In liver and pancreas recipients, surgical infections are most severe. The incidence of intra-abdominal infections is decreasing, but they remain a significant problem: they are the second most common reason (after vascular thrombosis) for graft loss in pancreas recipients.

Lengthy operations with significant blood loss, prolonged warm and cold ischemic times, and spillage of contaminated fluid (bile, urine, or bowel contents) predispose patients to intra-abdominal infections. Other prominent risk factors are the high level of induction immunosuppression immediately posttransplant and anastomotic leaks. Furthermore, pretransplant infections can reemerge or worsen.

The signs and symptoms of intra-abdominal infections are those of peritonitis: fever, hypotension, ileus, and abdominal pain, although the latter can be masked by immunosuppression. Treatment entails a prompt return to the operating room. Intra-abdominal infections are usually polymicrobial, involving several bacterial and fungal species. Common bacterial isolates include *Escherichia coli*, as well as *Enterococcus*, *Klebsiella*, and *Pseudomonas* species. Common fungal isolates are *Candida albicans*, *Candida krusei*, and *Candida glabrata*. Localized infections or abscesses can be treated with percutaneous drainage and antibiotics.

Medical infections include respiratory, urinary tract, and bloodstream infections. Medical treatment should also be aggressive, often including empiric antibiotics and antifungal medications even before culture results are available. Recipients of organs from infected donors should be treated per the results of donor culture speciation and the antibiotic sensitivity profile.

Late. Late infections primarily are due to chronic immunosuppression, specifically the depression of cell-mediated immunity that renders recipients susceptible to viruses, fungi, and parasites.

Members of the herpesvirus group are the most common etiologic agents of viral infections posttransplantation, with herpes simplex virus (HSV), CMV, and EBV being the most prominent. Pretransplant exposure to viruses may confer immunity. Recipients who are seronegative for HSV, CMV, and/or EBV have a higher incidence of posttransplant infections, especially if they receive donor allografts from seropositive donors.

CMV is a latent infection that can be transmitted to seronaive recipients by donor organs from seropositive individuals, can reactivate during immunosuppression, or both. Infections usually occur 3 to 6 months posttransplant or during treatment for rejection. The incidence of CMV has been greatly reduced with 12-week acyclovir prophylaxis.⁴⁰ CMV infections range from an asymptomatic or mild flu-like syndrome to tissue-invasive disease resulting in pneumonitis, hepatitis, and GI ulcerations. Symptomatic infections and all tissue-invasive CMV disease should be treated with intravenous (IV) ganciclovir, a reduction in immunosuppression, or both, although successful treatment of mild to moderate rejection and concurrent mild to moderate CMV disease has been described.

EBV infections range from a mild mononucleosis syndrome to severe hepatitis and highly morbid PTLD. PTLD ranges from a localized tumor to a progressive, diffuse infiltration of various organs including the brain. It results from the proliferation of EBV-positive B cells in immunosuppressed patients. The main risk factors are a high degree of immunosuppression and

a predisposing EBV serostatus (seronaive recipient, seropositive donor). Among patients with early lesions, the first line of treatment is to reduce immunosuppression. For those with more advanced PTLD, rituximab is used.

After 6 months posttransplant, the risk of invasive fungal infections is closely associated with environmental exposures. *Blastomyces dermatitidis* grows in moist soil in the Midwest and Southeast regions of the United States. Diagnosis is confirmed by biopsy; the preferred treatment is IV amphotericin B.

Coccidioides immitis can cause invasive coccidioidomycosis after inhalation of aerosolized infectious particles. It is endemic in the Southwest, Northern Mexico, and various parts of Central and South America. This infection can be resilient and difficult to treat. The first line of treatment is high-dose amphotericin B.

Histoplasma capsulatum is found in chicken, pigeon, and bat droppings in the Ohio River and Mississippi River valleys. Dissemination is commonplace; up to a quarter of patients have central nervous system (CNS) involvement. Treatment consists of prolonged (3 to 13 months) administration of oral itraconazole.

Opportunistic infections with *Aspergillus*, *Cryptococcus*, *Mucor*, and *Rhizopus* species are rare but can cause serious infections. Patients with invasive *Candida* or *Aspergillus* infections exhibit a 20% mortality rate. Prophylaxis with fluconazole has been shown to reduce invasive fungal infections in liver recipients.⁴¹

Pneumocystis jiroveci (also known as PCP) is ubiquitous and can cause pulmonary disease in immunocompromised patients. However, trimethoprim-sulfamethoxazole (TMP-SMX) is effective prophylaxis against PCP, and daily, lifelong administration has virtually eliminated this infection among transplant recipients.

Malignancies

Chronic immunosuppression increases the risk of developing certain types of malignancies. The most extensive data, from a cohort study involving more than 175,000 solid organ transplant recipients, showed that 10,656 of them developed malignancies. The standardized incidence ratio was 2:10 (as compared with the general population). Recipients had at least a fivefold increase (as compared with the general population) in these types of malignancies: Kaposi's sarcoma, nonmelanoma skin cancer, non-Hodgkin's lymphoma, and cancer of the liver, anus, vulva, and lip. In addition, recipients had a statistically significant increase (as compared with the general population) in melanoma, Hodgkin's lymphoma, and cancer of the lung, kidney, colon, rectum, and pancreas.⁴²

ORGAN PROCUREMENT AND PRESERVATION

Organ procurement is a key element in organ transplantation. Currently, over 100 organ procurement organizations (OPOs) exist in the United States, all members of the Organ Procurement and Transplantation Network (OPTN), which is a federally mandated network created by and overseen by UNOS. Each OPO is responsible for evaluating and procuring deceased donor organs for transplantation in a specific geographic region. Hospitals receiving any type of federal reimbursement for their services (whether transplant-related or not) are required to report all deaths to their OPO in a timely manner. Each OPO then determines the medical suitability of the deceased for organ

donation; requests consent for donation from family members; if consent is given, contacts the OPTN to analyze and identify potential recipients whose HLA antigens most closely match those of the donor; and arranges for the recovery and transport of any donated organs.

Strategies to increase organ donation and utilization have been successfully implemented in the last 10 to 15 years. The nationwide "Organ Donation Breakthrough Collaborative," sponsored by the U.S. Department of Health and Human Services in 2003, brought the OPOs and transplant communities into a single concerted program to develop best practices guidelines. However, a severe donor shortage remains. The number of living organ donors peaked in 2007 and has declined since.

Alternative options include tissue engineering and stem cell research, but those fields are in their infancy in terms of producing fully functional and vascularized human organs. With the development of genetic "knockout" pigs, xenotransplantation still shows promise, but two problems in particular—immunologic barriers and xenosis (also known as zoonosis) of endogenous porcine retroviruses—have yet to be satisfactorily addressed.

Today, the gap between patients waiting for organ transplants and the number of organs available continues to widen. More than 118,000 patients are on the waiting list for solid organ transplants, but only 33,611 transplants were performed in 2016.

Deceased Donors

Most transplants today utilize organs from deceased donors. Formerly, death was determined by the cessation of both cardiac and respiratory function.

Donation After Brain Death. In 1968, the concept of "irreversible coma" was introduced by an ad hoc committee report at Harvard Medical School; that concept was pivotal to the final acceptance, in 1981, of "brain death" as a legal definition in the United States. The legal language states that the declaration of brain death should be in accordance with acceptable medical standards but does not specify clinical methodology. It is customary for hospitals to establish their own policies to declare brain death, according to their standards of care and local regulations.

Typically, brain death is defined as the irreversible cessation of brain function, including the brainstem. The presence of medical conditions that mimic brain death—such as drug overdose, medication side effects, severe hypothermia, hypoglycemia, induced coma, and chronic vegetative state—need to be excluded. The latest evidence-based guideline on determining brain death in adults reaffirmed the validity of current clinical practice.⁴³ Briefly, the clinical diagnosis of brain death consists of four essential steps: (a) establishment of the proximate cause of the neurologic insult; (b) clinical examinations to determine coma, absence of brainstem reflexes, and apnea; (c) utilization of ancillary tests, such as electroencephalography (EEG), cerebral angiography, or nuclear scans, in patients who do not meet clinical criteria; and (d) appropriate documentation. A similar guideline on determining brain death in pediatric patients was recently developed.⁴⁴

Once the diagnosis of brain death has been established, the local OPO assumes the care of the potential donor and initiates the process of donor evaluation and organ donation, and the potential donor is screened for contraindications to donation. The medical history and social history are obtained from the available family members. A battery of tests, including serologic

or molecular detection of human immunodeficiency virus (HIV) and viral hepatitis, are performed. The exact medical conditions that preclude donation vary; nonetheless, in the United States, infections and other medical conditions that determine eligibility are dictated by UNOS bylaws and routinely reviewed and updated.

The OPO focuses on preserving organ function and optimizing peripheral oxygen delivery until organ procurement commences.⁴⁵ In all deceased donors, core temperature, systemic arterial blood pressure, arterial oxygen saturation, and urine output must be determined routinely and frequently. Arterial blood gases, serum electrolytes, blood urea nitrogen, serum creatinine, liver enzyme, hemoglobin, and coagulation tests need to be monitored regularly. In all brain-dead donors, elevated intracranial pressure triggers a compensatory catecholamine response to maintain cerebral perfusion pressure. Ischemic injury to the spinal cord and the sympathetic system may lead to a profound vasodilation. As a result, brain-dead donors frequently have severe hemodynamic and metabolic derangements, so aggressive monitoring and intervention are required to prevent loss of precious organs.

Previous studies of deceased donor care focused on organ-specific resuscitation protocols that resulted in only marginal gains in the number of organs transplanted. The latest developments center on multisystem protocols to increase the number of organs transplanted per donor (OTPD).^{46,47} The goals are to maintain a core temperature between 36.0°C and 37.5°C, a mean arterial pressure >70 mmHg or a systolic pressure >100 mmHg, and a hemoglobin level between 7 and 10 g/dL; hormonal therapy and aggressive treatment of arrhythmias and metabolic derangements are also called for.⁴⁷

Surgical Technique. Procurement of multiple organs (heart, lungs, kidney, liver, pancreas, and/or small bowel), or multivisceral procurement, was first described by the Pittsburgh group in 1987.⁴⁸ Since then, most centers have incorporated changes, especially with regard to the timing and location of dissection and flushing.^{49,50} The basic steps involve a long incision to provide wide exposure of all thoracic and abdominal organs (Fig. 11-3). A Cattell-Braasch maneuver (complete mobilization of the distal small bowel, right colon, and duodenum) is performed to allow for identification of the distal aorta, iliac

Figure 11-3. Exposure for thoracic and abdominal organ procurement.

bifurcation, and distal inferior vena cava (IVC). The infrarenal aorta is the site for inserting the cannula that will allow for flushing of the organs with cold preservation solution. Sometimes, division of the inferior mesenteric artery is necessary to facilitate the exposure of the distal aorta. The third portion of the duodenum is retracted cephalad to expose the root of the superior mesenteric artery (SMA). Limited dissection is performed at the root of the SMA, which is encircled with a vessel loop to enable its temporary occlusion at the time of flushing, thus reducing the incidence of overperfusion injury to the pancreas.

A large anomalous or replaced right hepatic artery typically rises from the SMA, and this should be identified and preserved. Lateral to the SMA is the inferior mesenteric vein (IMV), which can be cannulated for portal flushing. Dissection of the hepatic hilum and the pancreas should be limited to the common hepatic artery (CHA), and branches of the CHA (e.g., splenic, left gastric, and gastroduodenal arteries) are exposed. The gastrohepatic ligament is carefully examined to preserve a large anomalous or replaced left hepatic artery, if present. The supraceliac aorta can be exposed by dividing the left triangular ligament of the liver and the gastrohepatic ligament.

The common bile duct is transected at the superior margin of the head of the pancreas. The gallbladder is incised and flushed with ice-cold saline to clear the bile and sludge. If the pancreas is to be procured, the duodenum is flushed with antimicrobial solution. Before the cannulation of the distal aorta, systemic heparinization (300 units/kg) is administered. The supraceliac aorta is clamped; cold preservation fluid is infused via the aortic (systemic) and IMV (portal) cannulas. The thoracic organs, liver, pancreas, and kidneys are then removed.

