. The biologic behavior of this lesion is unfortunately no better than the typical ductal adenocarcinoma.³¹⁴ Acinar cell carcinoma is an uncommon type of pancreatic cancer that usually presents as a large tumor, often 10 cm in diameter or more, but the prognosis of patients with these tumors may be better than with ductal cancer.

Diagnosis and Staging. Exact pathologic staging of pancreatic cancer is important because it allows accurate quantitative assessment of results and comparisons between institutions. The tumor–node–metastasis (TNM) staging of pancreatic cancer was updated by the American Joint Committee on Cancer in 2017 (AJCC) (Table 33-21).

The important changes in the staging include more stratification for tumor size and stratification for number of lymph nodes involved. In the new system, tumors ≤ 2 cm remain as T1 lesions but are subcategorized as T1a (≤ 0.5 cm), T1b (>0.5 – $\rightarrow 1$ cm), and T1c (1–2 cm). Tumors that are >2 – ≤ 4 cm are categorized as T2, and tumors >4 cm are categorized as T3. Tumors that involve the celiac axis, superior mesenteric artery, and/or common hepatic artery are still categorized as T4 regardless of size. Metastasis in one to three regional lymph nodes is considered N1 disease, and involvement of ≥ 4 regional lymph nodes is N2. Patients without nodal involvement (N0) are stages IA, IB, and IIA based on tumor size (T1–T3, respectively). Patients with one to three regional lymph nodes involved (N2) are stage IIB regardless of tumor size. All patients with N2 disease without distant metastases are considered stage III regardless of tumor size. Patients with vascular involvement (T4) are stage III regardless of nodal involvement, and patients with distant metastases are, of course, stage IV.

Ten percent of pancreas cancer cases are diagnosed while the cancer is still confined to the primary site (localized stage); 29% are diagnosed after the cancer has spread to regional lymph nodes or directly beyond the primary site; 52% are diagnosed after the cancer has already metastasized (distant stage); and for the remaining 9%, the staging information was unknown. The corresponding 5-year relative survival rates were 31.5% for localized, 11.5% for regional, 2.7% for distant, and 5.1% for unstaged. The overall 5-year relative survival rate for patients with pancreatic cancer for 2007 to 2013 from Surveillance, Epidemiology, and End Results (SEER) was 8.2%.³⁰⁷

Figure 33-67. Pancreatic intraepithelial neoplasia (PanIN). Histology (*top panel*) showing grades PanIN-1A (A), PanIN-1B (B), PanIN-2 (C), and PanIN-3 (D), and schema of correlation of histology with mutational events (*bottom panel*) showing cumulative abnormalities of tumor-promoter and tumor suppressor factors such as kRAS, p53, etc., and their corresponding cellular phenotype. The most critical deficit in the ability to treat pancreatic cancer effectively is the lack of tools for early diagnosis. The pancreas is situated deep within the abdomen, and the early symptoms of pancreatic cancer often are too vague to raise suspicion of the disease. Ultimately, the majority of patients present with pain and jaundice. On physical examination, weight loss is evident and the skin is icteric; a distended gallbladder is palpable in about one-fourth of patients. More fortunate patients have tumors situated such that biliary obstruction and jaundice occurs early and prompts diagnostic tests. Unfortunately, however, the

vast majority of patients are not diagnosed until weight loss has occurred—a sign of advanced disease.

Although it is often taught that carcinoma of the pancreas presents with painless jaundice (to help distinguish it from cholelithiasis), this aphorism is not accurate. Most patients do experience pain as part of the symptom complex of pancreatic cancer, and it is often the first symptom. Therefore, awareness of the way pancreatic pain is perceived may help clinicians suspect pancreatic cancer. The pain associated with pancreatic cancer is usually perceived in the epigastrium but can occur in any

Table 33-21

Staging of pancreatic cancer

Tumor (T)			
TX	Tumor cannot be assessed		
T1	Tumor limited to the pancreas,* <2 cm		
T2	Tumor limited to the pancreas,* 2–4 cm		
T3	Tumor limited to the pancreas,* >4 cm; or tumor invading the duodenum or common bile duct		
T4	Tumor invading adjacent organs (stomach, spleen, colon, adrenal gland) or the wall of large vessels (celiac axis or the superior mesenteric artery)		
Regional Lymph Node (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node involvement		
N1	Regional lymph node involvement		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
M1a	Metastasis confined to liver		
M1b	Metastases in at least one extrahepatic site (e.g., lung, ovary, nonregional lymph node, peritoneum, bone)		
M1c	Both hepatic and extrahepatic metastases		
TUMOR	NODE	METASTASIS	STAGE
T1	N0	M0	I
T2	N0	M0	II
T3	N0	M0	II
T4	N0	M0	III
Any T	N1	M0	III
Any T	Any N	M1	IV

part of the abdomen, and often, but not always, penetrates to the back. When questioned in retrospect, patients often recall mild and vague pain for many months before diagnosis. A low threshold for ordering a CT scan with “pancreatic protocol” should be maintained for elderly patients with unexplained, persistent, although vague, abdominal pain. As mentioned previously, new-onset diabetes in an elderly patient, especially if combined with vague abdominal pain, should prompt a search for pancreatic cancer.

Unfortunately, at this time there is no sensitive and specific serum marker to assist in the timely diagnosis of pancreatic cancer. With jaundice, direct hyperbilirubinemia and elevated alkaline phosphatase are expected but do not serve much of a diagnostic role other than to confirm the obvious. With long-standing biliary obstruction, the prothrombin time will be prolonged due to a depletion of vitamin K, a fat-soluble vitamin dependent on bile flow for absorption. CA19-9 is a mucin-associated carbohydrate antigen that can be detected in

the serum of patients with pancreatic cancer. Serum levels are elevated in about 75% of patients with pancreatic cancer. However, CA19-9 is also elevated in about 10% of patients with benign diseases of the pancreas, liver, and bile ducts.¹⁵ CA19-9 is thus neither sufficiently sensitive nor specific to allow an early diagnosis of pancreatic cancer. Despite the fact that many tumor markers such as CA19-9 have been studied, there are still no effective screening tests for pancreatic cancer. Research taking advantage of recent advances in genomics, gene expression analysis, and proteomics has demonstrated thousands of genes and corresponding proteins that are differentially expressed in pancreatic tumors that have potential for early detection of pancreatic cancer.³¹⁶ Some of these proteins would be expected to be expressed at the cell surface or in pancreatic juice and may become useful as biomarkers for pancreatic cancer in the future.

In patients presenting with jaundice, a reasonable first diagnostic imaging study is abdominal ultrasound. If bile duct dilation is not seen, hepatocellular disease is likely. Demonstration of cholelithiasis and bile duct dilation suggests a diagnosis of choledocholithiasis, and the next logical step would be ERCP to clear the bile duct. In the absence of gallstones, malignant obstruction of the bile duct is likely, and a CT scan rather than ERCP would be the next logical step. For patients suspected of having pancreatic cancer who present without jaundice, a CT scan should be the first test.

The current diagnostic and staging test of choice for pancreatic cancer is a multidetector, dynamic, contrast-enhanced CT scan, and the techniques for obtaining high-quality images are constantly improving (Fig. 33-68). The accuracy of CT scanning for predicting unresectable disease is about 90% to 95%.³¹⁷ In contrast, CT scanning is less accurate in predicting resectable disease. CT scanning will miss small liver metastases, and predicting arterial involvement is sometimes difficult. CT findings that indicate a tumor is unresectable include involvement of $\geq 180^\circ$ of the celiac axis, hepatic or superior mesenteric artery, enlarged lymph nodes outside the boundaries of resection, ascites, and distant metastases (e.g., liver). Invasion of the superior mesenteric vein or portal vein is not in itself a contraindication to resection as long as the veins are patent. Tumors are considered “borderline resectable” if there is abutment of ≤ 180 degrees of the circumference of the SMA, celiac axis, or hepatic artery or if there is a short segment of vein occlusion. Also, patients with CT findings suspicious for metastatic disease, like 1 mm liver lesions too small to characterize or biopsy, are considered “borderline resectable” as are patients with multiple comorbidities or marginal performance status. There is growing consensus that neoadjuvant treatment should be considered in all patients with any radiographic evidence of extension to adjacent vascular structures.

Currently, multidetector CT is probably the single most versatile and cost-effective tool for the diagnosis and staging of pancreatic cancer. Abdominal MRI provides essentially the same information as CT scanning. Positron emission tomography scanning in locally advanced lesions may help rule out distant metastases. EUS can be used to detect small pancreatic masses that could be missed by CT scanning and is commonly used when there is a high suspicion for pancreatic cancer but no mass is identified by the CT scan. EUS has the added advantage of providing the opportunity for transluminal biopsy of pancreatic masses, although a tissue diagnosis before pancreaticoduodenectomy is not required. However, in specific patients a histologic diagnosis may be necessary such as for those in a

Figure 33-68. Computed tomography scan demonstrating resectable pancreatic cancer. SMA = superior mesenteric artery.

neoadjuvant clinical trial or before chemotherapy in advanced tumors. EUS is a sensitive test for portal/superior mesenteric vein invasion, although it is somewhat less effective at detecting superior mesenteric artery invasion. When all of the current staging modalities are used, their accuracy in predicting resectability has improved.