Donation After Cardiac Death. Given the severe shortage of donor organs, donation after cardiac death (DCD)—also known as donation by non-heart-beating donors (NHBDs)—was reintroduced to the transplant community in the 1990s.⁵¹ The category of DCD (Maastricht classification) was initially proposed at an international workshop and is now widely adopted for organ procurement.⁵² Currently, most NHBDs in the United States meet Maastricht classification III; that is, they have suffered a devastating injury with no chance of a meaningful recovery but do not meet the criteria for brain death. After consent for donation is obtained from the next of kin, the donor's life support is removed. After the cessation of cardiac and respiratory function, organ procurement commences. DCD procurement protocols vary between states; religious and cultural differences need to be taken into consideration. The surgical team must be familiar with, and respect, the local protocol.

With cardiac death (as opposed to brain death), warm ischemic injury to organs can occur during the period between circulatory cessation and rapid core cooling through perfusion of preservation solution. However, the difference in long-term outcomes is negligible for recipients of organs from either type of donor. Still, a significant percentage of liver grafts procured after cardiac death, especially those with more than 25 minutes of warm ischemic time, develop devastating ischemic cholangiopathy and fail.⁵³

A new development to minimize ischemic injury to organs procured after cardiac death has been the application of extracorporeal membrane oxygenation (ECMO). With ECMO, DCD differs in two key ways: (a) cannulation occurs *before* withdrawal of life support and (b) organs are perfused via ECMO with warm oxygenated blood *after* declaration of cardiac death.

The initial experience with organs procured using ECMO has been encouraging.

Surgical Technique. Surgeons who perform multiple organ retrieval should be familiar and experienced with the super-rapid technique described by the Pittsburgh group.⁵⁴ Preferably, NHBDs undergo withdrawal of life support in the operating room *after* the surgical site is prepped and draped, as soon as the surgical team is ready. Alternatively, the NHBD is transported to the operating room after declaration of cardiac death.

A midline incision is used to rapidly gain entry into the abdominal cavity. An assistant retracts the small bowel and the sigmoid colon laterally, so that the bifurcation of the aorta can be easily identified on the left side of the vertebral column. A short segment of the distal aorta is dissected out from the retroperitoneum. A moist umbilical tape is passed around the aorta, which is used to secure a cannula. The distal aorta is clamped. Next, a cannula is passed cephalad through an aortotomy and secured. Flushing with cold preservation solution is started at once, followed by cross-clamping the aorta proximally (thoracic aorta) and venting through the vena cava. The portal flush is then instituted.

The rest of the procedure is similar to procurement after brain death, with two noticeable differences. First, to avoid injury to a large anomalous or replaced left hepatic artery, the gastrohepatic ligament and the left gastric artery are separated from the stomach at the lesser curvature. Second, to avoid injury to a large anomalous or replaced right hepatic artery, the SMA is examined before it is divided. If the pancreas is not procured, a common aortic patch encompassing both the SMA and the celiac artery can be procured with the liver.

Living Donors

The maxim of medical ethics is “*primum non nocere*” (first, do no harm), and for that reason, living organ donation presents unique ethical and legal challenges. Performing potentially harmful operations to remove organs from healthy individuals seems, at first glance, to contradict that maxim. But in fact, the ethical framework of living organ donation rests on three guiding principles respected in all discussions of medical practice: *beneficence* to the recipient, *nonmaleficence* to the donor, and the donor’s *right to autonomy*.⁵⁵ In order to achieve optimal outcomes (the common good), transplant professionals should focus on maximizing the benefits for the recipient and minimizing the damage to the donor. The Uniform Anatomical Gift Act adopted by all states in the United States (with slight variations) provides the legal framework for competent adult living donors to decide whether or not to donate. It is the fiduciary duty of transplant professionals to explain the risks of organ donation. Any decision to donate should be uncoerced, and no enticements should be offered.

The use of living donors offers numerous advantages for recipients in need. First and foremost is the availability of lifesaving organs for those who would otherwise succumb to the progression of their end-stage disease. In certain parts of the world, such as East Asia, the concept of brain death and the use of deceased donors conflict with the prevailing culture or religion. Even in countries where the use of deceased donors is accepted, the use of living donors may significantly shorten the waiting time for recipients. A shorter waiting time generally implies a healthier recipient—one whose body has not been ravaged by prolonged end-stage organ failure. Moreover, with the use of living donors, transplants are planned (rather

than emergency) procedures, allowing for better preoperative preparation of the recipient. Receiving an organ from a closely matched relative may also have immunologic benefits. And long-term results may be superior with the use of living donors, as is certainly the case with kidney transplants.

The major disadvantage is the risk to the living donor. Medically, there is no possibility of benefit to the donor, only the potential for harm. The risk of death associated with donation depends on the organ being removed. For a nephrectomy, the estimated mortality risk is less than 0.05%; for a partial hepatectomy, about 0.2%. The risk of surgical and medical complications also depends on the procedure being performed. In addition, long-term complications may be associated with a partial loss of organ function after donation. The guiding principle should be minimization of risk to the donor. All potential risks must be carefully explained to the potential donor, and written informed consent must be obtained.⁵⁶

Surgical Technique. The kidney, the first organ to be transplanted from living donors, is still the most common organ donated by these individuals. The donor’s left kidney is usually preferable because of the long vascular pedicle. Use of living donor kidneys with multiple renal arteries should be avoided in order to decrease the complexity of the vascular reconstruction and to help avoid graft thrombosis. Most donor nephrectomies are now performed via minimally invasive techniques, that is, laparoscopically, whether hand-assisted or not. With laparoscopic techniques, an intraperitoneal approach is most common: it involves mobilizing the colon, isolating the ureter and renal vessels, mobilizing the kidney, dividing the renal vessels and the distal ureter, and removing the kidney (Fig. 11-4). Extensive dissection around the ureter should be avoided, and the surgeon should strive to preserve as much length of the renal artery and vein as possible.

Liver transplants with living donors are not as commonly performed, given the significantly higher rates of donor mortality and morbidity. Initially, only adult donors for pediatric recipients were selected, but now, living donor liver transplants also involve adult donors for adult recipients. In dual graft living donor liver transplants, segmental grafts from two living donors augment the recipient’s graft size.⁵⁷ The donor hepatectomy is similar to a major lobar hepatectomy, except that it is important to preserve the integrity of the vascular structure until graft resection (Fig. 11-5).

Living donor transplants of organs other than the kidney and liver are fairly uncommon, but certain centers do perform such transplants. Living donor pancreas transplants involve performing a distal pancreatectomy, with the graft consisting of the body and tail of the pancreas; vascular inflow and outflow are provided by the splenic artery and splenic vein. Living donor intestinal transplants usually involve removal of about 200 cm of the donor’s ileum, with inflow and outflow provided by the ileocolic vessels. Living donor lung transplants involve removal of one lobe of one lung from each of two donors; both grafts are then transplanted into the recipient.

Organ Preservation

The development and continuing refinement of organ preservation methods have completely revolutionized the transplant field. Extending the time that organs can be safely stored after procurement has enabled better organ utilization and better recipient outcomes.^{58,59} Hypothermia and pharmacologic inhibition are the two most frequent methods. Both slow—yet cannot

Figure 11-4. Laparoscopic left donor nephroureterectomy. **A.** Takedown of splenic flexure of colon to expose the left renal hilum. **B.** Dissection of left ureter off the psoas muscle. **C.** Dissection of left renal vein and gonadal vein. Left ureter seen lateral to the dissection. **D.** Dissection of left renal artery. Lumbar veins clipped and divided. **E.** Endo-TA stapler transection of the left renal artery. **F.** Placement of ports and Pfannenstiel incision for the donor kidney extraction.

Figure 11-5. Donor hepatectomy (right hepatectomy). **A.** The liver parenchymal transection line (c, the Cantlie line) marked with cautery. Right portal vein (p) and right hepatic artery (a) isolated. b = bile duct. Cystic duct was cannulated for intraoperative cholangiography. **B.** Exposure of hepatic veins after transection of the parenchyma. IVC = inferior vena cava; L = left hepatic vein; M = middle hepatic vein; R = right hepatic vein.

completely shut down—the removed organ’s metabolic activity, so both have adverse effects, such as cellular swelling and degradation. Cold storage solutions were introduced to mitigate some of the adverse effects of hypothermia or pharmacologic inhibition alone. Such solutions help prevent cellular swelling and the loss of cellular potassium.

One, and perhaps the most effective, preservation solution was developed at the University of Wisconsin and remains in wide use.⁶⁰ Its ingredients include lactobionate (which helps prevent cellular swelling and reperfusion injury), raffinose, and hydroxyethyl starch (which helps reduce swelling of endothelial cells, thereby decreasing edema). Histidine-tryptophan-ketoglutarate solution is also currently in wide use.⁶¹

Despite enhancements in preservation methods, the amount of time that an organ can be safely stored remains relatively short (hours, not days), particularly with organs from marginal donors. Among kidney recipients, delayed graft function becomes significantly more frequent after cold ischemic times of more than 24 hours, necessitating temporary dialysis, which is associated with increased risks of graft loss and higher costs.⁶² Among liver recipients, primary nonfunction and biliary complications ensue after prolonged cold ischemic times. In the case of heart and lung recipients, ischemic times should be under 6 hours. All of those times assume the use of normal donors.

There is revived interest in the use of the pulsatile perfusion pump, a kidney graft preservation method that has been available for more than 40 years.⁶³ With the increasing shortage of available donor organs and the rise in the use of organs after cardiac death, the pulsatile perfusion pump is garnering renewed enthusiasm as an adjunct method of preservation, even for donor organs other than kidneys.^{64,65}

KIDNEY TRANSPLANTATION

Introduction

Ullman reported the first attempted human kidney transplant in 1902.⁶⁶ For the next 50 years, sporadic attempts all ended in either technical failure or in graft failure from rejection. Joseph Murray performed the first successful kidney transplant in 1954, an epochal event in the history of organ transplantation. In that first case, the immunologic barrier was circumvented by transplanting a kidney between identical twins.⁶⁷ For his pivotal contribution, Murray shared the Nobel Prize in Physiology or Medicine in 1990 with E. Donnall Thomas for their discoveries concerning “organ and cell transplantation in the treatment of human disease.”

The introduction of AZA (Imuran) in 1960 marked the beginning of a new era in kidney transplantation. With the combination of steroids and AZA for maintenance immunosuppression, the 1-year graft survival rate with a living related donor kidney approached 80%; with a deceased donor kidney, the rate was 65%.⁶⁸ In the ensuing years, major milestones included the introduction of more effective immunosuppressive medications with lower toxicity profiles, such as polyclonal antilymphocyte globulin in the 1970s, cyclosporine in the 1980s, tacrolimus in the 1990s, and biologics in the first decade of the 21st century, as previously mentioned.

Parallel to the developments in medical science were the transplant community’s concerted efforts to improve use of healthcare resources. In the United States, the Social Security amendments of 1972 provided Medicare coverage for patients

with end-stage renal disease (ESRD). The National Organ Transplant Act of 1984 initiated the process of creating what later became UNOS, an umbrella organization to ensure access to organs by patients in need, to enhance organ procurement and allocation, and to improve posttransplant outcomes. This infrastructure later became the blueprint for other countries to follow. As a result, organ transplantation is the most transparent field of medicine. Data such as transplant center performance are readily available on public websites; penalties for violation of regulations and for underperformance often result in transplant programs being shut down.

Today, a kidney transplant remains the most definitive and durable renal replacement therapy for patients with ESRD. It offers better survival and improved quality of life and is considerably more cost-effective than dialysis.^{69,70} According

4▶ to the 2016 Scientific Registry of Transplant Recipients (SRTR) annual report, nearly 100,000 adult patients were on the kidney transplant waiting list, while nearly 20,000 patients underwent renal transplantation. Trends over the past decade indicated that living related transplants remained relatively stable, while the number of deceased donor transplants rose. Posttransplant outcomes have continued to improve: in 2015, the 1-year graft survival rate with a living donor kidney was nearly 98%; with a deceased donor kidney, the rate was approximately 95.0%.⁷¹

The advantages of a living donor kidney transplant include better posttransplant outcomes, avoidance of prolonged waiting time and dialysis, and the ability to coordinate the donor and recipient procedures in a timely fashion. Living donor kidney recipients enjoy better long-term outcomes, a low incidence of delayed graft function, and reduced risks of posttransplant complications. Furthermore, the elective nature of living donor kidney transplants provides unique opportunities for recipient desensitization treatment if the donor and recipient are ABO-incompatible or if the HLA cross-match results are positive.

Some of the challenges transplant professionals face today are closing the growing gap between supply and demand and thereby reducing the current prolonged waiting times; refining immunosuppressive medications to achieve better outcomes with reduced toxicity; and caring for patients who develop rejection, especially antibody-mediated rejection.

Pretransplant Evaluation

Active infection or the presence of a malignancy, active substance abuse, and poorly controlled psychiatric illness are the few absolute contraindications to a kidney transplant. Studies have demonstrated the overwhelming benefits of kidney transplants in terms of patient survival, quality of life, and cost-effectiveness, so most patients with ESRD are referred for consideration of a kidney transplant. However, to achieve optimal transplant outcomes, the many risks (such as the surgical stress to the cardiovascular system, the development of infections or malignancies with long-term immunosuppression, and the psychosocial and financial impacts on compliance) must be carefully balanced.

Any problems detected during the evaluation of transplant candidates are communicated to their referring physician and/or to a specialist if advanced evaluation and treatment are needed, ultimately improving overall care. Essentially, the pretransplant evaluation is a multifaceted approach to patient education and disease management.

Before the pretransplant medical evaluation begins, kidney transplant candidates are encouraged to attend a group meeting

focused on patient education. The meeting is coordinated by a transplant physician or surgeon. The intent is to familiarize patients with the pretransplant evaluation process and with pertinent medical concepts and terms. In an open forum format, important decisions such as type of donor (living vs. deceased) are discussed. The group meeting empowers patients to fully participate in their care and serves as an impetus for a meaningful dialogue with healthcare professionals.

Medical Evaluation

Cardiovascular Disease. Diabetes and hypertension are the leading causes of chronic renal disease. Concomitant cardiovascular disease (CVD) is a common finding in this population. An estimated 30% to 42% of deaths with a functioning kidney graft are due to CVD.^{72,73} Therefore, assessment of the potential kidney transplant candidate's cardiovascular status is an important part of the pretransplant evaluation.

In fact, the American Heart Association and the American College of Cardiology Foundation recently published their expert consensus on CVD evaluation and management for solid organ transplant candidates.⁷⁴ The process should focus on careful screening for the presence of significant cardiac conditions (e.g., angina, valvular disease, and arrhythmias) and for a prior history of congestive heart failure, coronary interventions, or valvular surgery. The perioperative risk assessment is based on patient symptoms and exercise tolerance. For all kidney transplant candidates, a resting 12-lead electrocardiogram (ECG) should be obtained. In addition, in this population, the use of echocardiography to analyze left ventricular function and to assess for pulmonary hypertension is useful.

Stress testing may be considered in patients with no active cardiac condition but with risk factors such as diabetes, hemodialysis for more than 1 year, left ventricular hypertrophy, age greater than 60 years, smoking, hypertension, and dyslipidemia. The utility of noninvasive stress testing (as compared with angiographic studies) for evaluating coronary artery disease is controversial; an additional prognostic marker is the troponin T (cTnT) level.

Malignancies. Because of the long-term use of immunosuppressive medications, transplant recipients are at increased risk for development of malignancies. Untreated and/or active malignancies are absolute contraindications to a transplant (with two exceptions: nonmelanocytic skin cancer and incidental renal cell cancer identified at the time of concurrent nephrectomy [i.e., for polycystic kidney disease] and renal transplantation). For most patients who have undergone treatment of low-grade tumors with a low risk of recurrence (e.g., completely locally excised low-grade squamous cell cancer of the skin, colon cancer in a polyp absent stalk invasion), a wait of at least 2 years after successful treatment is recommended before a kidney transplant can be considered. However, for certain types of tumors, especially at advanced stages or those with a high risk of recurrence (e.g., melanoma, lymphoma, renal cell cancer, breast cancer, colon cancer), a delay of at least 5 years is advisable. According to the Israel Penn International Transplant Tumor Registry, tumor recurrence posttransplant is not infrequent: the recurrence rate is 67% in patients with multiple myeloma, 53% in nonmelanocytic skin cancer, 29% in bladder cancer, and 23% in breast cancer.⁷⁵

Infections. A thorough history of infections and immunizations should be obtained from transplant candidates, who need

all recommended age-appropriate vaccinations according to the Centers for Disease Control and Prevention (CDC) guidelines. Ideally, vaccinations should be completed at least 4 to 6 weeks before the kidney transplant takes place. Immunosuppressive medications blunt the immune response and reduce the effectiveness of vaccinations; even more important, with attenuated vaccines, vaccine-derived infections could occur. If a splenectomy is anticipated (e.g., in recipients whose donor is ABO-incompatible or whose HLA cross-match results are positive), then they should be immunized against encapsulated organisms (such as *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*) well in advance of the splenectomy.

Transplant candidates should undergo routine tuberculosis (TB) screening. According to the Centers for Disease Control (CDC), in 2016, 9272 TB cases were diagnosed in the United States with 68.5 percent of cases occurring in foreign-born persons.⁷⁶ Serologic screening combined with a chest roentgenogram for fungal infections such as coccidioidomycosis or histoplasmosis, in patients who either have a history of those infections or are from an endemic area, are recommended. Chronic infections such as osteomyelitis or endocarditis must be fully treated; a suitable waiting period after successful treatment must occur, in order to ensure that relapse does not occur.

Hepatitis can be caused by five different type of viruses, hepatitis virus A, B, C, D, and E, with the first three being the most common. Acute viral hepatitis is a contraindication to a kidney transplant; however, chronic viral hepatitis (most commonly caused by hepatitis B [HBV] or C [HCV]) does not preclude a recipient from undergoing a kidney transplant. In such candidates, obtaining a liver biopsy is essential to assess the disease severity. Recipients infected with HBV should undergo antiviral treatment (e.g., lamivudine) to prevent reactivation and progression of liver disease. Note that HBV is a noncytopathic virus; the liver damage is the result of an immune-mediated process.⁷⁷ Moreover, the presence of normal liver enzymes in patients with HBV antigenemia does not predict the severity of parenchymal damage.

Transplant candidates with chronic HCV infection often have HCV-related glomerulonephritis. As with HBV infection, the clinical presentation and biochemical findings with HCV infection are often unreliable in predicting liver damage. In such patients who also exhibit evidence of cirrhosis, a combined liver-kidney transplant should be considered. In appropriate candidates, pretransplant antiviral treatment with interferon- α may be considered. However, after a kidney transplant, interferon treatment is not recommended because it is an immunosuppressant, and thus HIV may precipitate graft rejection.

Thanks to the excellent outcomes of highly active antiretroviral therapy (HAART), infection with HIV is no longer considered a contraindication to a kidney transplant. Kidney transplant candidates with HIV must have an undetectable HIV viral load and a CD4 lymphocyte count greater than 200/mm³; in addition, they must not have developed any opportunistic infection in the previous year.⁷⁸

Latent viral infections such as CMV and EBV are of particular interest in the field of transplantation, given the risks of reactivation posttransplant and their detrimental effects on graft and patient survival. Knowing the CMV and EBV serologic status of the recipient and donor helps transplant professionals gauge the risk of immunosuppressive regimens in relation to potential infection, thereby guiding plans for posttransplant antiviral prophylaxis treatment or, as noted earlier,

avoiding transplants between a seropositive donor and a seronegative recipient.

Kidney Disease. The third most common cause of graft loss in kidney transplant recipients is recurrence of glomerular diseases such as focal segmental glomerulosclerosis (FSGS), immunoglobulin A (IgA) nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, and membranoproliferative glomerulonephritis. FSGS deserves special mention due to its frequent occurrence and dramatic presentation of early graft loss. An estimated 30% to 40% of FSGS patients develop recurrent disease posttransplant; of those, up to half eventually lose their graft.⁷⁹ In recipients with a history of FSGS, posttransplant nephrotic proteinuria should be promptly investigated; if diagnosis is confirmed by transplant kidney biopsy, rescue plasmapheresis should be instituted at once. Adjuvant therapy with rituximab has been proposed.⁸⁰

Hypercoagulopathy. Kidney transplant candidates with a history of thrombotic events, repeated miscarriages, or a family history of thrombophilia should be screened for the following coagulopathic disorders: activated protein C resistance ratio, factor V Leiden mutation, factor II 20210 gene mutation, antiphospholipid antibody, lupus anticoagulant, protein C or S deficiency, antithrombin III deficiency, and hyperhomocysteinemia. In recipients at risk for hypercoagulopathy, pediatric kidney grafts and any kidney allografts with a complex vascular anatomy should be avoided.⁸¹ A perioperative anticoagulation protocol is recommended in this population.

Surgical Evaluation

Urologic Evaluation. Kidney transplant candidates (pediatric patients, in particular) with chronic kidney disease as a result of congenital or genitourinary abnormalities should undergo a thorough urologic evaluation. A voiding cystourethrogram and a complete lower urinary tract evaluation to rule out outlet obstruction are essential. Indications for a native nephrectomy include chronic pyelonephritis, large polycystic kidneys with loss of intra-abdominal domain, significant vesicoureteral reflux, or uncontrollable renovascular hypertension.

Vascular Evaluation. The potential implant sites for a kidney graft include the recipient's iliac vessels and, less commonly, the aorta and vena cava. Careful physical examination often reveals significant central and/or peripheral vascular disease. Findings such as a pulsatile intra-abdominal mass, diminished or absent peripheral pulse, claudication, rest pain, and tissue loss in lower extremities should be further evaluated by abdominal computed tomography scan or ultrasound, Doppler studies, and/or angiography. With the popularity of endovascular interventions, transplant surgeons also should be familiar with such technology and obtain detailed anatomic studies of patients with vascular stents.

Immunologic Evaluation. ABO blood typing and HLA typing (HLA-A, -B, and -DR) are required before a kidney transplant. The method of screening for preformed antibodies against HLA antigens (because of prior transplants, blood transfusions, or pregnancies) continues to evolve. The panel-reactive antibody (PRA) assay is a screening test that examines the ability of serum from a kidney transplant candidate to lyse lymphocytes from a panel of HLA-typed donors. A numeric value, expressed as a percentage, indicates the likelihood of a positive cross-match with a donor. A higher PRA level identifies patients at

high risk for a positive cross-match and therefore serves as a surrogate marker to measure the difficulty of finding a suitable donor and the subsequent risk of graft rejection.

An important development in anti-HLA antibody screening is Luminex technology, using HLA-coated fluorescent microbeads and flow cytometry, which is considered the "gold standard." This technology pinpoints donor-specific antibodies (DSAs) in the serum of a kidney transplant candidate with a high PRA level. Since all organ donors must undergo HLA typing, a negative cross-match for recipients with a high PRA level can be ensured by avoiding the selection of donors carrying unacceptable antigens (i.e., a virtual cross-match).⁸² Kidney transplant candidate data (including ABO blood types, HLA types, and DSAs) are entered into a nationwide central database to facilitate deceased donor kidney allocation, as described earlier.

Psychosocial Evaluation. Psychiatric disorders have been recognized as important contributing factors to poor outcomes posttransplant. Patients with uncontrolled psychiatric disorders are at high risk for noncompliance with drug treatment, impaired cognitive function, and the development of substance abuse. A robust psychosocial evaluation is essential to ensure that transplant candidates understand the risks and benefits of the procedure and that they adhere to the lifetime immunosuppressive medication regimen.

Recipient Operation

Kidney allografts usually are transplanted heterotopically. The iliac fossa is recognized as the ideal position because of its proximity to the recipient's bladder and iliac vessels.^{83,84}

Retroperitoneal allograft placement also allows easy access for percutaneous biopsies and interventions for ureteral complications. The right iliac fossa is the preferred site because of its easy access to the recipient's iliac vessels. However, if a pancreas transplant is anticipated in the future or if now failed kidney grafts have been placed at the right iliac fossa, then the left iliac fossa is used for implantation. The current surgical technique for kidney transplants was developed and popularized in the 1950s and 1960s and has changed little since.⁸⁵

A large-bore three-lumen urinary catheter is inserted after the recipient is anesthetized, and it is occluded with a clamp beneath the surgical drapes. Recipients whose native kidneys produce urine will naturally fill up the urinary bladder; those individuals whose kidneys do not will require insufflation of saline prior to creation of the ureteral anastomosis.

Exposure of the operative field starts with a curvilinear skin incision, one to two finger widths above the midline pubic bone and the lateral edge of the rectus sheath. Superiorly, the extension of the incision depends on the recipient's body habitus and the size of the donor kidney. The anterior rectus sheath is incised, medially to laterally, until the lateral edge of the rectus sheath is exposed. The posterior rectus sheath is missing below the arcuate line, thus providing direct access to the extraperitoneal space. The rectus muscle can be easily mobilized medially without being divided. The remainder of the fascial incision is along the lateral edge of the rectus sheath until the desired exposure is achieved (Fig. 11-6).