As imaging continuously improves and high-quality imaging is always obtained before surgery, the chance of bringing a patient to the operating room with the intent of a curative resection and finding upon exploration that the patient has unresectable disease is becoming increasingly uncommon.

In an attempt to avoid such futile laparotomies, preliminary laparoscopy has been advocated for patients with disease felt to be resectable by CT imaging (Fig. 33-69). Diagnostic laparoscopy with the use of US is reported to improve the accuracy of predicting resectability to about 98%.³¹⁸ The technique

Figure 33-69. Liver metastases identified at diagnostic laparoscopy.

involves more than simple visualization with the scope and requires the placement of multiple ports and manipulation of the tissues. A general exploration of the peritoneal surfaces is carried out. The ligament of Treitz and the base of the transverse mesocolon are examined for tumor. The gastrocolic ligament is incised, and the lesser sac is examined. The ultrasound probe is used to examine the liver, porta hepatis and the portal vein, the celiac axis, and the superior mesenteric artery.

The percentage of patients in whom a positive laparoscopy helps avoid a nontherapeutic laparotomy varies from 10% to 30% in carcinoma of the head of the pancreas, but it may be as high as 50% in patients with tumors in the body and tail of the gland. Resection for pancreatic cancer is being approached laparoscopically, particularly for tumors in the body and tail of the pancreas thus eliminating the need for any separate staging laparoscopy procedure. Also, as the quality of CT scanning has improved, the value of routine diagnostic laparoscopy has decreased. The morbidity of diagnostic laparoscopy is less than that of laparotomy, and the procedure can be performed on an outpatient basis. Patients who are found to have unresectable disease recover more rapidly from a laparoscopy than a laparotomy and can receive palliative chemotherapy and radiation sooner. The potential immunosuppressive effects of a major surgical procedure also are avoided, as well as the negative psychologic impact of a major painful operation with little benefit.

Biliary obstruction can be relieved with an endoscopic approach in almost all cases. When large (10F) plastic stents are used, most patients do not require replacement for about 3 months. Metallic wall stents last about 5 months on average and usually fail only with tumor ingrowth.³¹⁹ Keeping in mind that patients with unresectable pancreatic cancer usually live <1 year, the requirement for numerous stent changes is unlikely.

Diagnostic laparoscopy is possibly best applied to patients with pancreatic cancer on a selective basis. Diagnostic laparoscopy will have a higher yield in patients with large tumors (T3,

Figure 33-70. Diagnostic and treatment algorithm for pancreatic cancer. If computed tomography (CT) scan demonstrates a potentially resectable tumor, patients are offered participation in a clinical trial after histologic confirmation by CT or endoscopic ultrasound (EUS)-guided biopsy. If CT scan demonstrates resectable disease, diagnostic laparoscopy is used selectively in patients with tumors in the body/tail, equivocal findings of metastasis or CT scan, ascites, high CA19-9, or marked weight loss. Patients also have diagnostic laparoscopy if they elect to participate in a neoadjuvant clinical trial. In cases where no mass is demonstrated on CT scan, but suspicion of cancer remains, EUS or endoscopic retrograde cholangiopancreatography (ERCP) with brushings are performed, and the CT may be repeated after an interval of observation.

>4 cm), tumors located in the body or tail, patients with equivocal findings of metastasis or ascites on CT scan, and patients with other indications of advanced disease such as marked weight loss or markedly elevated CA19-9 (>1000 U/mL). An algorithm for the diagnosis, staging, and treatment of pancreatic cancer is shown in Fig. 33-70. In practice, many of these patients are selected for neoadjuvant chemotherapy and then undergo restaging CT and staging laparoscopy prior to surgery.

Palliative Surgery and Endoscopy. Most patients with pancreatic cancer (85–90%) have disease that clearly precludes surgical resection. For these patients, appropriate and effective palliative treatment is critical to the quality of their remaining life. Because of the poor prognosis of the disease, it is not appropriate to use invasive, toxic, and expensive regimens in patients with extremely advanced disease and poor performance status. When patients do desire antineoplastic therapy, it is important to encourage them to enroll in clinical trials so that therapeutic advances can be made. In general, there are three clinical problems in advanced pancreatic cancer that require palliation: pain, jaundice, and duodenal obstruction. The mainstay of pain control is oral narcotics. Sustained-release preparations of morphine sulfate are frequently used. Invasion of retroperitoneal nerve trunks accounts for the severe pain experienced by patients with advanced pancreatic cancer. A celiac plexus nerve block can control pain effectively for a period of months, although the procedure sometimes needs to be repeated.³²⁰

Jaundice is present in the majority of patients with pancreatic cancer, and the most troublesome aspect for the patient is the accompanying pruritus. Biliary obstruction may also lead to cholangitis, coagulopathy, digestive symptoms, and hepatocellular failure. In the past, surgeons traditionally performed a biliary and enteric bypass when unresectable disease was found at laparotomy. This is an increasingly uncommon situation for

the surgeon because locally advanced unresectable disease is now detected by high-quality preoperative imaging. Metastatic disease is also more reliably predicted by preoperative imaging and, in select cases, staging laparoscopy.

In current practice, jaundice is usually palliated by an endoscopic biliary stent, often prior to surgical referral. Duodenal obstruction is usually a late event in pancreatic cancer and occurs in only about 20% of patients.³²¹ In cases of biliary and duodenal obstruction, several options need to be considered. Endoscopic metallic duodenal stents are an option, but the patient's poor prognosis, the cost, and the fact that duodenal stents often do not result in ideal palliation has to be considered. The results of three RCTs examining endoscopic metallic stenting for malignant gastric outlet obstruction demonstrated that major and minor complications were comparable to gastrojejunostomy but time to tolerating oral intake and hospital stay was shorter.³²² Robot-assisted laparoscopic biliary-enteric bypass is now available at many centers. Although this should result in similar palliation as an open bypass and may be associated with more rapid recovery, the potential complications, the patient's life expectancy, and cost of this procedure must be considered. As many patients today already have a bile duct stent in place by the time of referral to a surgeon, it is not clear that operative biliary bypass is required. In patients with extensive metastases, an alternative short-term palliative option to consider in patients with gastric outlet obstruction is a percutaneous endoscopic gastrostomy tube or gastrojejunal feeding tube that allows decompression of the stomach and feeding into the jejunum.

If an operative bypass is performed, choledochojejunostomy is the preferred approach. Although an easy procedure to perform, choledochoduodenostomy is felt to be unwise because of the proximity of the duodenum to tumor. Some have discouraged the use of the gallbladder for biliary bypass; however, it

Figure 33-71. Biliary-enteric bypass to palliate unresectable pancreatic cancer. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

is suitable as long as the cystic duct clearly enters the common duct well above the tumor. The jejunum is brought anterior to the colon, if possible, rather than retrocolic, where the tumor potentially would invade the bowel sooner. Some surgeons use a loop of jejunum with a jejunojejunostomy to divert the enteric stream away from the biliary-enteric anastomosis. Others use a Roux-en-Y limb with the gastrojejunostomy located 50 cm downstream from the hepaticojejunostomy (Fig. 33-71). Potential advantages of the defunctionalized Roux-en-Y limb include the ease with which it will reach up to the hepatic hilum, probable decreased risk of cholangitis, and easier management of biliary anastomotic leaks. If a gastrojejunostomy is performed, it should be placed dependently and posterior along the greater

curvature to improve gastric emptying, and a vagotomy should not be performed. Endoscopic stents are definitely not as durable as a surgical bypass. Recurrent obstruction and cholangitis is more common with stents and results in inferior palliation. However, the endoscopic approach is associated with considerably less initial morbidity and mortality than surgical bypass. Expandable metallic wall stents have superior patency and provide better palliation than plastic stents (Fig. 33-72).

If an initial diagnostic laparoscopy reveals a contraindication to the Whipple procedure, such as liver metastases, it is not appropriate to perform a laparotomy simply to create a biliary bypass. In such a patient, it is better to place an endoscopic stent. In contrast, in the uncommon scenario where a laparotomy has already been performed as part of the assessment of resectability and the Whipple procedure is not possible, a surgical bypass is usually performed. However, if the patient has a functioning endoscopic stent already in place, it may be reasonable to forego surgical bypass.

Chemotherapy and Radiation for Locally Advanced/Metastatic Disease. Patients with locally advanced unresectable disease are treated with chemotherapy and possibly radiation, and patients with stage IV metastatic disease are treated with systemic chemotherapy. The role of RT in unresectable, locoregionally advanced pancreas cancer remains controversial. RT may slow the progression of local disease and possibly alleviate or prevent symptoms including pain, biliary obstruction, bleeding, and bowel obstruction. However, the likelihood of micrometastatic distant disease is high, treatment is not expected to be curative, and radiation can result in toxicity. Stereotactic body radiotherapy (SBRT) has been used to limit toxicity by targeting high-dose short-course radiation to enhance local response prior to surgery. In a phase 2 multi-institutional trial evaluating gemcitabine and SBRT in patients with locally advanced unresectable pancreatic cancer, 10% of patients with locally advanced disease who would not have been candidates for initial surgery were deemed to have resectable tumors following therapy, and 8% ultimately underwent R0 and node-negative resection.³²³ A number of chemotherapy regimens are available for pancreatic cancer, but the results are not impressive. Gemcitabine (Gemzar) was approved by the U.S. Food and Drug Administration (FDA) for use in pancreatic cancer in 1996. In patients with unresectable pancreatic cancer, gemcitabine results in symptomatic

Figure 33-72. Expandable metallic biliary stent. After ERCP cannulation of the distal bile duct (*left*) the stent is advanced over the cannula and placed across the obstruction in the distal bile duct (*right*).

improvement, improved pain control and performance status, and weight gain.³²⁴ However, survival is improved by only 1 to 2 months. Prior to gemcitabine, 5-fluorouracil (5-FU) was used as the standard treatment for unresectable pancreatic cancer. Both of these drugs are still used today. 5-FU or capecitabine (Xeloda), a similar but orally administered drug, are frequently used as a radiosensitizer during radiation therapy. Single-agent gemcitabine is still commonly used in patients with a poor performance status.

Erlotinib (Tarceva) was approved in 2005 based on very minimal improvement in overall survival in combination with gemcitabine.³²⁵ The study showed that erlotinib in combination with gemcitabine results in a statistically significant improvement in overall survival in patients with advanced pancreatic cancer in the first-line setting. Although the absolute benefit in overall survival was modest with a median survival difference between the two arms of only 2 weeks.

FOLFIRINOX, a combination of three chemotherapy drugs (5-FU/leucovorin, irinotecan, and oxaliplatin) is now commonly used as first-line treatment for metastatic pancreatic adenocarcinoma in patients with a relatively good performance status. In 2010, a Phase 3 clinical trial showed positive results for patients treated with FOLFIRINOX.³²⁶ The objective response rate was improved from 9% to 32%, and median overall survival of patients with metastatic pancreatic cancer improved from 7 to 11 months, but the improvement was associated with increased toxicity, so patient selection is important. Patients treated with FOLFIRINOX may experience more severe side effects than those treated with gemcitabine alone, so this combination is usually reserved for patients with a good performance status.

In 2013, another combination therapy was approved as first-line treatment for metastatic pancreatic adenocarcinoma.³²⁷ Albumin-bound paclitaxel (Abraxane) was approved to be used in combination with gemcitabine (Gemzar). The median overall survival was improved to 8.5 months in the nabpaclitaxel-gemcitabine group as compared with 6.7 months in the gemcitabine group. Progression-free survival and the response rate were also improved. Rates of peripheral neuropathy and myelosuppression were increased, but this regimen is less toxic than FOLFIRINOX.

In 2015, Irinotecan (ONIVYDE), in combination with 5-FU (fluorouracil) and leucovorin, was approved as treatment for metastatic pancreatic adenocarcinoma that has progressed following treatment with a gemcitabine based therapy.³²⁸ The median overall survival in patients assigned to nanoliposomal irinotecan plus fluorouracil and folinic acid was 6.1 months vs. 4.2 months with fluorouracil and folinic acid. Common side effects for this second-line therapy were neutropenia, diarrhea, vomiting, and fatigue.

These results may warrant treatment in patients who understand the benefits and risks. However, the lack of significant survival advantage should encourage physicians to refer motivated patients for experimental protocols because it is only through continued clinical research that more meaningful treatments for pancreatic cancer will be developed.

Ablation for Locally Advanced Unresectable Disease. Persistent arterial vascular encasement after neoadjuvant therapy contraindicates resection. Irreversible electroporation utilizes delivery of high-voltage millisecond electrical pulses resulting in permanent disruption of the cellular membranes and subsequent apoptosis. This process leads to cell death, but does not injure the extracellular matrix, thus allowing cellular tumor

ablation while preserving structural components of tissues. Collagen-based structures such as vessels or the pancreatic duct are not disrupted. Furthermore, because IRE is not based on thermal damage of cancer cells, the heat-sink phenomenon is not a concern, and even lesions abutting large vessels can be ablated with radical intent. Irreversible electroporation using the Nanoknife is reported to enable treatment of pancreatic tumors abutting vascular structures without compromise of the vessels or concern for the heat sink effect of nearby blood flow.³²⁹ Martin has created a registry and accumulated multi-institutional data on 200 patients with locally advanced pancreatic cancer showing OS of 28.3 months for patients with borderline resectable pancreatic cancer and 23.2 months in patients with unresectable pancreatic cancer. Those numbers compare favorably with the survival of patients treated with chemoradiation alone, which is 13 months in historical controls.³³⁰ This modality is new, but these early reports indicate it may be safe in combination with chemotherapy and are of particular interest because of the potential to down stage and offer surgery to patients initially diagnosed with locally advanced unresectable disease. It is also important to understand that a significant learning curve exists to achieve safety and optimization of the technique. Proper patient selection, technical ability with intraoperative ultrasound to allow precise IRE electrode bracketing, and standardization of the IRE energy delivery is important. Randomized prospective trials are needed before adoption of this technique can be expanded.

Surgical Resection: Pancreaticoduodenectomy. In a patient with appropriate clinical and/or imaging indications of pancreatic cancer, a tissue diagnosis before performing a pancreaticoduodenectomy is not essential. Although percutaneous CT-guided biopsy is usually safe, complications such as hemorrhage, pancreatitis, fistula, and abscess can occur. Tumor seeding along the subcutaneous tract of the needle is uncommon. Likewise, FNA under EUS guidance is safe and well tolerated. The problem with preoperative or even intraoperative biopsy is that many pancreatic cancers are not very cellular and contain a significant amount of fibrous tissue, so a biopsy may be misinterpreted as showing chronic pancreatitis if it does not contain malignant glandular cells. In the face of clinical and radiologic preoperative indications of pancreatic cancer, a negative biopsy should not preclude resection. In patients who are not candidates for resection because of metastatic disease, biopsy for a tissue diagnosis becomes important because these patients may be candidates for palliative chemotherapy trials. It is especially important to make an aggressive attempt at tissue diagnosis before surgery in patients whose clinical presentation and imaging studies are more suggestive of alternative diagnoses such as pancreatic lymphoma or pancreatic islet cell tumors. These patients might avoid surgery altogether in the case of lymphoma or warrant an aggressive approach in the case of islet cell carcinoma.

Pancreaticoduodenectomy can be performed through a midline incision from xiphoid to umbilicus or through a bilateral subcostal incision. The initial portion of the procedure is an assessment of resectability. The liver and visceral and parietal peritoneal surfaces are thoroughly assessed. The gastrohepatic omentum is opened, and the celiac axis area is examined for enlarged lymph nodes. The base of the transverse mesocolon is examined for tumor involvement.

The ascending and hepatic flexure of the colon are mobilized off the duodenum and head of the pancreas and reflected medially. A Kocher maneuver is performed by dissecting behind

the head of the pancreas. The superior mesenteric vein is identified early in the case and dissected up toward the inferior border of the neck of the pancreas. The gastroepiploic vein and artery are ligated to prevent any traction injury. Often, the middle colic vein and right gastroepiploic vein share a common trunk before entering into the superior mesenteric vein. Knowledge of this anatomy helps reduce injury to the veins and unnecessary blood loss. The relation of the tumor to the superior mesenteric vein and artery cannot be accurately assessed by palpation at this point and is not completely determined until later in the operation when the neck of the pancreas is divided and the surgeon is committed to resection. Mesenteric vascular involvement is best determined by a high quality preoperative CT scan.

It is important to assess for an aberrant right hepatic artery, which is present in 20% of patients. The aberrant artery commonly arises from the superior mesenteric artery posterior to the pancreas and ascends parallel and adjacent to the superior mesenteric and portal veins. The presence of an aberrant right hepatic artery should be apparent on the preoperative CT scan and can be identified intraoperatively by palpation on the back side of the hepatoduodenal ligament, where a prominent pulse will be felt posterior and to the right of the portal vein.

The porta hepatis is examined. Enlarged or firm lymph nodes that can be swept down toward the head of the pancreas with the specimen do not preclude resection. If the assessment phase reveals no contraindications to the Whipple procedure (Table 33-22), the resection phase commences.

If the pylorus is to be preserved, the stomach and proximal duodenum are mobilized off the pancreas, preserving the gastroepiploic vessels down to the pylorus. The proximal hepatic artery is identified usually by removing a lymph node that commonly lies just anterior to the artery. The hepatic artery is dissected and traced toward the porta hepatis. The gastroduodenal branch of the hepatic artery is identified. A test clamping is performed to ensure that a strong pulse remains in the proper hepatic artery before division of the gastroduodenal artery. In cases of celiac occlusion, flow comes from the superior mesenteric artery and retrograde through the gastroduodenal artery to the proper hepatic artery. Ligation of the gastroduodenal in this case would be equivalent to hepatic artery ligation. A bypass to the hepatic artery would be required. Once the test clamping is negative and the gastroduodenal artery is divided, the hepatic artery is retracted medially, and the common bile duct is retracted laterally to reveal the anterior surface of the portal vein behind them. Dissection is performed only on the anterior surface of the vein. If there is no tumor involvement, the neck of the

pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. The tunnel under the neck of the pancreas can then be completed mostly under direct vision from inferior and superior.