The retroperitoneal space of the iliac fossa is entered by mobilizing the peritoneum medially. The inferior epigastric vessels, the round ligament (in females), and the spermatic cord and its vasculature (in males) are encountered in this space; the former two structures are divided, while the latter is retracted with a vascular loop. A self-retained retractor is used to expose

Figure 11-6. Incision and exposure for kidney transplant. **A.** Mark for the skin incision. **B.** Anterior rectus sheath incised obliquely. The abdominal muscle transected lateral to the rectus muscle. **C.** External iliac artery and vein dissected.

the surgical field. The iliac vessels should be dissected with great care. To minimize the risk of lymphocele development postoperatively, dissection of the iliac artery should be limited; the intertwining lymphatics around the iliac vessels should be ligated. In general, the donor's renal artery and vein are anastomosed to the recipient's external iliac vessels in an end-to-side fashion (Fig. 11-7). In recipients with a severely calcified iliac artery, the internal iliac artery can be used as an alternative, and in select cases, an endarterectomy must be performed.

After restoring the circulation to the donor's kidney, urinary continuity can be established via several approaches. The approach chosen depends on such factors as the length of the donor ureter and a recipient history of bladder surgery, native nephrectomy, or pelvic radiation. The two most common procedures to restore urinary continuity are the Leadbetter-Politano and a modification of the Lich (e.g., extravesical) ureteroneocystostomy.

During the former procedure, a large cystostomy is created in the dome of the bladder, and the donor ureter is brought through a lateral and somewhat inferior 1-cm submucosal tunnel into the bladder, the end of which is spatulated and then sewn in

place without tension with interrupted absorbable sutures placed through the mucosa and submucosa on the inside of the bladder.

An extravesical ureteroneocystostomy is performed by careful dissection of a 1-cm portion of the muscular layers on the anterolateral portion of the bladder until a "bubble" of mucosa is exposed. The donor ureter is spatulated in a diamond-shaped fashion, the bladder mucosa is incised, absorbable interrupted sutures are placed in four quadrants, and a mucosa-to-mucosa anastomosis is created using running absorbable sutures with a temporary ureteral stent in place of the first three-quarters of the anastomosis. The muscular layers of the bladder are then carefully approximated over the anastomosis to prevent reflux.

The decision to place a ureteral stent depends on the surgeon, who must try to balance the risk of infectious complications with the possible technical complications of a ureteral anastomosis, but in general, this is not required except during the rarely performed donor ureter to recipient ureter anastomosis or in the case of a pediatric kidney transplant. Fixation of the donor's kidneys is not necessary, except in the case of small kidneys (usually from a pediatric donor) or en bloc kidneys.

Figure 11-7. Vascular anastomoses of kidney transplant. **A.** Arterial anastomosis: donor renal artery with Carrel patch to recipient external iliac artery, end-to-side. **B.** Venous anastomosis: donor renal vein with caval extension conduit to recipient external iliac vein, end-to-side.

IVC = inferior vena cava; R = right renal vein. **B.** Three renal arteries anastomosed to external iliac artery separately.

Grafts With Multiple Renal Arteries

In 10% to 30% of donor kidneys, multiple renal arteries are encountered. Unless kidney transplant candidates have hypercoagulopathy, grafts with multiple renal arteries fare as well as those with single vessels.⁸⁶ Vascular reconstruction options include implanting the donor's arteries separately, reconstructing the multiple arteries into a common channel, or combining multiple arteries into a common Carrel patch (Fig. 11-8).

En Bloc Grafts

Debate persists about whether to implant kidneys obtained from young donors (<5 years or whose body weight is under 20 kg) as a single en bloc unit into one recipient or separately into two recipients. The underlying issues are the shortage of donor organs, the complexity of the surgical procedure, the risks of graft thrombosis, ureteral complications, and long-term outcomes.

In en bloc kidney transplants, the donor aorta and vena cava are used as the vascular inflow and outflow conduits. Therefore, reconstruction of the en bloc graft pretransplant is key to a successful transplant. The donor's suprarenal vena cava and aorta are oversewn. The lumbar branches of the cava and aorta are ligated. Dissection around the renal hilum should be avoided. The orientation of the cava and aorta should be clearly marked, in order to avoid torsion of the anastomosis. If the color of the two kidneys looks different after reperfusion, repositioning should be attempted to rule out vascular torsion; fixation of the en bloc kidneys to the retroperitoneum is often necessary. The donor's ureters are implanted to the recipient's bladder, either as two separate anastomoses or as a common patch (Fig. 11-9). Only a handful of centers have performed en bloc kidney transplants, but the long-term outcomes are encouraging.^{87,88}

Donor aorta anastomosed to recipient's external iliac artery; donor cava, to recipient's external iliac vein.

Perioperative Care

Preoperatively, a thorough history and physical examination should be performed. Any changes in transplant candidates' recent medical history should be investigated in great detail. In those recipients with a historically negative PRA level who have recently undergone blood transfusions, a prospective tissue cross-match is necessary to avoid graft rejection. Electrolyte panels should be checked. Emergency dialysis may be necessary for transplant candidates experiencing hyperkalemia or fluid overload.

For dialysis-dependent transplant candidates, the catheter sites should be examined preoperatively to rule out infections. Vascular access for hemodialysis is essential to avoid complications related to posttransplant acute tubular necrosis (ATN). Vascular evaluation is mandatory; any changes in results should be investigated by appropriate imaging studies.

As is routine for other major surgical procedures, transplant candidates should preoperatively undergo a chest X-ray, a 12-lead ECG, blood typing, cross-match tests, and prophylaxis against surgical site infection (by administration of a nonnephrotoxic antibiotic with activity against both common skin microflora and gram-negative pathogens); candidates should receive nothing to eat or drink.

Intraoperatively, transplant recipients should be kept well hydrated to avoid ATN and should receive heparin prior to vascular occlusion. Before reperfusion of the transplanted kidney, the desired central venous pressure should be maintained at around 10 mmHg, and the systolic blood pressure should be above 120 mmHg. In pediatric recipients of an adult graft, a superphysiologic condition may be necessary to avoid ATN or graft thrombosis. Mannitol often is administered before reperfusion as a radical scavenger and diuretic agent, and a diuretic such as furosemide is administered as well.

Postoperatively, the guiding principles for the care of kidney transplant recipients are the same as for other surgical patients. The crucial elements include hemodynamic stability and fluid and electrolyte balance. To achieve a euvolemic state, the recipient's urine output is replaced with either an equal or a reduced volume of IV fluid on an hourly basis, depending on the medical status. In recipients undergoing brisk diuresis, aggressive replacement of electrolytes (including calcium, magnesium, and potassium) may be necessary. In recipients experiencing ATN, fluid overload, or hyperkalemia, however, fluid restriction, treatment for hyperkalemia, and even hemodialysis may be necessary.

Hypotension is an unusual event immediately posttransplant. The differential diagnoses include hypovolemia, vasodilation, and myocardial infarction with cardiac failure. Immediate action should be taken to avoid life-threatening complications. Posttransplant hypertension can be mediated by catecholamines, fluid overload, or immunosuppressive agents.

Postoperatively, urine output is used as a surrogate marker to monitor graft function. Among recipients whose native kidneys produce significant amounts of urine, normal or increased urine output can be misleading; for them, serum blood urea nitrogen and creatinine levels are more reliable indicators of kidney graft function.

Suddenly decreased or minimal urine output requires immediate attention. A change in volume status is the most common cause, but other culprits include blockage of the urinary catheter, urinary leak, vascular thrombosis, hypotension, drug-related nephrotoxicity, ATN, and rejection (all of which

must be thoroughly investigated). Diagnostic studies such as Doppler ultrasound, nuclear renograms, or biopsies should be considered.

Postoperative bleeding is an uncommon event after a kidney transplant. Recipients on anticoagulation or antiplatelet treatments are at increased risk. Signs and symptoms (such as an expanding hematoma over the surgical site, increased pain over the graft, a falling hemoglobin level, hypotension, and tachycardia) should arouse suspicion of hemorrhage. Doppler ultrasound is useful to establish the underlying cause. Surgical exploration seldom is required because the accumulated hematoma tamponades the bleed. Indications for surgical exploration include ongoing transfusion requirement, hemodynamic instability, and graft dysfunction from hematoma compression. For recipients on anticoagulation or antiplatelet treatments, the threshold for surgical exploration is lower. Small unligated vessels at the donor's renal hilum or recipient's retroperitoneum are likely sources of bleeding.

One of the most devastating postoperative complications in kidney recipients is graft thrombosis. It is rare, occurring in fewer than 1% of recipients. The recipient risk factors include a history of recipient hypercoagulopathy and severe peripheral vascular disease; donor-related risk factors include the use of en bloc or pediatric donor kidneys, procurement damage, technical factors such as intimal dissection or torsion of vessels, and hyperacute rejection. Graft thrombosis usually occurs within the first several days posttransplant. Acute cessation of urine output in recipients with brittle posttransplant diuresis and the sudden onset of hematuria or graft pain should arouse suspicion of graft thrombosis. Doppler ultrasound may help confirm the diagnosis. In cases of graft thrombosis, an urgent thrombectomy is indicated; however, it rarely results in graft salvage.

Urologic complications are seen in up to 5% of recipients. The cause is often related to ureteral ischemia, damage during procurement of the donor's distal ureter, or technical errors. Symptoms of urine leak include fever, pain, swelling at the graft site, increased creatinine level, decreased urine output, and cutaneous urinary drainage. Diagnosis can be confirmed by a combination of ultrasound, nuclear renography, drainage of perinephric fluid collection, and comparison of serum and fluid creatinine levels. Depending on the location and volume of the urine leak, satisfactory results can be achieved by surgical exploration and repair or by percutaneous placement of a nephrostomy and ureteral stenting.

Early urinary obstruction can be due to edema, blood clots, torsion of the ureter, or compression from a hematoma. Late urinary obstruction is often related to ischemia. The appearance of hydronephrosis on ultrasound is a good initial indicator. Treatment includes percutaneous placement of a nephrostomy and ureteral stenting. If transluminal intervention fails, surgical intervention (such as ureteral reimplantation or a ureteropyelostomy) can be undertaken.

Results

A kidney transplant remains the most common solid organ transplant in the world today. With the introduction of induction immunosuppressive therapy and ever-improving, less toxic immunosuppressive medications, posttransplant outcomes have become better and better. And, as noted above, posttransplant outcomes have continued to improve: in 2014 allograft and patient survival rates were well over 90%, and in 2015, the 1-year graft survival rate with a living donor kidney was nearly

98%; with a deceased donor kidney, the rate was approximately 95%.^{71,89}

The biggest improvements have been in the reduction of 1-year graft failure. With a deceased donor kidney, the 1-year graft failure rate dropped from approximately 20% in 1989 to less than 7% in 2009 to 4.8% in 2015; with a living donor kidney, the rate dropped from 8.5% in 1989 to less than 3% in 2015.⁸⁹ Furthermore, steroid-free protocols⁹⁰ and calcineurin-free protocols⁹¹ have been validated and implemented in the last several decades, further reducing medication-related side effects and vastly improving the quality of life for tens of thousands of recipients.

Currently, the most common cause of graft loss is recipient death (usually from cardiovascular causes) with a functioning graft. The second most common cause is chronic allograft nephropathy; characterized by a slow, unrelenting deterioration of graft function, it likely has multiple causes (both immunologic and nonimmunologic).^{92,93} The graft failure rate due to complications related to surgical technique has remained at about 1% to 2%.

PANCREAS TRANSPLANTATION

A successful pancreas transplant currently is the only definitive long-term treatment for patients with insulin-dependent diabetes mellitus (IDDM) that (a) restores normal glucose hemostasis without exposing patients to the risk of severe hypoglycemia and (b) prevents, halts, or, in some cases, reverses the development or progression of secondary complications of diabetes.⁹⁴

Given its vast medical, social, and financial implications, diabetes mellitus is a huge burden to patients and to society as a whole. An estimated 10% to 15% of the U.S. population is affected by it; of all diabetic patients, 10% have early-onset disease. In the United States, diabetes mellitus is the most common cause of end-stage kidney disease, blindness, impotence, major limb amputations, and coronary or peripheral vascular bypass procedures. It is one of the most common causes of death, along with myocardial infarction and stroke. Diabetes significantly decreases not only the quality of life but also life expectancy.