The gallbladder is then mobilized from the liver, the cystic duct and artery are ligated, and the gallbladder is removed. The common hepatic duct is circumferentially dissected. Either the duodenum is divided 2 cm distal to the pylorus (which defines the procedure as a pylorus-preserving pancreaticoduodenectomy, or PPPD) or the antrum is divided, as classically described by Whipple. The jejunum is divided beyond the ligament of Treitz, and the mesentery is ligated until the jejunum can be delivered posterior to the superior mesenteric vessels from left to right.

The common hepatic duct is then divided usually just above the entrance of the cystic duct, and the bile duct is dissected down to the superior margin of the duodenum. Inferior traction on the distal bile duct opens the plane to make visible the anterior portion of the portal vein. The pancreatic neck is divided anterior to the portal vein (Fig. 33-73). The use of cautery is avoided in the area of the pancreatic duct. The pancreatic head and uncinate process then are dissected off of the right lateral aspect of the superior mesenteric vein, ligating the fragile branches draining the head and uncinate process into the portal vein (Fig. 33-74). The uncinate process is then dissected off of the posterior and lateral aspect of the superior mesenteric artery. This can be the most tedious portion of the operation,

Figure 33-73. Division of the pancreatic neck. The pancreatic neck is separated from the anterior surface of the portal vein and then divided. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. Table 33-22

Findings at exploration

Findings contraindicating resection

- Liver metastases (any size)
- Celiac lymph node involvement
- Peritoneal implants
- Hepatic hilar lymph node involvement

Findings not contraindicating resection

- Invasion at duodenum or distal stomach
- Involved peripancreatic lymph nodes
- Involved lymph nodes along the porta hepatis that can be swept down with the specimen

but thoroughly clearing all tissue from the mesenteric vessels helps avoid incomplete resection. The wound is irrigated and meticulous hemostasis is assured at this point because the view of the portal vein area and retroperitoneum is more difficult after the reconstruction phase is completed.

The reconstruction involves anastomoses of the pancreas first, then the bile duct, and, finally, the duodenum or stomach. There are various techniques for the pancreatic anastomoses. After the pancreatic anastomosis is completed, the choledochojejunostomy is performed about 10 cm down the jejunal limb from the pancreatic anastomosis. This is usually performed in an end-to-side fashion with one layer of interrupted sutures. The duodenojejunostomy or gastrojejunostomy is performed another 10 to 15 cm downstream from the biliary anastomosis, using a two-layer technique.

Pancreaticoduodenectomy With Vascular Resection.

Accurate staging of pancreatic cancer with a high-quality preoperative CT scan is extremely important. Involvement of the superior mesenteric artery, the celiac axis, or hepatic artery indicate a T4/stage 3 tumor that is locally advanced and unresectable. However, involvement of the portal vein or superior mesenteric vein does not necessarily preclude resection as long as there is a patent superior mesenteric vein-portal vein confluence. Reconstruction can often be accomplished with a primary anastomosis of the vein. When resection of more than 2 cm of

vein is required, an interposition graft such as the internal jugular vein can be used for a tension-free reconstruction.

In a systematic review of 28 retrospective studies from high-volume pancreas centers, the morbidity, mortality, and survival outcome after undertaking extended pancreaticoduodenectomy with vascular resection for pancreatic cancer with venous involvement and/or limited arterial involvement was acceptable.³³¹ Another more recent report from five teaching hospitals demonstrated that the Whipple procedure combined with vascular resection and reconstruction could achieve complete removal of tumors without significantly increasing the mortality rate, and the median survival time was higher than that of patients who underwent palliative treatment.³³² However, contrary to the findings of analyses from expert pancreas centers, a retrospective cohort analysis using the National Surgical Quality Improvement Program data from 2005 to 2009 demonstrated increased 30-day postoperative morbidity and mortality in pancreaticoduodenectomy with vein resection when compared with pancreaticoduodenectomy alone.³³³ These data indicate that pancreaticoduodenectomy with vascular resection is only a reasonable option when it is performed after neoadjuvant therapy and at very-high-volume centers where the morbidity of the operation can be kept to a minimum.

Minimally Invasive Pancreatectomy. Laparoscopic distal pancreatectomy has been proven to be safe and is appropriate for essentially all indications for pancreatectomy. This approach is associated with decreased blood loss and quicker recovery. Centrally located lesions near the splenoportal confluence must be approached laparoscopically with caution. Robotic technology may make dissection and control of major vessels in this area easier and perhaps safer. Interest in laparoscopic pancreaticoduodenectomy is increasing throughout the United States with some early adopters reporting excellent outcomes comparable to the open procedure.³³⁴ Early results indicate this technique is feasible, but considerable expertise is required in both open pancreatic resection as well as advanced laparoscopic techniques to achieve these outcomes. Whether the advantages seen in other areas of minimally invasive surgery apply to the Whipple procedure is an area of current investigation.

Variations and Controversies. The preservation of the pylorus has several theoretical advantages, including prevention of reflux of pancreaticobiliary secretions into the stomach, decreased incidence of marginal ulceration, normal gastric acid secretion and hormone release, and improved gastric function. Patients with pylorus-preserving resections have appeared to regain weight better than historic controls in some studies. Return of gastric emptying in the immediate postoperative period may take longer after the pylorus-preserving operation, and it is controversial whether there is any significant improvement in long-term quality of life with pyloric preservation.³³⁵⁻³³⁶

Techniques for the pancreaticojejunostomy include end-to-side or end-to-end and duct-to-mucosa sutures or invagination (Fig. 33-75). Pancreaticogastrostomy has also been investigated.

Some surgeons use stents, glue to seal the anastomosis, or octreotide to decrease pancreatic secretions. No matter what combination of these techniques is used, the clinically significant pancreatic leakage rate is always about 10%. Therefore, the choice of techniques depends more on the surgeon's personal experience.

Traditionally, most surgeons place drains around the pancreatic and biliary anastomoses because disruption of the pancreaticojejunostomy cannot be avoided in one out of 10 patients.

This complication can lead to the development of an upper abdominal abscess or can present as an external pancreatic fistula. Usually, a pure pancreatic leak is controlled by the drains and will eventually seal spontaneously. Combined pancreatic and biliary leaks are cause for concern because bile will activate the pancreatic enzymes. In its most virulent form, disruption leads to necrotizing retroperitoneal infection, which can erode major arteries and veins of the upper abdomen, including the exposed portal vein and its branches or the stump of the gastroduodenal artery. Impending catastrophe is often preceded by a

small herald bleed from the drain site. Depending on the clinical situation, such an event is an indication to perform an angiogram or return the patient to the operating room to widely drain the pancreaticojejunostomy and to repair the involved blood vessel. Open packing may be necessary to control diffuse necrosis and infection. Some studies have questioned the practice of routine drain placement after pancreatectomy with reliance on postoperative percutaneous drainage when leaks occur.³³⁷ However, a randomized, controlled, multicenter trial showed that patients who develop a leak after pancreaticoduodenectomy are

at a substantially increased risk of mortality if a drain was not placed at the time of resection.³³⁷ In contrast, the outcome does not seem to be as dramatically affected by drain placement in the setting of distal pancreatectomy.³³⁸ In the absence of a fistula, drains should be removed early in the postoperative period, preferably by postoperative day 5.³³⁹

Many patients with pancreatic cancer are malnourished preoperatively and suffer from gastroparesis in the immediate postoperative period. Routine placement of a feeding jejunostomy tube and gastrostomy tube has become less common, and most surgeons use these tubes selectively. Gastrostomy tubes may decrease the length of stay in patients who might

Figure 33-75. (Continued)

be predicted to have severe gastroparesis. Jejunostomy tubes are certainly not benign and can result in leaks and intestinal obstruction. However, parenteral nutrition is also associated with serious complications such as line sepsis, loss of gut mucosal integrity, and hepatic dysfunction. Enteric tubes should be considered in patients at risk such as malnourished patients who have received neoadjuvant chemotherapy.

Because of the high incidence of direct retroperitoneal invasion and regional lymph node metastasis at the time of surgery, trails of more extended resections including extension of the pancreatic resection to the middle body of the pancreas, segmental resection of the portal vein, if necessary, resection

of retroperitoneal tissue along the right perinephric area, and lymphadenectomy to the region of the celiac plexus were examined. In the hands of experienced surgeons, these techniques are associated with greater blood loss but no increase in mortality. However, improved survival has not been demonstrated. Total pancreatectomy has also been considered in the past. Although pancreatic leaks are eliminated, major morbidity from brittle diabetes and exocrine insufficiency outweigh any theoretical benefit.

Pancreatic cancer can recur locally after pancreaticoduodenectomy. Intraoperative radiotherapy (IORT) delivers radiation to the operative bed at the time of resection. Radiation to

surrounding normal areas is minimized, but the radiation is delivered all in one setting, rather than in fractionated doses over time. Favorable results were recently reported among a series of patients with locally advanced unresectable or borderline-resectable PDAC who received intensive neoadjuvant treatment followed by exploratory laparotomy and IORT.³⁴⁰

Complications of Pancreaticoduodenectomy. The operative mortality rate for pancreaticoduodenectomy has decreased to <5% in high-volume centers (where individual surgeons perform more than 15 cases per year), suggesting that patients in rural areas would benefit from referral to large urban centers.³⁴¹⁻³⁴² The most common causes of death are sepsis, hemorrhage, and cardiovascular events. Postoperative complications are unfortunately still very common and include delayed gastric emptying, pancreatic fistula, and hemorrhage.

Delayed gastric emptying is common after pancreaticoduodenectomy and is treated conservatively as long as complete gastric outlet obstruction is ruled out by a contrast study. In the acute phase, intravenous erythromycin may help, but the problem usually improves with time.

Considerable attention has been focused on the prevention of pancreatic leak after pancreas resection. Modifications of the anastomotic technique (end-to-side or end-to-end, duct-to-mucosa, or invaginated), the use of jejunum or the stomach for drainage, the use of pancreatic duct stents, the use of octreotide, and various sealants have all been evaluated.

Long-acting synthetic analogues of somatostatin have been evaluated as a pharmacologic therapy to reduce pancreatic secretion and the rate of pancreatic fistula after pancreatic resection. Some European studies supported benefit particularly in selected higher risk patients, while previous North American trials concluded there was no benefit.³⁴³⁻³⁴⁹ A recent single-center, randomized trial with pasireotide (a newer analog) suggested potential benefit.³⁵⁰

Many technical modifications to the classic pancreaticoduodenectomy have been described. However, numerous technical variations to the pancreaticoenteric anastomosis have not clearly demonstrated an objective method to consistently decrease the rate of clinically significant postoperative pancreatic fistula, which in most series is about 10%. Yeo compared the incidence of pancreatic fistula in patients who had a pancreaticoduodenectomy with reconstruction via a pancreaticogastrostomy or pancreaticojejunostomy.³⁵¹ There was no significant difference between the two techniques in the incidence of pancreatic fistula. A recent meta-analysis summarized the results of 16 trials comparing pancreaticogastrostomy to pancreaticojejunostomy. All of the observational clinical studies reported superiority of pancreaticogastrostomy over pancreaticojejunostomy, most likely influenced by publication bias. In contrast, all randomized prospective trials failed to show advantage of a particular technique, suggesting both techniques provide equally good results.³⁵²

Other options to consider when performing the pancreatic anastomosis are the duct-to-mucosa vs. the invagination techniques. Some surgeons choose the technique at the time of operation, depending on the size of the pancreatic duct and the texture of pancreas favoring invagination when the duct is small and the pancreatic texture is soft.³⁵³ Other surgeons use the same technique every time. The duct-to-mucosa anastomosis results in a low pancreatic fistula rate, particularly in patients with a large pancreatic duct and a fibrotic pancreas.³⁵⁴

Use of a pancreatic duct stent across the anastomosis has been suggested as a means of preventing a pancreatic leak and as an aid in technical precision. Both internal stenting as well as external stenting have been practiced. A recent Cochrane analysis of eight randomized, controlled trials failed to identify any convincing evidence of benefit with internal or external pancreatic duct stents.³⁵⁵ Some previous studies indicated that stents might be harmful. A recent multicenter randomized trial comparing external to internal pancreatic duct stents during pancreaticoduodenectomy showed a lower rate of pancreatic fistula with internal stents, so this controversy is likely to continue.³⁵⁶

Reconstruction with an isolated Roux-en-Y pancreaticoenteric anastomosis has been suggested as a method to decrease postoperative pancreatic leak.³⁵⁷⁻³⁵⁸ The logic behind this technical modification is that the use of separate Roux-en-Y limbs for biliary and pancreatic secretions may protect the pancreatic anastomosis from activated pancreatic enzymes. However, data is limited, and this is not a common practice.

Avoiding the pancreatic anastomosis altogether by ductal ligation or occlusion has also been evaluated as a potential technique to reduce the rate of postoperative pancreatic fistula.³⁵⁹⁻³⁶⁰ Ductal occlusion with neoprene or prolamine, which are nonresorbable glues, has been abandoned due to pancreatic atrophy and loss of exocrine function. Duct occlusion in pancreaticojejunostomy significantly increases the risk of endocrine insufficiency without a decrease in the postoperative complication rate. To avoid long-term loss of function, absorbable glues, such as fibrin glue, have been evaluated to limit the action of pancreatic enzymes until the anastomosis is healed. Fibrin glue has been used for both duct occlusion and has also been applied to the surface of the pancreatic stump and anastomotic site without clear improvement in pancreatic fistula rate. The effect of BioGlue applied to the anastomotic surface after the Whipple procedure and pancreatic stump after distal pancreatectomy was evaluated in a retrospective cohort study. There were no statistically significant differences in the incidence or severity grades of postoperative pancreatic fistulas.³⁶¹ A randomized prospective trial of application of fibrin glue to the surface of the pancreaticojejunostomy in high-risk patients did not reduce the incidence of pancreatic fistula or total complications after pancreaticoduodenectomy.³⁶²

If not combined with a biliary leak, pancreatic fistula, although serious, can usually be managed conservatively. In about 95% of cases, reoperation is not indicated, and prolonged drainage, using drains placed in the original operation or percutaneously after resection, results in spontaneous closure of the fistula.³⁶³

Hemorrhage can occur either intraoperatively or postoperatively. Intraoperative hemorrhage typically occurs during the dissection of the portal vein. A major laceration of the portal vein can occur at a point in the operation at which the portal vein is not yet exposed. Temporary control of hemorrhage is generally possible in this situation by compressing the portal vein and superior mesenteric vein against the tumor with the surgeon's left hand behind the head of the pancreas. An experienced assistant is needed to divide the neck of the pancreas to the left of the portal vein and achieve proximal and distal control. Sometimes, the vein can be sutured closed with minimal narrowing. Other times, a segmental resection and interposition graft (internal jugular vein) may be needed.

Postoperative hemorrhage can occur from inadequate ligation of any one of numerous blood vessels during the procedure.

Hemorrhage can also occur due to digestion of retroperitoneal blood vessels due to a combined biliary-pancreatic leak. Uncommonly, a stress ulcer, or later, a marginal ulcer, can result in GI hemorrhage. Typically, a vagotomy is not performed when pancreaticoduodenectomy is performed for pancreatic cancer, but patients are placed on proton pump inhibitors.

Outcome and Value of Pancreaticoduodenectomy for Cancer. Survival figures indicate that perhaps few patients are cured indefinitely of pancreatic cancer with pancreaticoduodenectomy. This has led to a nihilistic view toward patients with this disease which has further contributed to poor outcomes. Using the National Cancer Data Base (1995–2004), Bilimoria reported on 9559 patients with early stage potentially resectable tumors (pretreatment clinical Stage I: T1N0M0 and T2N0M0).³⁶⁴ Multivariate models were employed to identify factors predicting failure to undergo surgery and assess the impact of pancreatectomy on survival. This study identified a striking underuse of pancreatectomy in the United States. Of clinical stage I patients, 71.4% (6823/9559) did not undergo surgery; 6.4% (616/9559) were excluded due to comorbidities; 4.2% (403/9559) refused surgery; 9.1% (869/9559) were excluded due to age; and 38.2% (3644/9559) with potentially resectable cancers were not offered surgery. Patients were less likely to undergo surgery if they were older than 65 years, were black, were on Medicare or Medicaid, had pancreatic head lesions, earned lower annual incomes, or had less education. Patients were less likely to receive surgery at low-volume and community centers. Patients who were not offered surgery had worse survival than patients who underwent resection. Overall survival from PDAC would significantly increase if more patients with stage I tumors were identified and offered surgery at high-volume centers (Fig. 33-76).

Although pancreaticoduodenectomy may be performed with the hope of the rare cure in mind, the operation more importantly provides better palliation than any other treatment, and it is the only modality that offers any meaningful improvement in survival. If the procedure is performed without major complications, many months of palliation are usually achieved. However, it is the surgeon's duty to make sure patients and their families have a realistic understanding of the true goals of pancreaticoduodenectomy in the setting of pancreatic cancer.