Despite improvements in exogenous insulin administration (including the use of devices such as insulin pumps), wide fluctuations in glucose levels and the risk of hypoglycemic episodes are common. The Diabetes Control and Complications Trial (DCCT) demonstrated in the late 1990s that intensive insulin therapy may slow the rate of secondary complications of diabetes—yet at the expense of (life-threatening) iatrogenic hypoglycemia. The annual mortality rate of patients with insulin-induced inadvertent hypoglycemia is estimated to be as high as 2% to 3%.

Since the first pancreas transplant in December 1966, performed by William Kelly and Richard Lillehei at the University of Minnesota, more than 25,000 pancreas transplants in the United States and more than 10,000 pancreas transplants from all over the world have been reported to the International Pancreas Transplant Registry (IPTR).^{94,95}

Pancreas transplants are performed in three recipient categories:

- *Simultaneous pancreas and kidney (SPK) transplant in diabetic and uremic patients.* Almost 80% of pancreas transplants are performed in this category. The recipient is already

obligated to lifelong immunosuppressive therapy, due to the need for a kidney transplant, so only the surgical risk of a pancreas transplant is added. A successful SPK transplant renders the recipient dialysis-free and insulin-independent.

- *Pancreas after kidney (PAK) transplant in diabetic and posturemic patients.* Approximately 15% of all pancreas transplants fall into this category. These patients previously underwent a kidney transplant with either a living or deceased donor, but are candidates for a subsequent pancreas transplant because of poor glucose control or because of progression of secondary diabetic complications (which may include the development of diabetic nephropathy in the transplanted kidney).
- *Pancreas transplant alone (PTA) in nonuremic patients with brittle diabetes mellitus.* Only about 5% of all pancreas transplants are in this category. These patients have not yet developed advanced diabetic nephropathy, but their glucose levels are extremely labile despite best efforts of control. Because of the lifelong need for immunosuppressive therapy, the surgical risk has to be balanced with the medical risks of brittle diabetes (e.g., frequent episodes of hypoglycemia and hypoglycemic unawareness).

In SPK recipients, a plethora of literature exists that demonstrates significant improvements in secondary diabetic complications (across all organ systems) posttransplant. Improvements have been reported in diabetic nephropathy, neuropathy (autonomic and peripheral), micro- and macrovascular disease, retinopathy, gastroparesis, and other secondary complications.⁹⁶ Currently, more than 1000 pancreas transplants are performed annually in the United States, with the goal of conferring the following benefits: excellent glucose control (similar to that of a functioning native pancreas), prevention or improvement of secondary diabetic complications, and increased quality of life and life expectancy. In addition, pancreas transplants can be successfully performed in patients who have undergone a total pancreatectomy for benign disease (such as chronic pancreatitis) to treat both endocrine and exocrine deficiency after surgery.⁹⁷

Donor Operation

The general criteria for selecting deceased donors for pancreas procurement are similar to those for other solid organs; a history of type 1 diabetes mellitus obviously is a contraindication. Relative contraindications include previous pancreatic procedure(s), as well as pancreatic disorders, such as chronic pancreatitis and intraductal papillary mucinous neoplasm. Hyperglycemia in itself is not a contraindication to pancreas procurement because its cause in brain-dead donors usually is severe insulin resistance, which is rarely observed in recipients.

In light of better anatomic understanding and improved surgical skills, all three abdominal organs that share a common blood supply (pancreas, liver, and intestine) can be procured at the same time and transplanted into three different recipients (Fig. 11-10). During pancreas procurement, a “no-touch” technique of the gland is preferred; dissection of the pancreas is carried out in a way that avoids direct manipulation of the organ such that simultaneous procurement of the spleen, duodenum, and surrounding connective tissues occurs.

In contrast to the liver and kidneys, the pancreas should not be extensively flushed at the end of the procurement. To minimize the amount of preservation fluid that reaches the pancreas, the splenic artery and SMA can be temporarily clamped

Figure 11-10. Simultaneous pancreas, in situ split-liver, and intestine procurement. IPDA = inferior pancreaticoduodenal artery; LHV = left hepatic vein; MCA = middle cerebral artery; MHV = middle hepatic vein; RCA = right coronary artery; RHV = right hepatic vein. (Reproduced from Gruessner RWG, Sutherland DER: Transplantation of the Pancreas. New York, NY: Springer, 2004.)

at their origin from the aorta. Usually, the celiac axis with an aortic Carrel patch is retained with the liver. The splenic artery is divided close to its origin and is retained with the pancreas. The SMA is also procured with an aortic Carrel patch and is retained with the pancreas.

In case of a replaced or aberrant right hepatic artery, this first branch off of the SMA is carefully dissected out from the posterior surface of the pancreas. A replaced or aberrant right hepatic artery does not transverse the pancreas and is not a contraindication to combined pancreas and liver procurement. But with this anatomic variant, an aortic Carrel patch with the proximal SMA and replaced or aberrant right hepatic artery remains with the liver; the distal SMA with the inferior pancreaticoduodenal artery remains with the pancreas.

In the relatively rare event that the liver is not procured, then neither the splenic nor the gastroduodenal arteries need to be divided at their respective takeoff; the donor's celiac axis and the SMA are included on a common Carrel patch. This technique allows a single arterial anastomosis to be performed in the recipient without reconstruction. At the end of the procurement, the pancreas is attached to the spleen, duodenum, and proximal jejunum, which is stapled at both ends.⁹⁸

Back Table Preparation of the Pancreas Graft

Back table preparation of the pancreas graft consists of four steps: (a) removal of the spleen; (b) shortening, restapling, and/

or suture reinforcement of the mesenteric root; (c) trimming of any excess distal and proximal duodenum, along with reinforcement of the proximal staple line; and (d) arterial reconstruction.

Back table preparation is carried out in a basin filled with chilled preservation solution. The most common technique to create a single arterial inflow to the pancreas graft is the "Y-graft" reconstruction, using a resected segment of the donor iliac artery bifurcation. In this technique, the donor external iliac artery is anastomosed end-to-end to the donor SMA, and the donor internal iliac artery is anastomosed end-to-end to the splenic artery (Fig. 11-11). This procedure allows the donor common iliac artery to be anastomosed as a single vessel to the recipient's common iliac artery. For venous outflow, the portal vein is kept relatively short, in order to avoid the risk of venous thrombosis by kinking or impingement.⁹⁸

Recipient Operation

Over the years, different surgical techniques have been described for (a) the management of exocrine pancreatic secretions and (b) the type of venous drainage. For the secretions, the two most common techniques are drainage of the duodenal segment to the bladder (bladder drainage) or to the small bowel (enteric drainage) (Figs. 11-12 and 11-13). For venous drainage, systemic venous drainage is preferred over portal venous drainage.

The pancreas graft is usually placed intra-abdominally and preferably on the right side because the iliac vessels are

Figure 11-11. Posterior view of the pancreas graft with Y-graft reconstruction. EIA = external iliac artery; IIA = internal iliac artery; SA = splenic artery; SMA = superior mesenteric artery. (Reproduced from Gruessner RWG, Sutherland DER: *Transplantation of the Pancreas*. New York, NY: Springer, 2004.)

in a more shallow position on the right than on the left side; moreover, the vessels are already appropriately aligned for the vascular anastomoses (i.e., a lateral position for the common iliac vein, a medial position for the common iliac artery). Venous and arterial anastomoses are performed end-to-side. After restoration of blood flow to the graft, hemostasis must

be meticulously maintained. Because the donor portal vein purposely is kept short, ligation and transection of all of the recipient's internal iliac vein branches are frequently performed in order to prevent tension on the venous anastomosis. The pancreas usually is placed with the pancreatic head and duodenum pointing caudally.

Bladder drainage is performed using either a hand-sewn or a stapled anastomosis in which the antimesenteric side of the donor duodenum is sewn to the superior portion of the dome of the bladder. The stapled technique requires that a circular cutting stapler be inserted through the open distal end of the donor duodenum, which is subsequently closed. Bladder drainage has two main advantages. First, rejection of the exocrine pancreas precedes rejection of the endocrine pancreas by 5 to 7 days. Amylase levels are measured routinely in the recipient's urine. With bladder drainage, antirejection treatment can successfully be implemented when the recipient is still normoglycemic and only hypoamylasuric. In the absence of hyperglycemia, more than 90% of pancreas rejection episodes are reversible. Second, bladder drainage avoids the bacterial contamination that occurs with enteric drainage. If an anastomotic leak occurs, it is easier to treat because the infection usually remains localized to the right lower quadrant.

Enteric drainage is more physiologic and has advantages as well. The antimesenteric side of the donor's duodenum is anastomosed to the antimesenteric portion of the recipient's jejunum in a side-to-side fashion. The enteric anastomosis can also involve a defunctionalized Roux-en-Y loop, which minimizes the potential complications if an enteric leak occurs.⁹⁸ Currently, in the United States, more than 80% of all pancreas transplants are performed with enteric drainage for the exocrine pancreatic secretions, and more than 90% employ systemic venous drainage.⁹⁵

Figure 11-12. Whole-organ transplant with systemic vein and bladder exocrine drainage. (Reproduced from Gruessner RWG, Sutherland DER: *Transplantation of the Pancreas*. New York, NY: Springer, 2004.)

Figure 11-13. Whole-organ transplant with systemic vein and enteric exocrine drainage. (Reproduced from Gruessner RWG, Sutherland DER: *Transplantation of the Pancreas*. New York, NY: Springer, 2004.)

Complications

The technical complication rate for pancreas transplants is higher than for any other solid organ transplant. Four factors contribute to the high surgical complication rate⁹⁹: (a) the nature of the organ itself with inherent organ-specific surgical complications (e.g., pancreatitis, abscesses, necrosis, fistulas, and pseudocysts) and its low blood flow (which significantly increases the risk of thrombosis, as compared with a kidney or liver transplant); (b) the risk of a leak or infection after connecting two hollow viscera (the duodenum and either the bladder or small intestine); (c) the increased incidence of rejection episodes because the pancreas is one of the most immunogenic solid organs; and (d) the underlying disease of diabetes mellitus, predisposing patients not only to infections but also to cardiovascular and other complications.

The most common surgical complications are thrombosis (an incidence of 5%–15%), intra-abdominal abscesses (5%–10%), and bleeding (6%–8%). Other pancreas-specific complications include graft pancreatitis (frequently due to procurement or reperfusion injury), pancreatic fistulas, and pancreatic pseudocysts. Anastomotic leaks do not always require a graft pancreatectomy, but arterial pseudoaneurysms, arteriovenous fistulas, and wound dehiscence may. Bleeding frequently requires relaparotomy.

Thrombosis usually occurs within the first week posttransplant. It manifests as a sudden increase in insulin requirements or as a sharp drop in urinary amylase levels. Venous thrombosis, which is more common than arterial thrombosis, is associated with distinct clinical symptoms, including a swollen and tender graft, hematuria, lower extremity edema, and deep vein thrombosis, the latter two occurring ipsilaterally. Arterial thrombosis is less symptomatic and may not initially cause pain; its diagnosis is usually confirmed by Doppler ultrasonography. Surgical exploration in recipients with thrombosis usually requires a graft pancreatectomy.

With the advent of advanced interventional radiologic procedures to drain intra-abdominal abscesses, the reoperation rate has markedly decreased. Pancreas transplant recipients are usually kept on broad-spectrum antimicrobial agents for the first 7 days posttransplant.

The most common nonsurgical complication posttransplant is rejection. The incidence of rejection is about 30% within the first year. The diagnosis is usually based on an increase in serum amylase and lipase levels and, in bladder-drained recipients, a decrease in urinary amylase levels. A sustained drop in urinary amylase levels greater than 25% from baseline should prompt a pancreas graft biopsy to rule out rejection. In enteric-drained recipients, one must rely on serum amylase and lipase levels only. Other signs and symptoms of rejection include tenderness over the graft, unexplained fever, and hyperglycemia, which usually is a late finding; fewer than 5% of all rejection episodes can be reversed in its presence. The diagnosis of rejection should be confirmed by a percutaneous pancreas graft biopsy.

Other nonsurgical complications include infections with CMV, HCV, or extra-abdominal bacteria or fungi; malignancies, such as PTLD; and, rarely, graft-versus-host disease. For such complications, the diagnosis and treatment are similar to what is recommended after other solid organ transplants.

Bladder-drained pancreas recipients may experience an array of unique urologic complications. Usually the result of the irritating nature of pancreatic enzymes on the urothelium in the bladder and urethra, these urologic complications can lead to cystitis, hematuria, and dysuria. With the loss of bicarbonate from pancreatic secretions, dehydration and metabolic acidosis are not uncommon. Many of these complications are chronic, such that approximately 20% to 30% of all bladder-drained recipients require conversion to enteric drainage within the first 5 years posttransplant.¹⁰⁰

Living Donor Pancreas Transplants

Pancreas transplants using living donors also can be performed safely and successfully in select donors and recipients. Since 1979, about 150 such transplants have been performed worldwide, with 1-year graft survival rates in excess of 85% over the last decade. A meticulous donor evaluation using standard criteria remains key to a low donor metabolic and surgical complication rate. The concept of procuring the distal pancreas from a living donor is based on the observation that patients with benign or malignant pancreatic disorders can undergo a distal hemipancreatectomy without any serious change in endocrine function.

Living donor pancreas transplants are ideal for patients with an identical twin, but other relatives can be suitable donors as well. In particular, patients with high PRA levels should be considered for a living donor transplant.

Living donor pancreas transplants decrease the number of deaths of diabetic patients on the waiting list, help overcome the organ shortage, reduce mortality and morbidity, and improve the quality of life for patients with debilitating side effects of diabetes. The use of living donors also reduces the risk of graft rejection, as compared with the use of deceased donors. Yet living donor pancreas transplants remain relatively rare, performed under very selective circumstances. In terms of surgical technique, the donor splenic artery and vein are anastomosed to the recipient's external iliac artery and vein in an end-to-side fashion, and exocrine drainage can occur via an anastomosis

Figure 11-14. Segmental transplant with systemic vein and bladder exocrine drainage. The donor splenic artery and splenic vein are anastomosed end-to-side to the recipient's external iliac artery and vein. The splenic artery anastomosis is lateral and proximal to the splenic vein anastomosis. A two-layer ductocystostomy is constructed. of the pancreatic duct and transected end of the pancreas to the bladder or bowel¹⁰¹ (Fig. 11-14).

Results

As of December 2010, more than 35,000 pancreas transplants had been reported to the IPTR: more than 25,000 transplants in the United States and more than 10,000 in other countries. According to IPTR data, recipient age at the time of the transplant has increased significantly, and so has the number of transplants for patients with type 2 diabetes. The trend over time has been toward stricter donor criteria, with a concentration on younger donors, preferably trauma victims, and on short pancreas graft preservation time.

Drainage techniques have changed over time, too: enteric drainage of exocrine pancreatic secretions is now predominant, in combination with systemic drainage of the venous effluent of the pancreas graft. Immunosuppressive protocols have developed toward antibody induction therapy, followed by administration of tacrolimus and MMF for maintenance. Steroid avoidance has increased over time in all three recipient categories.

Between 2005 and 2009 and 2010 and 2014, the number of U.S. pancreas transplants declined by over 20%, while the overall number of pancreas transplants performed outside the United States has increased. The decline in U.S. numbers is predominantly due to the decline in primary and secondary pancreas after kidney transplants (PAK). During the time period studied, the number of PAK transplants dropped by 50%. In contrast, the number of simultaneous pancreas/kidney transplants (SPK) declined by only 10%, and the number of pancreas transplants alone (PTA) by 20%. Over 90% of pancreas transplants worldwide were performed, with a simultaneous

kidney transplant and excellent results. Transplant outcomes in SPK improved significantly because of a decrease in the rates of technical and immunologic graft loss. In 2010 to 2014 vs. 2005 to 2009, U.S. SPK transplant patient survival at 1 year posttransplant increased from 95.7% to 97.4%, pancreas graft function increased from 88.3% to 91.3%, and kidney function increased from 93.6% to 95.5%. A significant improvement was also noted in PAK transplants. One-year patient survival increased from 96.4% to 97.9%, and pancreas graft function increased from 81.0% to 86.0%. PTA 1-year patient survival remained constant at 97%, and pancreas 1-year graft survival improved from 81.0% to 85.7%. IPTR data show significant improvements in patient survival and pancreas graft function rates since the inception of UNOS, over a course of 24 years.^{92,95,99,102} Clearly, pancreas transplants now offer excellent outcomes for patients with IDDM.

Islet versus Pancreas Transplants

Pancreas transplants are frequently compared with islet transplants (vide infra), which are less invasive and, therefore, more appealing. It is important to emphasize that these two types of transplants are not mutually exclusive but rather complementary. The results of islet transplants have improved over the past decade, but overall islet graft function, specifically long-term function, still significantly trails overall pancreas graft function.¹⁰³

6▶ Islet transplants involve pancreas procurement (as described earlier) and then separation of islets from the exocrine pancreatic tissues using proteolytic enzymes (as described later). The human pancreas contains about one million islets, of which half are lost during the isolation process. About 10,000 islets per kilogram of body weight are needed to achieve insulin independence when transplanted into the liver. Frequently, one donor pancreas does not suffice; in fact, up to four donor pancreases have been used for one islet recipient.

Because of the relatively disappointing long-term outcomes, insurance providers in the United States do not provide reimbursement for islet transplants. Transplant centers with both pancreas and islet transplant programs follow an algorithm that favors islet transplants in patients with a high surgical risk and pancreas transplants in patients with a low surgical risk. Although solitary donor pancreases are not in short supply, only one donor pancreas is required for a successful pancreas transplant; in contrast, two to four donor pancreases are commonly used for one islet recipient with less favorable long-term outcomes.

Of note, the primary goal of current islet transplant trials is not insulin independence but rather a reduction in the incidence and severity of hypoglycemic events, a reduction in exogenous insulin requirements, and an amelioration of hemoglobin A_{1c} levels. Islet transplants rarely maintain long-term insulin independence. A recent study showed a higher rate of insulin independence in PTA recipients than in recipients of an islet transplant alone, despite the use of up to three donor pancreases in each of the islet recipients.¹⁰⁴ Until islet transplant results significantly improve and include long-term insulin independence, a pancreas transplant remains the treatment of choice for β -cell replacement therapy in patients with IDDM.

ISLET TRANSPLANTATION

Transplanting islets of Langerhans isolated from deceased donor pancreases is an appealing option for patients with type 1 diabetes. An islet transplant involves the procurement of a

donor pancreas and its transportation to a specialized islet isolation facility, where the pancreas is enzymatically digested; then, the islets are purified from the rest of the digested pancreas using density gradients. The purified islets are then cultured and evaluated for their identity, viability, and potency, before being infused into the portal vein of a diabetic recipient. When the procedure is successful, these islet cells engraft into the recipient and secrete insulin, providing excellent moment-to-moment control of blood glucose, as is seen with a whole-pancreas transplant.

A successful islet transplant offers advantages over exogenous insulin injections—advantages that are similar to those of a whole-pancreas transplant. These advantages include restoring β -cell secretory capacity, improving glucose counterregulation, restoring hypoglycemia awareness, providing perfect or near-perfect glucose homeostasis, and, potentially, preventing secondary diabetic complications.

Unlike a whole-pancreas transplant, an islet transplant does not involve a major surgical procedure with its associated mortality and morbidity. Instead, it can generally be performed as an outpatient procedure using percutaneous catheter-based therapy to cannulate a branch of the portal vein, with minimal recovery time for the recipient. Potential complications associated with islet injection include portal hypertension, portal vein thrombosis, hepatic abscesses, and bacteremia. Theoretically, islet transplants could have wider application (as compared with current practice and with whole-pancreas transplants), given the significantly lower surgical risk, the relatively small tissue volume transplanted, and the potential for islet immunomodulation or immunoisolation, which could minimize or eliminate the need for immunosuppression.

The first reported attempt at an islet transplant was in 1893 by Watson-Williams and Harsant: they transplanted a sheep's minced pancreas into the subcutaneous tissue of a young boy with ketoacidosis.¹⁰⁵ The discovery of insulin may have reduced interest in islet transplants as a treatment for diabetes, at least until the realization that insulin could not provide perfect glycaemic control and that, therefore, patients ultimately suffered devastating secondary complications. Several milestones ensued: the first whole-pancreas transplants,¹⁰⁶ early success with rodent islet transplants,¹⁰⁷ and then, in the 1970s, human islet *autotransplants* after pancreatectomy, in order to address the intractable pain associated with chronic pancreatitis, by Sutherland, Najarian, and colleagues in Minnesota.¹⁰⁸

Until recently, attempts to extend those trailblazing findings of clinical islet autotransplants to clinical islet *allografts* in patients with type 1 diabetes met with generally very poor success. For example, in 1995, a report of the International Islet Transplant Registry indicated that of 270 recipients, only 5% were insulin-independent at 1 year posttransplant.

In 2000, Shapiro and colleagues reported the results of the Edmonton protocol, which enabled consistent diabetes reversal and short-term (<1 year) insulin independence.¹⁰⁹⁻¹¹¹ The Edmonton protocol prescribed transplanting a large number of freshly isolated islets (>10,000 islet equivalents per kilogram body weight, typically requiring the use of two to four pancreases) with a specialized “islet-sparing,” steroid-free immunosuppressive protocol consisting of low-dose tacrolimus, sirolimus, and IL-2 receptor antibody induction. Those results were replicated at other experienced transplant centers,^{112,113} but the rates of long-term (>5 year) insulin independence remained poor, well below those of whole-pancreas transplants.¹¹⁴ Still,

despite the low rates of long-term insulin independence, most islet recipients were C-peptide positive and retained hypoglycemia awareness, indicating residual islet function and benefit. In fact, at 9 years posttransplant, 15% remained insulin-independent, and 73% had hypoglycemia awareness and corrected hemoglobin A_{1c} levels.¹¹⁵

In the mid-2000s, new trials began with the goal of establishing protocols that enable insulin independence, using islets from a single donor pancreas; the results were good, especially with strict donor and recipient selection.^{116,117} In the most experienced centers, long-term rates of diabetes reversal are now about 50% at 5 years posttransplant. The reasons include refinements in pancreas preservation, islet isolation, and culture protocols, as well as the use of newer induction immunosuppressive agent combinations, such as a T-cell-depleting antibody (anti-CD3 antibody, alemtuzumab, or antithymocyte globulin) and a tumor necrosis factor- α (TNF- α) inhibitor (etanercept or infliximab). Presumably, viable β -cell mass is now preserved, both pre- and posttransplant.¹¹⁶⁻¹²⁰ Thus, islet transplant results are approaching those of whole-pancreas transplants; however, because islets from more than one pancreas are typically needed, those results cannot be directly compared with the results of whole-pancreas transplants.^{121,122}

In the United States, an islet transplant is still officially deemed an experimental procedure. In contrast, since 2001, it has been considered a standard of care and is fully reimbursed in Canada and, more recently, in the United Kingdom, Sweden, Switzerland, France, and Italy as well.¹¹⁸ The full potential of islet transplants remains to be realized, but the future is exciting. As the latest improvements in pancreas preservation, islet isolation and purification, islet culture, and islet immunoisolation are implemented clinically, the hope is that sustained insulin independence may become consistently possible with a single pancreas donor and without the need for systemic immunosuppression.

LIVER TRANSPLANTATION

The first attempts at liver transplants in the late 1960s through the 1980s were largely experimental endeavors, with a 1-year survival rate of only 30%. But breakthroughs in immunosuppression, surgical technique, organ preservation, anesthesia, and critical care have improved that rate to approximately 85% today. Liver transplants remain daunting, especially in the face of an organ shortage that results in sicker potential candidates. Unfortunately, the perioperative mortality rate and the 1-year mortality rate are among the highest of any surgical operation currently performed.

History

The first experimental liver transplants in dogs are often attributed to C. Stuart Welch in 1955 and then Jack Cannon in 1956. However, current scholarship reveals that Vittorio Staudacher first described the technique in 1952.¹²³ A series of canine experiments followed, which refined the surgical technique to ensure perioperative survival.

The next obstacle—immunologic rejection—was addressed by drug immunosuppression with AZA and prednisone. The first human liver transplant trials started in 1963 with Thomas Starzl, but a series of deaths led to a voluntary moratorium for 3.5 years. With the resumption of clinical transplants in 1967, Starzl performed the first successful liver transplant.

Still, for the next decade, survival rates were dismal: only 20% of the 170 liver transplant recipients in Starzl's program at the University of Colorado survived more than 5 years.¹²⁴

Several innovations dramatically improved outcomes. The advent of better immunosuppressive drugs was instrumental. In 1978, cyclosporine was introduced clinically in England. It was soon combined with prednisone to great effect. The arrival of tacrolimus in the 1990s further improved graft survival.