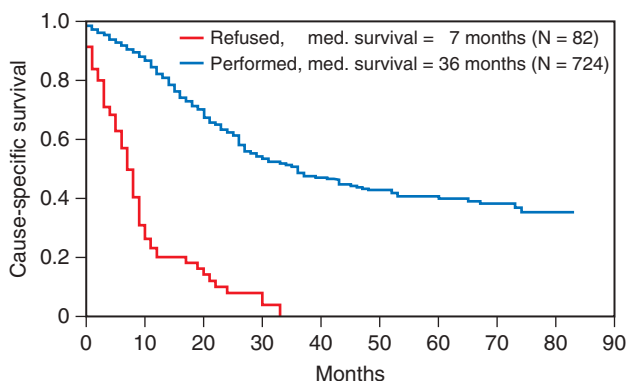

Figure 33-76. Effect of surgery on survival in early stage pancreatic cancer. Survival comparison for cases (combined stages IA and IB) for which resection was recommended, and resection was either performed or refused. Adjuvant Chemotherapy and Radiation. Small studies in the 1980s suggested that adjuvant chemotherapy with 5-FU combined with radiation improves survival by about 9 months after pancreatic resection for pancreatic adenocarcinoma.³⁶⁵ Subsequent, noncontrolled studies have reinforced that concept; however, the data have been criticized due to the low number of patients and low dose of radiation therapy that was given. In addition, gemcitabine has replaced 5-FU as standard therapy in pancreatic cancer but is thought to be too toxic when given with radiotherapy without dose reduction. A recent large European multicenter trial concluded that there was no value to chemoradiotherapy, although the study suggested the possibility that chemotherapy alone might have survival benefit.³⁶⁶ Randomized trials have failed to resolve the debate regarding the role of adjuvant radiation therapy in resectable pancreas cancer. A reasonable consideration in a disease with high rates of distant metastases is to begin with adjuvant chemotherapy, followed by radiation therapy in patients who do not progress, particularly in patients where there may be increased concern about local recurrence such as in patients with close margins.

Remarkable results in adjuvant therapy were reported by the Virginia Mason Clinic with combination 5-FU, cisplatin, interferon- γ , and external beam radiation.³⁶⁷ Although the toxicity was high (42% hospitalized for GI toxicity), the promising results prompted larger confirmatory studies. Unfortunately, one such study was stopped due to toxicity, and this protocol has not been widely adopted. More recent results with FOLFIRINOX in the setting of metastatic disease have encouraged clinical trials using this regimen in the adjuvant setting, which are currently underway (*ClinicalTrials.gov* identifier: NCT02172976). Nevertheless, pending further study, it is typical in the United States for patients with acceptable functional status to receive some form of adjuvant chemotherapy and sometimes chemoradiotherapy after surgery.

Neoadjuvant Treatment. There are several potential advantages to the use of chemotherapy or chemoradiation before an attempt at surgical resection. For example, it avoids the risk that adjuvant treatment is delayed by complications of surgery. Neoadjuvant treatment also may decrease the tumor burden at operation, increasing the rate of resectability and killing some tumor cells before they can be spread intraoperatively. Another potential advantage is that it allows patients with occult metastatic disease to avoid the morbidity of pancreatic resection. As many as 20% of patients treated with neoadjuvant chemoradiation develop metastatic disease detected by restaging CT and do not go on to surgery. This approach may separate patients into a subset likely to benefit from resection and a subset in whom surgery would be unlikely to provide clinical benefit. Preoperative chemoradiation has been shown not to increase the perioperative morbidity or mortality of pancreaticoduodenectomy. It may even decrease the incidence of pancreatic fistula. Prospective randomized trials investigating this concept are ongoing but are difficult to complete due to the high number of patients who fail to complete or receive a full course of either therapy. Studies have shown that neoadjuvant therapy is associated with a lower rate of lymph node positivity and improved survival is achieved among the patients who do not develop disease progression during neoadjuvant therapy and go on to resection. Neoadjuvant therapy should be considered an acceptable alternative to surgery first followed by adjuvant therapy for resectable pancreatic cancer. Patients should be encouraged to consider available

clinical trials of neoadjuvant therapy for resectable pancreatic cancer.³⁶⁸ Unfortunately, a recent trial attempting to randomize patients with resectable pancreatic cancer to neoadjuvant versus adjuvant therapy failed to demonstrate an advantage for the neoadjuvant approach. However, the study was inconclusive because it was stopped after 73 of a planned 254 patients due to slow accrual, with only 66 eligible for analysis. Other trials are ongoing. The NEOPA trial (*ClinicalTrials.gov* identifier: NCT01900327) is a prospectively randomized phase 3 trial of patients receiving neoadjuvant chemoradiation followed by curative surgery vs. primary surgery followed by adjuvant therapy with a primary endpoint of 3-year overall survival.³⁶⁹

Most pancreatic surgeons agree that neoadjuvant chemotherapy, and perhaps chemoradiotherapy, should be offered to patients with locally advanced but resectable disease (vein involvement) and to patients with “borderline resectable disease” (abutment of ≤ 180 degrees of the circumference of the SMA, celiac axis, or hepatic artery or if there is a short segment of vein occlusion, CT findings suspicious for metastatic disease, like 1 mm liver lesions too small to characterize or biopsy, and patients with multiple comorbidities or marginal performance status). This strategy acknowledges the fact that these patients are at high risk of early distant recurrence and/or R1 resection with early local recurrence. Neoadjuvant treatment helps select the right patients for surgery and may reduce the incidence of a margin positive resection.

Postoperative Surveillance. Recurrence after successful resection usually manifests as hepatic metastases. Adjuvant chemotherapy with or without radiation is usually administered for 6 months. During this time period, patients are monitored with frequent physical examinations and laboratory tests, including CA19-9. CT scans are typically ordered every 3 months in the first 2 years after resection or when a rising CA19-9 or new symptoms suggest recurrence. Surgical therapy for recurrent disease is usually reserved only for select patients with limited disease who remain reasonable operative candidates who develop symptomatic gastric outlet or bowel obstruction.

Ampullary and Periampullary Cancer. Ampullary cancers need to be distinguished from periampullary cancers. The ampulla is the junction of the biliary and pancreatic ducts within the duodenum. Periampullary cancer includes tumors arising from the distal bile duct, duodenal mucosa, or pancreas just adjacent to the ampulla, and the ampulla can be overgrown by cancers that arise from these adjacent areas, making it impossible to determine the true site of origin. Clinically, the term *periampullary cancer* is, therefore, a nonspecific term used to refer to a variety of tumors arising at the intersection of these four sites. The term *ampullary cancer* is more specific and is reserved for tumors that arise at the ampulla. Based on their location, ampullary cancers are usually detected relatively early due to the appearance of jaundice and have a more favorable prognosis. The ampulla of Vater is lined by an epithelial layer that transitions from pancreatic and biliary ductal epithelium to duodenal mucosal epithelium. Ampullary adenocarcinomas can therefore have an intestinal and/or pancreaticobiliary histologic morphology, with the former having a better prognosis. Patients with ampullary cancer have a 10-year survival of about 35%, which is a much better prognosis than patients with pancreatic adenocarcinoma. The difference in survival is not entirely explained by an earlier presentation and lower incidence of lymph node metastases. There are biologic, particularly

molecular, differences between ampullary and pancreatic adenocarcinoma of the pancreas.³⁷⁰ Intestinal type ampullary cancers have a lower incidence of EGFR and mutant p53 overexpression, and fewer activating *K-ras* mutations. These tumors are more likely to have genetic changes similar to colon cancer such as microsatellite instability and adenomatous polyposis coli mutations.

Management of Periampullary Adenomas. Benign tumors such as ampullary adenomas can also originate at the ampulla. The accuracy of endoscopic biopsy in distinguishing ampullary cancer from benign adenoma is poor, with false-negative rates from 25% to 56% even if sphincterotomy precedes the biopsy. However, benign villous adenomas of the ampullary region can be excised locally. This technique is applicable only for small tumors (approximately 2 cm or less) with no evidence of malignancy upon biopsy. EUS may help to accurately determine if there is invasion into the duodenal wall. In the absence of invasion, adenomas may be amenable to an endoscopic or transduodenal excision. A longitudinal duodenotomy is made and the tumor is excised with a 2- to 3-mm margin of normal duodenal mucosa. In some centers, small periampullary adenomas can also be removed endoscopically. A preoperative diagnosis of cancer is a contraindication to transduodenal excision, and pancreaticoduodenectomy should be performed. Likewise, if final pathologic examination of a locally excised tumor reveals invasive cancer, the patient should be returned to the operating room for a pancreaticoduodenectomy. An important subset of patients are those with FAP who develop periampullary or duodenal adenomas. These lesions have a high incidence of harboring carcinoma and frequently recur unless the mucosa at risk is resected. A standard (not pylorus-sparing) Whipple is the procedure of choice in FAP patients with periampullary lesions.

Cystic Neoplasms of the Pancreas. A cystic neoplasm needs to be considered when a patient presents with a fluid-containing pancreatic lesion. Asymptomatic cystic neoplasms of the pancreas may be more frequent than previously recognized and are being identified with increasing frequency as the use of abdominal CT scanning and MRI has increased. Pancreatic cysts are now thought to be present in about 9% of the population age 80 and older.³⁷¹ When symptoms are clearly attributable to a pancreatic cyst, resection is indicated in patients who are fit candidates for surgery. However, management of asymptomatic pancreatic cysts is nuanced and can trigger significant anxiety for patients and their surgeons. Invasive surveillance and aggressive surgical intervention can cause harm, decrease quality of life, and increase costs. While the overall risk that an incidental pancreatic cyst is malignant is very low (about 1 in 10,000), the risks of surgery are very significant with a 2% to 5% mortality and 30% to 40% morbidity. However, some of these neoplasms slowly undergo malignant transformation and thus represent an opportunity for surgical cure, which is uncommon after transformation to invasive pancreatic adenocarcinoma. The dilemma for the surgeon is to identify the minority of cysts that pose a significant risk and provide individual patients with an accurate assessment of their unique risk-benefit ratio of resection vs. surveillance.