Technical advances were also significant. Donor procurement techniques and cold organ preservation protocols were standardized, and the recipient operation was also refined. Choledochocholedochostomy or choledochojejunostomy to a Roux-en-Y limb became standard and significantly decreased the frequency of biliary complications. Innovations, including living donor liver transplants and deceased donor split-liver transplants, enabled more pediatric recipients to be transplanted. Improvements in portosystemic shunting and perioperative critical care also were contributory.

Indications

In general, any form of irreversible liver disease is an indication for a liver transplant. Chronic alcoholic disease and HCV are the most common indications in the United States. An extensive list of acute and chronic diseases of the liver that are treatable by a liver transplant is provided in Table 11-6.

Offering transplants to alcoholic patients has always drawn some opposition because of the perception of it being a self-inflicted illness, as well as concerns about recidivism and the recipient's possible inability to maintain postoperative immunosuppression and care. Yet studies have shown that such patients have excellent outcomes and that liver transplants for

them are cost-effective.¹²⁵⁻¹²⁷ Because patients who drink 4 to 8 ounces of liquor daily for 10 to 15 years have an increased risk of developing cirrhosis, the general requirement for acceptance as a transplant candidate is 6 months of abstinence. Furthermore, most transplant centers recommend rehabilitation and Alcoholics Anonymous programs.

Transplants for HCV have yielded worse outcomes than transplants for other diseases.¹²⁸ The reason is the universal recurrence of the virus posttransplant. Viral levels reach pretransplant levels as early as 72 hours posttransplant.¹²⁹ The course of the viral infection is often accelerated posttransplant: 10% to 20% of recipients develop cirrhosis after just 5 years.¹³⁰ Studies have suggested that use of older donors may increase the chance of aggressive recurrence.¹³¹ The best method to prevent recurrence would be to eradicate the infection pretransplant, but doing so is not always possible because patients with decompensated cirrhosis often cannot tolerate treatment. Once recurrence occurs, treatment methods are limited. One study found that pegylated interferon and ribavirin therapy achieved a sustained viral response in 44% of patients.¹³²

A substantial number of patients undergo liver transplants for cholestatic disorders. Primary biliary cirrhosis, an autoimmune disease, is characterized by damage to the intralobular bile ducts that progresses to liver cirrhosis. Trends toward earlier treatment may explain the slight decrease in liver transplants for this disorder.¹³³ Posttransplant outcomes in patients with this disorder have been excellent, with many centers achieving 1-year survival rates of 90% to 95%. Recurrence is relatively uncommon: a large series reported a 30% recurrence rate at 10 years posttransplant.¹³⁴

The second most common cholestatic disorder among liver transplant candidates is primary sclerosing cholangitis. It is characterized by inflammation and fibrosis of large intra- and extrahepatic biliary ducts; 70% of such patients also have inflammatory bowel disease. Recurrent cholangitis is common and increases mortality rates beyond what would be expected on the basis of laboratory values. On behalf of such patients, appeals can often be made for priority in allocation to the UNOS regional review boards. Posttransplant outcomes for such patients have been excellent. Primary sclerosing cholangitis is a significant risk factor for cholangiocarcinoma, so annual screenings (including imaging and measurement of serum CA 19-9 levels) should be carried out. Recurrence is fairly uncommon: studies have reported a recurrence rate of up to 20% at 10 years posttransplant.¹³⁵

Progressive metabolic disorders also are treatable with liver transplants. Hemochromatosis, an inherited disorder, results in excessive intestinal iron absorption. Iron deposition can cause cirrhosis and severe cardiomyopathy. Careful cardiac evaluation is necessary pretransplant.

Another metabolic disorder, α_1 -antitrypsin deficiency, is characterized by insufficient levels of a protease inhibitor, resulting in early-onset emphysema and cirrhosis. Careful pulmonary evaluation is necessary pretransplant.

Wilson's disease, an autosomal recessive disorder characterized by impaired cellular copper transport, leads to copper accumulation in the liver, brain, and cornea. Patients can develop significant neurologic complications and cirrhosis. Several reports suggest improvement of neurologic deficiencies posttransplant.^{136,137}

Transplants can also be performed in patients with hepatic malignancies, but only in accordance with strict criteria.

Table 11-6

Diseases amenable to treatment by a liver transplant

Autoimmune liver diseases
Autoimmune hepatitis
Primary biliary cirrhosis
Primary sclerosing cholangitis
Congenital
Biliary atresia
Viral hepatitis
Hepatitis B
Hepatitis C
Alcoholic liver disease
Metabolic diseases
α_1 -Antitrypsin deficiency
Cystic fibrosis
Hemochromatosis
Tyrosinemia
Wilson's disease
Hepatic malignancy
Hepatocellular carcinoma
Neuroendocrine tumor metastatic to liver
Fulminant hepatic failure
Other
Alagille syndrome
Cryptogenic cirrhosis
Budd-Chiari syndrome
Polycystic liver disease
Amyloidosis

Hepatocellular carcinoma (HCC), a complication of cirrhosis, is the most common type of hepatic malignancy. Resection is the first line of treatment if possible, but often, cirrhosis is too advanced. If the tumor meets the Milan criteria, a liver transplant can be performed. These criteria were established by a landmark paper in 1996 showing that patients with a single tumor under 5 cm in diameter, or with three tumors under 3 cm in diameter, in the absence of vascular invasion, had a 4-year survival rate of 85%.¹³⁸ Patients with such tumors receive exception points, based on their UNOS region, allowing for a timely transplant before their tumors spread.

Transplants for cholangiocarcinoma remains controversial but may be performed if the center has an experimental protocol in place that entails strict recipient selection. The use of a multimodality oncologic approach including neoadjuvant chemo radiotherapy with subsequent OLT achieves excellent results for patients with localized, regional lymph node-negative phCCA. Patient survival after OLT is comparable to the results of OLT for other causes.¹³⁹

Acute fulminant hepatic failure also is an indication for a liver transplant; in fact, such patients are the highest priority for the next available liver in their UNOS region. This devastating illness is defined by acute and severe liver injury with impaired synthetic function and encephalopathy in a person who had normal liver function. It is often caused by acetaminophen overdose; acute fulminant viral hepatitis A, B, and E; other viral infections; drug toxicity; ingestion of *Amanita* mushrooms; acute fatty liver of pregnancy; or Wilson's disease. A significant number of patients will recover with supportive care. The difficulty lies in predicting who will *not* recover and therefore would benefit from a liver transplant. The King's College criteria were developed for this purpose: patients with acetaminophen-induced disease, a pH <7.3 or grade III/IV encephalopathy, a prothrombin time >100 seconds, and serum creatinine >3.4 mg/dL meet those criteria.¹⁴⁰ Management of acute liver failure is very intensive. Such patients suffer from severe coagulopathy, hypoglycemia, lactic acidosis, and renal dysfunction. They are susceptible to infections, which are frequently overwhelming. Cerebral edema, a serious complication of acute liver failure, is a leading cause of death from brain herniation. Intracranial pressure monitoring and serial imaging are often necessary; if a patient develops irreversible brain damage, a transplant is not performed.

Recipient Selection

The diagnosis of cirrhosis itself is not an indication for a transplant. Patients may have compensated cirrhosis for years such that the traditional indication for a transplant is decompensated cirrhosis, manifested by hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, portal hypertensive bleeding, and hepatorenal syndrome (each described below).

Hepatic encephalopathy is an altered neuropsychiatric state caused by metabolic abnormalities resulting from liver failure. The early stages result in sleep disturbances and depression. As the liver disease progresses, patients can become somnolent and confused and, in the end stages, comatose. Ammonia is produced by enterocytes from glutamine and from colonic bacterial catabolism, and the use of serum ammonia levels as a marker of encephalopathy is controversial because a variety of factors can influence levels. Hyperammonemia suggests worsening liver function and bypass of portal blood flow around the liver. GI bleeding and infection can exacerbate hepatic encephalopathy.

Ascites (the accumulation of fluid in the abdominal cavity) that is caused by cirrhosis is a transudate with a high serum-ascites gradient (>1.1 g/dL). Associated with portal hypertension, it is treated initially with sodium restriction and diuretics. Refractory ascites necessitates large-volume paracentesis and eventually a transjugular intrahepatic portosystemic shunt (TIPS). Contraindications to TIPS placement include significant hepatic encephalopathy, advanced liver disease, congestive heart failure, renal insufficiency, and severe pulmonary hypertension.¹⁴¹

Spontaneous bacterial peritonitis, an infection of the ascitic fluid without an evident intra-abdominal source, is characterized by fever, abdominal pain, and an ascitic fluid polymorphonuclear count ≥ 250 cell/mm³ on paracentesis. The first line of empiric treatment is with a third-generation cephalosporin because the majority of cases are caused by aerobic gram-negative microbes such as *E. coli*, although Gram stain and culture results should be used to guide therapy.

Portal hypertensive bleeding can be a devastating event for patients with cirrhosis. Each bleeding event carries a 30% mortality rate and accounts for a third of all deaths related to cirrhosis. Only 50% of bleeding events cease spontaneously, so treatment must be expedient. The initial medical treatment is with vasopressin and octreotide. The initial intervention is endoscopy with sclerotherapy and band ligation of bleeding varices. If those initial attempts fail, more aggressive treatment is necessary with a balloon tamponade (using a Sengstaken-Blakemore tube) and with emergent TIPS placement. The last line of treatment is emergency surgery to place a portosystemic shunt, transect the esophagus, or devascularize the gastroesophageal junction (Sugiura procedure). Preventing variceal bleeding is essential and can be achieved, with some success, using β -blockers.

Hepatorenal syndrome is a form of acute renal failure that develops as liver disease worsens. The etiology is unclear, but splanchnic vasodilation from portal hypertension and increased production of circulating vasodilators result in a decline in renal perfusion. Characterized by oliguria (<500 mL of urine/day) and low urine sodium levels (<10 mEq/L), hepatorenal syndrome is often reversed by a liver transplant, even after dialysis dependence. Pretransplant, other causes of renal failure need to be excluded, including ATN, drug nephrotoxicity, and chronic renal disease. The initial medical therapy includes octreotide, midodrine, and vasopressin analogs, but the syndrome often progresses to dialysis dependence.

The Model for End-Stage Liver Disease (MELD) was originally developed to assess risk for TIPS placement.¹⁴² Later analysis revealed it to be an excellent model to predict survival among patients with cirrhosis, especially those on the waiting list for a liver transplant.¹⁴³ In 2002, liver graft allocation was restructured to be based on the MELD score.

Although the historic indication for a liver transplant is decompensated cirrhosis, a landmark analysis comparing waiting list mortality with posttransplant mortality established that a minimum MELD score of 18 is necessary to have a survival benefit posttransplant. A MELD score between 15 and 18 does not confer a survival advantage, but a transplant may be justified if the patient has significant morbidity from cirrhosis.¹⁴⁴

Acute liver failure itself is an indication for a liver transplant. To qualify for Status 1 (first priority for a donor liver within the UNOS region), the transplant candidate must meet the following criteria: (a) onset of hepatic encephalopathy within 8 weeks after the first symptoms of liver disease;

(b) absence of preexisting liver disease; and (c) ventilator dependence, dialysis, or an international normalized ratio (INR) >2.0 .

Contraindications

In general terms, contraindications to a liver transplant include insufficient cardiopulmonary reserve, uncontrolled malignancy or infection, and refractory noncompliance. Older age is only a relative contraindication: carefully selected recipients over the age of 70 years can achieve satisfactory outcomes.¹⁴⁵

Patients with reduced cardiopulmonary reserve are unlikely to survive a liver transplant. Candidates should have a normal ejection fraction. If coronary arterial disease is present, they should undergo revascularization pretransplant. Severe chronic obstructive pulmonary disease (COPD) with oxygen dependence is a contraindication. Severe pulmonary hypertension with a mean pulmonary artery pressure greater than 35 mmHg that is refractory to medical therapy is also a contraindication. Candidates with pulmonary hypertension should be evaluated with a right heart catheterization.

For candidates with alcoholic liver disease, few reliable predictors of posttransplant relapse exist.¹⁴⁶ Most centers require 6 months of abstinence from drugs and alcohol. Insurance companies often make more stringent demands, including random drug screening and 1 year of abstinence.