Surveillance programs are of questionable value in patients who are not candidates for surgery due to age and or multiple comorbidities and limited life expectancy. Surgeons also need to clearly explain to the patient the risks and benefits of surveillance itself. MRI is the preferred surveillance imaging modality

over computed tomography because MRI does not expose the patient to radiation and better demonstrates the structural relationship between the pancreatic duct and associated cyst. Also, MRI is less invasive than EUS. EUS is therefore reserved for further evaluation of higher risk cysts. Another problem to confront is when to stop surveillance in a cyst that has been stable during observation. Some clinicians stop following after 5 years but data is lacking to guide this decision. In addition, patients who have undergone resection of a pancreatic cystic neoplasm with high grade dysplasia may warrant continued surveillance after surgery particularly when there is a possible field effect such as in IPMN or concern that all of the disease has not been resected. Individualized decision-making and multidisciplinary input is ideal.³⁷²

Pseudocysts. The most common cystic lesion of the pancreas is the pseudocyst, which, of course, has no epithelial lining and is a nonneoplastic complication of pancreatitis or pancreatic duct injury. As discussed in “Complications of Chronic Pancreatitis,” the diagnosis is usually straightforward from the clinical history. Although not usually necessary, analysis of pseudocyst fluid would reveal a high amylase content. The danger comes in mistaking a cystic pancreatic neoplasm for a pseudocyst and incorrectly draining a cystic neoplasm into the GI tract rather than resecting the neoplasm. For this reason, biopsy of the pseudocyst wall is a requirement in the management of pancreatic pseudocysts.

Cystadenoma. Serous cystadenomas are essentially considered benign tumors without malignant potential. Serous cystadenocarcinoma has been reported very rarely (<1%). Therefore, malignant potential should not be used as an argument for surgical resection, and the majority of these lesions can be safely observed in the absence of symptoms due to mass effect or rapid growth. The average rate of growth is about 0.5 cm per year. About 50% of cystadenomas are asymptomatic and detected as an incidental finding. Most symptomatic patients have mild upper abdominal pain, epigastric fullness, or moderate weight loss. Occasionally, cystadenomas can grow to a size capable of producing jaundice or GI obstruction due to mass effect (Fig. 33-77). For symptomatic patients with serous cystadenoma, surgical resection is indicated. For lesions in the tail, splenectomy is not necessary, given the benign nature of the tumor. In appropriate candidates, a laparoscopic approach

to distal pancreatectomy with or without splenic preservation can be considered. These cysts are frequently found in older women in which pancreatic resection for a benign neoplasm should be avoided in the absence of significant symptoms. All regions of the pancreas are affected, with half in the head/uncinate process, and half in the neck, body, or tail of the pancreas. They have a spongy appearance, and multiple small cysts (microcystic) are more common than larger cysts (macrocytic or oligocystic). These lesions contain thin serous fluid that does not stain positive for mucin and is low in CEA (<200 ng/mL). Typical imaging characteristics include a well-circumscribed cystic mass, small septations, fluid close to water density, and sometimes, a central scar with calcification. If a conservative management is adopted, it is important to be sure of the diagnosis. EUS-FNA should yield nonviscous fluid with low CEA and amylase levels, and if cells are obtained, which is rare, they are cuboidal and have a clear cytoplasm.

Mucinous Cystadenoma and Cystadenocarcinoma. Mucinous cystic neoplasms (MCNs) encompass a spectrum ranging from benign but potentially malignant to carcinoma with a very aggressive behavior (Table 33-23). There is often heterogeneity within the lesions with benign and malignant-appearing regions, making it impossible to exclude malignancy with biopsy. MCNs are commonly seen in perimenopausal women, and about two-thirds are located in the body or tail of the pancreas. Like cystadenomas, most MCNs are now incidental findings identified during imaging performed for other reasons. When symptoms are present, they are usually nonspecific and include upper abdominal discomfort or pain, early satiety, and weight loss. On imaging studies, the cysts have thick walls and do not communicate with the main pancreatic duct (Fig. 33-78). There may be nodules or calcifications within the wall of the cyst. The cysts are lined by tall columnar epithelium that fills the cyst with viscous mucin. The submucosal layer consists of a highly cellular stroma of spindle cells with elongated nuclei similar to the “ovarian stroma,” which is a key pathologic feature distinguishing these lesions. Elevated CEA levels in the fluid (≥ 200 ng/mL) are consistent with mucinous lesions and may suggest malignant transformation.³⁷³ Solid areas may contain atypical cells or invasive cancer, and extensive sampling of the specimen is necessary to accurately predict prognosis.

a. Pancreatitis may be an indication for surgery for relief of symptoms.

b. Differential diagnosis includes mucin. Mucin can move with change in patient position, may be dislodged on cyst lavage and does not have Doppler flow. Features of true tumor nodule include lack of mobility, presence of Doppler flow and FNA of nodule showing tumor tissue

c. Presence of any one of thickened walls, intraductal mucin or mural nodules is suggestive of main duct involvement. In their absence main duct involvement is inconclusive.

d. Studies from Japan suggest that on follow-up of subjects with suspected BD-IPMN there is increased incidence of pancreatic ductal adenocarcinoma unrelated to malignant transformation of the BD-IPMN(s) being followed. However, it is unclear if imaging surveillance can detect early ductal adenocarcinoma, and, if so, at what interval surveillance imaging should be performed.

Figure 33-78. Algorithm for management of pancreatic cystic neoplasms. CEA = carcinoembryonic antigen; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; FNA = fine-needle aspiration; Hx = history; IPMN = intraductal papillary mucinous neoplasm of the pancreas; MCN = mucinous cystic neoplasm; MRCP = magnetic resonance cholangiopancreatography. (Reproduced with permission from Tanaka M, Adsay V, Chari S, et al. *International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas*, *Pancreatology*. 2012 May-Jun;12(3):183-197.)

Resection is the treatment of choice for most mucin-producing cystic tumors. Malignancy cannot be ruled out without removal and extensive sampling of the entire tumor. Malignancy has been reported in 6% to 36% of MCNs. Current thinking is that all of these tumors will eventually evolve into cancer if left untreated. However, for individual patients, the surgeon is often faced with a difficult decision. The risk of pancreas surgery in an older patient with multiple comorbidities and a relatively short life expectancy regardless of their pancreatic cyst is frequently weighed against the potential future risk that the cyst, particularly a small cyst, will transform into an incurable invasive cancer.

The utility of detailed DNA analysis of pancreatic cyst fluid to diagnose mucinous and malignant cysts has been evaluated in the PANDA study.³⁷⁴ The study concluded that cyst fluid *K-ras* mutation was helpful in the diagnosis of mucinous cysts with a 96% specificity. Components of DNA analysis detecting malignant cysts included allelic loss amplitude over 82% and high DNA amount. The criteria of high amplitude *K-ras* mutation followed by allelic loss showed maximum specificity

(96%) for malignancy. However, this test lacks sensitivity. In clinical practice, the surgeon must take all of these complementary factors into consideration when determining the malignant potential of a pancreatic cystic neoplasm.

Because most MCNs are located in the body and tail of the pancreas, distal pancreatectomy is the most common treatment. For small lesions, it may be appropriate to preserve the spleen, but splenectomy ensures removal of the lymph node basin that can potentially be involved. It is very important not to rupture the cyst during resection, and the tumor should be removed intact, not morselized. Therefore, a laparoscopic approach may not be appropriate for larger lesions. Completely resected MCNs without atypia are usually cured especially if small (<3 cm). Even patients with moderate dysplasia or carcinoma in situ are usually cured by complete resection. Noninvasive MCNs require no surveillance after resection. For MCNs with an associated invasive carcinoma, prognosis depends on the extent of the invasive component, tumor stage, and resectability. The 2-year survival rate and 5-year survival rate of patients with

resected MCN with an associated invasive carcinoma are about 67% and 50%, respectively.³⁷⁵

Intraductal Papillary Mucinous Neoplasm. Intraductal papillary mucinous neoplasms (IPMNs) usually occur within the head of the pancreas and arise within the pancreatic ducts. The ductal epithelium forms a papillary projection into the duct, and mucin production causes intraluminal cystic dilation of the pancreatic ducts (Fig. 33-79). Imaging studies demonstrate diffuse dilation of the pancreatic duct, and the pancreatic parenchyma is often atrophic due to chronic duct obstruction. However, classic features of chronic pancreatitis, such as calcification and a beaded appearance of the duct, are not present. At ERCP, mucin can be seen extruding from the ampulla of Vater, a so-called *fish-eye lesion* that is virtually diagnostic of IPMN (Fig. 33-80). Initial reports suggested a male predominance, but more recent series indicate an equal distribution. Patients are usually in their seventh to eighth decade of life and present with abdominal pain or recurrent pancreatitis, thought to be caused by obstruction of the pancreatic duct by thick mucin. Some patients

Figure 33-79. Computed tomography appearance of massive multiseptated serous cystadenoma in head of pancreas with central stellate scar (*left*) and resected specimen (*right*).

Figure 33-80. Intraductal papillary mucinous neoplasm histology. Papillary projections of ductal epithelium resemble villous morphology and contain mucin-filled vesicles. (5–10%) have steatorrhea, diabetes, and weight loss secondary to pancreatic insufficiency.

Some IPMNs primarily involve the main pancreatic duct, while others involve the branch ducts. The mean frequency of malignancy in main duct IPMN (MD-IPMN) is 62% (Fig. 33-81). Considering this high incidence of malignant lesions and the low 5-year survival rates (31–54%), international consensus guidelines recommend resection for all surgically fit patients with MD-IPMN.³⁷² If the margin is positive for high-grade dysplasia, additional resection should be attempted to obtain at least moderate-grade dysplasia at the surgical margin.

The surgical management of IPMNs is complicated by the fact that the lesion itself is small and preoperative imaging studies show a dilated pancreatic duct but not necessarily the mass. Mucus can dilate the duct proximal and distal to the lesion. Furthermore, these lesions can spread microscopically along the duct, and there can be skip areas of normal duct between the diseased portions. Therefore, thorough preoperative imaging including EUS, MRCP, or ERCP, and sometimes pancreatic ductoscopy, which can also be repeated intraoperatively, is useful (see Fig. 33-80). The surgeon needs to be prepared to extend the resection, if necessary, based on intraoperative findings and frozen section of the margin. Extending the resection to the point of total pancreatectomy is controversial due to the morbidity of this operation. Like MCNs, the IPMNs require careful histologic examination of the entire specimen for an invasive cancer (Fig. 33-82).

Survival of patients with IPMN, even when malignant and invasive, can be quite good. As with MCN, patients with borderline tumors or carcinoma in situ are usually cured. For this reason, if recurrence occurs in the remaining pancreas, further resection is warranted because several series have shown that some of these cases are salvageable. Patients with IPMN are also at risk for other malignancies and should undergo colonoscopy and close surveillance.

Branch-duct type IPMNs (BD-IPMN) are often found in the uncinate process, are sometimes asymptomatic, and are less frequently associated with malignant transformation (6–46%). Asymptomatic, small suspected BD-IPMNs are frequently

observed with serial imaging. High-risk features such as mural nodules, a dilated main duct, positive cytology or cyst fluid CEA >200 need to be ruled out. In the absence of these features, continued observation with serial imaging is appropriate, especially in patients who are not ideal operative candidates. The mean frequency of invasive cancer in resected BD-IPMN is 18%. BD-IPMN mostly occurs in elderly patients, and the annual malignancy rate is only 2% to 3%. These factors support conservative management with follow-up in patients who do not have any symptoms or risk factors predicting malignancy such as mural nodule, rapidly increasing cyst size, and high-grade atypia in cytology. There is insufficient data to support immediate resection for all BD-IPMNs <3 cm without “high-risk stigmata” and “worrisome features.” Branch-duct IPMNs ≥3 cm should be resected.³⁷²

Four histologic subtypes of IPMNs have been characterized: gastric, intestinal, pancreatobiliary, and oncocytic. Most of BD-IPMNs are composed of gastric-type epithelium. However, intestinal type is more common in MD-IPMN. In a recent report, the four subtypes of IPMNs were associated with significant differences in survival.³⁷⁶ Patients with gastric-type IPMN had the best prognosis, whereas those with intestinal and pancreatobiliary type had a bad prognosis.

Workup of Asymptomatic Pancreatic Cystic Neoplasms

Incidentally discovered asymptomatic pancreatic cystic neoplasms are evaluated by MRI with MRCP to check for “high-risk stigmata or worrisome features.” An enhancing solid component or main pancreatic duct (MPD) dilation ≥10 mm are considered “high-risk stigmata.” Cysts ≥3 cm, thickened enhancing cyst walls, nonenhancing mural nodules, MPD size of 5 to 9 mm, abrupt change in the MPD caliber with distal pancreatic atrophy, and lymphadenopathy are considered “worrisome features.” All cysts with high risk stigmata are resected. All cysts with worrisome features and cysts >3 cm without worrisome features are further evaluated with EUS. If EUS shows a definite mural nodule, main duct features suspicious for involvement or the cytology is positive or suspicious for malignancy, then resection

is recommended. In the absence of worrisome features, no further initial work-up is recommended, but surveillance is still required.

The interval between surveillance imaging is based on the size of the cyst with a lengthening of the interval once stability is established. Patients with noninvasive MCNs require no surveillance after resection, but patients with IPMNs need surveillance after resection. In the absence of residual lesions, repeat MRI at 2 and 5 years may be reasonable. If there is low or moderate-grade dysplasia at the margin, MRI every 6 months is recommended.

Resection is indicated in all surgically fit patients with MD-IPMN, and additional resection is indicated if there is high-grade dysplasia at the margin. Resection is also indicated in all surgically fit patients with MCN. BD-IPMN <3 cm without worrisome features or high-risk stigmata can undergo surveillance.

When patients are deemed unacceptable for resection due to comorbidities, ablation of the cyst can be considered. However, at this time, cyst ablation is considered experimental and should be done as part of a clinical trial. Gastroenterologists have limited experience with injection of a cytotoxic agent into the cyst in an attempt to ablate the cyst epithelium. Ethanol has been used and more recently this has been combined with paclitaxel. The combination of ethanol and paclitaxel injection resulted in elimination of the cysts, as determined by CT scanning, in 29 out of 47 (62%) of patients in a median follow-up period of 21.7 months.³⁷⁷

Recently, the American Gastroenterological Association (AGA) published guidelines for asymptomatic mucinous cysts (<http://www.gastro.org/guidelines/pancreatic-cysts>) that are different from all previously published guidelines in the following areas: 2-year interval for cyst of any size undergoing surveillance, stopping surveillance after 5 years if no change, surgery only if more than one concerning feature on MRI confirmed on EUS and only in centers with high volumes of pancreatic surgery, and no surveillance after surgery if no invasive cancer or dysplasia. Although based on extensive literature review and synthesis, these recommendations have resulted in significant controversy because, in an effort to reduce the costs of health care delivery and perhaps decrease inadvertent harm to patients, they advocate less frequent follow-up and a higher threshold before offering EUS and/or surgery.

Solid-Pseudopapillary Tumor. Solid-pseudopapillary tumors are rare and typically occur in young women. Previous names for this entity include, *solid and cystic*, *solid and papillary*, *cystic and papillary*, and *papillary-cystic tumor*. They are typically well circumscribed on CT (Fig. 33-83). The cysts are not true epithelial-lined cysts but rather represent a necrotic/degenerative process. Histology may be similar to neuroendocrine tumors, but they do not stain positive for neuroendocrine markers such as chromogranin. Most are cured by resection, but liver and peritoneal metastases have been reported.

Other Cystic Neoplasms. Rarely, typical ductal adenocarcinoma of the pancreas may undergo cystic degeneration due to central necrosis. Occasionally, this will create difficulty in the proper preoperative diagnosis and should be kept in mind when deciding to conservatively follow a cystic pancreatic neoplasm. It is more common, 5% to 10%, for neuroendocrine tumors of the pancreas to contain cysts. These cysts are filled with serosanguineous fluid rather than necrotic debris. Lymphoepithelial

Figure 33-83. Abdominal computed tomographic scan of a 25-year-old woman demonstrating a well-circumscribed cystic lesion with septation in body/tail of pancreas. At surgery, the tumor was adherent to the splenic artery. Pathologic diagnosis was solid-pseudopapillary carcinoma.

cysts of the pancreas usually occur in men in their fifth to sixth decade. These benign lesions may be unilocular or multilocular and vary widely in size. The contents of the cyst are also variable and may be thin serous fluid or cheesy/caseous material if there is increased keratin formation. A substantial number of patients with von Hippel-Lindau syndrome develop pancreatic cysts that resemble serous cystadenomas. There may be multiple lesions scattered throughout the pancreas. Patients with polycystic kidney and hepatic disease may also develop benign pancreatic cysts (cystadenomas). With all of these rare cystic neoplasms, careful clinical history, high-quality pancreatic imaging, and sampling of the cyst fluid for analysis will guide proper treatment.

Pancreatic Lymphoma. Lymphoma can affect the pancreas. Primary involvement of the pancreas with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases. If the diagnosis cannot be confirmed preoperatively, laparoscopic exploration and biopsy are indicated.³⁷⁸ There is no role for resection in the management of pancreatic lymphoma. Endoscopic stenting to relieve jaundice followed by chemotherapy is the standard treatment, and long-term remission is often achieved.