Uncontrolled infections pretransplant are a substantial risk posttransplant when the patient becomes significantly immunosuppressed. Fungal and multidrug-resistant bacterial infections are relative contraindications. Some centers require an extended period of treatment and documented eradication pretransplant. HIV infection is a relative contraindication; some centers have strict protocols that exclude patients with a history of acquired immunodeficiency syndrome (AIDS)-related illnesses as well as those who are coinfecting with HCV.

Ideally, patients with a history of malignancy (with the exception of HCC) should be cured of the cancer pretransplant. In most cases, this means eradication, completion of curative therapy, and absence of recurrence over a certain period of time, which varies by the tumor type, but can be up to 5 years or longer for aggressive tumors (see “Malignancies”).

Surgical Procedure

A liver transplant is among the most extensive operations performed, and it can be associated with considerable blood loss. A bilateral subcostal incision with midline extension is used. Mechanical retraction spreads the rib cage to allow access. The ligamentous attachments of the liver are dissected free. The vascular structures are isolated, including the suprahepatic and infrahepatic vena cava, the portal vein, and hepatic artery (Fig. 11-15). The bile duct, portal structures, and vena cava are divided, completing the hepatectomy (Fig. 11-16)—often the bloodiest and most difficult part of the operation, particularly in the presence of extensive varices and severe coagulopathy.

After the liver is removed, the anhepatic phase begins. This phase is characterized by the absence of inferior vena caval return to the heart and by portal congestion due to clamping of the portal vein. Significant hemodynamic instability and increased variceal bleeding can occur. Patients who are unable to tolerate this phase can be placed on venovenous bypass, with cannulas drawing blood from the IVC via the femoral vein and via the portal vein, returning it to the systemic circulation via the subclavian vein. Venovenous bypass itself can cause complications, including air embolism, thromboembolism, and trauma to the cannulated vessels.

Figure 11-15. Cirrhotic liver immobilized in preparation for complete hepatectomy.

The donor liver is placed in the orthotopic position. The suprahepatic vena caval anastomosis is performed first in an end-to-end fashion, followed by the infrahepatic vena caval and portal anastomosis, both also end-to-end. The liver is then reperfused, often leading to a period of hemodynamic instability and cardiac arrhythmias due to the release of byproducts of ischemia from the donor liver. Coagulopathy also can worsen because of these byproducts as well as fibrinolysis.

The arterial anastomosis between the donor common hepatic or celiac trunk is most often performed with the recipient CHA in an end-to-end fashion. Of course, many variations are possible. After arterial reperfusion, the bile duct anastomosis is performed between the donor and recipient common ducts, also in an end-to-end fashion. If necessary for technical reasons, the recipient common duct can be joined to a Roux-en-Y limb. Some surgeons choose to insert a T-tube or place internal stents in the common bile duct to protect the anastomosis.

The piggyback technique is a common variation of the standard technique. The recipient's IVC is preserved by carefully dissecting off the posterior aspect of the liver. This added dissection is a disadvantage of this variation, often increasing hepatectomy time and blood loss. The recipient's liver is

Figure 11-16. Isolation and division of the hilar structures to diseased liver-hepatic artery, portal vein, and common bile duct.

removed by dividing it at the confluence of the hepatic veins. The preserved IVC is an advantage of this variation, allowing venous return from the lower body to the heart during the anhepatic phase and improving renal perfusion. No randomized studies, however, have demonstrated the superiority of the piggyback technique over the standard technique.

Pediatric Transplants

Outcomes after pediatric liver transplants are among the best after any type of transplant, with a 1-year survival rate of 90%. The most common indication is biliary atresia. After diagnosis is confirmed, a Kasai procedure is promptly carried out: a Roux-en-Y loop of bowel is directly anastomosed to the hilum of the liver. The Kasai procedure often allows time for the children to grow in size, reducing the risk of a transplant when it is required, as it eventually is in 75% of such children.

The other common indication for a pediatric liver transplant is a metabolic disorder, such as α_1 -antitrypsin deficiency, tyrosine metabolism deficiencies, and primary oxalosis. Since the MELD score was developed for adults, pediatric liver allocation is based on an analogous model, the Pediatric End-Stage Liver Disease (PELD) score, which incorporates bilirubin levels, INR, albumin levels, age, and growth failure.

The surgical procedure is similar to the adult procedure. Graft implantation is more challenging, given the pediatric recipient's smaller vascular structures. As a result, surgical complications are much more common in pediatric recipients. Hepatic artery thrombosis is about three times more common. Donor size matching is very important in the pediatric population and often limits the donor pool for pediatric recipients. To address this issue, deceased donor split-liver transplants and living donor transplants (both described in the following sections) have been developed.

Deceased Donor Split-Liver Transplants

A deceased donor allograft can be split into two grafts, most frequently into a left lateral segment for a child and an extended right segment for an adult (Fig. 11-17). It can be done *in vivo* (during the donor operation) or *ex vivo* (on the back table after the donor liver is removed). Both techniques have similar outcomes. Increased morbidity is associated with splitting allografts, whether for adult or pediatric recipients; however, the technique is justified given the donor shortage and has been important for improving access to transplants for pediatric recipients.¹⁴⁷

Living Donor Transplants

Donation by an adult living donor to an adult recipient requires either the right or left lobe of the liver (Fig. 11-18). Donation by an adult living donor to a pediatric recipient requires the left lateral lobe (Fig. 11-19). Donor safety is paramount. The overall donor mortality rate after donation was 0.4%, and the overall complication rate was 40%, with multiple complications occurring in 19% of the patients. The rate of serious complications resulting in lasting disability was 1.1%, with liver failure or death in 0.4%.¹⁴⁸ Careful donor selection is vital. Potential donors should be medically and psychologically healthy, their hepatic anatomy should be amenable to donation, and absolutely no coercion can occur. A separate donor team should serve as the donor advocate and thoroughly explain all risks.

Careful recipient selection is essential. Transplant candidates also must qualify for a deceased donor liver transplant because a significant number of living donor transplant

Figure 11-17. Donor and recipient procedure for living donor liver transplant into a pediatric recipient.

recipients will eventually require a retransplant. Transplant candidates should be medically fit enough to withstand the rigors of the operation and of the postoperative course with a partial graft. An absolute contraindication is a critical illness: the limited success of such transplants does not justify the risks to the living donor. The obvious advantages of a living donor transplant are that it can be done expediently (avoiding the waiting list mortality associated with candidates for a deceased donor transplant) and that it can be planned.

Postoperative Care

A liver transplant imposes significant trauma on the major organ systems. Immediately posttransplant, the first goal is to stabilize those systems. Acid-base equilibrium and hemodynamic stability are often difficult to maintain but are essential. Periods of hypotension can increase the risk of hepatic artery thrombosis. Careful attention needs to be paid to ongoing bleeding. Appropriate hemoglobin levels should be maintained. Ongoing bleeding mandates a return trip to the operating room; the rate of reoperation can be as high as 25% among high-risk patients. Transfusion of platelets and fresh frozen plasma must be done prudently because theoretically their administration can increase the risk of hepatic artery thrombosis. Graft function should be evaluated frequently; if it is impaired, an ultrasound is urgently required to assess for the presence of vascular complications.

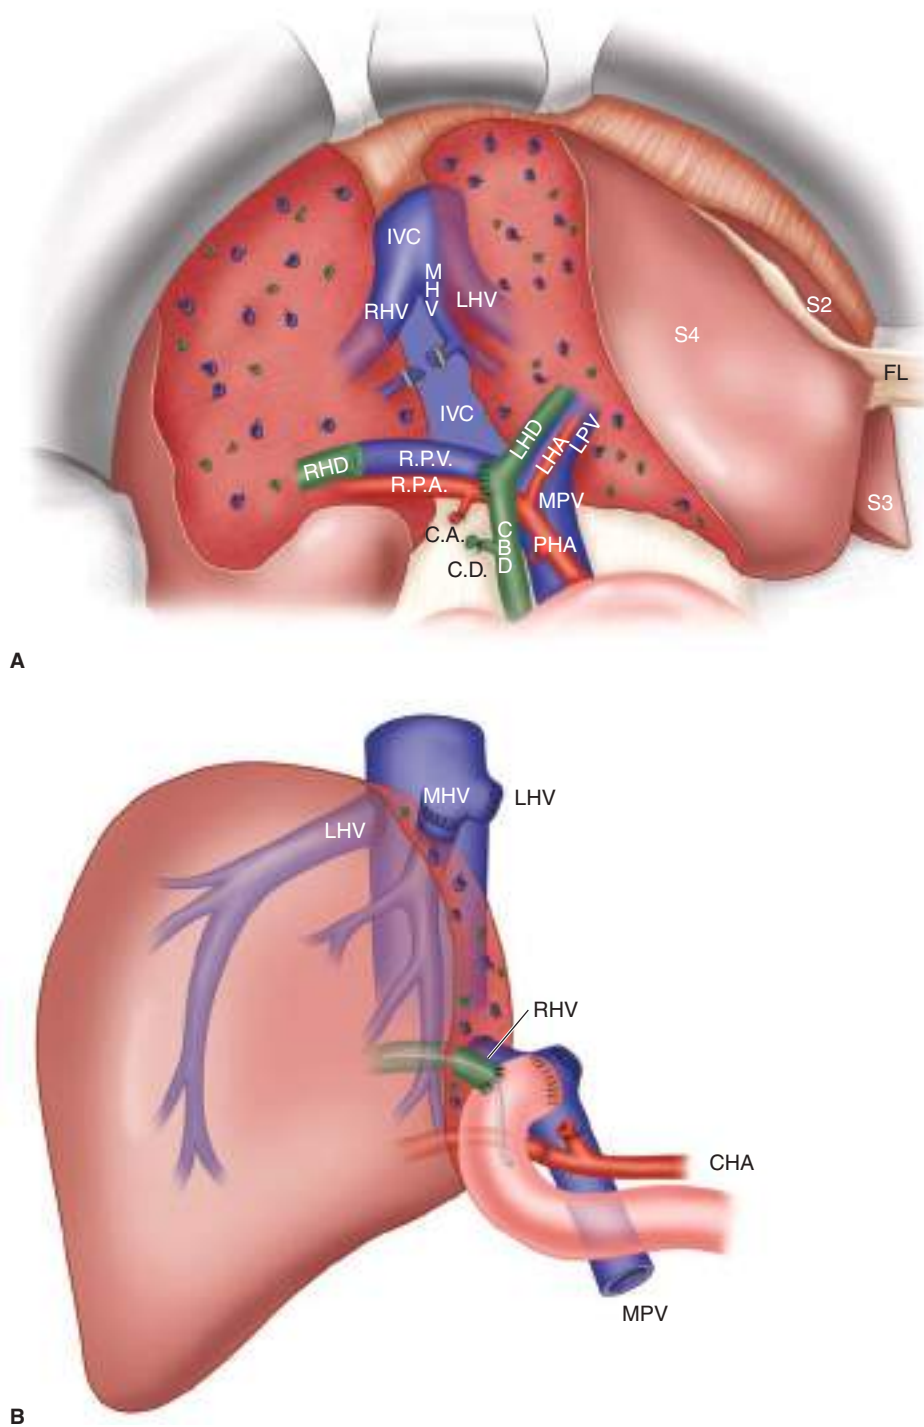

Figure 11-18. **A.** Hepatic transection completed for right lobe removal. CA = cystic artery; CBD = common bile duct; CD = cystic duct; FL = falciform ligament; IVC = inferior vena cava; LHD = left hepatic duct; LHV = left hepatic vein; MHV = middle hepatic vein; MPV = main portal vein; PHA = proper hepatic artery; RHA = right hepatic artery; RHV = right hepatic vein; RPV = right portal vein; S2, S3, S4 = segments 2, 3, and 4. **B.** Implantation of the donor right lobe with the MHV. CHA = common hepatic artery. (Reproduced with permission from Gruessner RWG, Benedetti E: Living Donor Organ Transplantation. New York, NY: McGraw-Hill Education; 2008.)

Evaluation of Graft Function

Evaluation of the graft begins in the operating room. Its appearance overall, any swelling, and the quantity and quality of bile production after reperfusion can help assess function. In the intensive care unit, hemodynamic stability, correction of coagulopathy, euglycemia, successful temperature

regulation, clearance of lactic acid, and restoration of neurologic status are all signs of a functioning graft, even before the first set of liver function test results are obtained. Transaminases usually peak by postoperative day 2. An aspartate transaminase (AST) level greater than 2500 IU/L is suggestive of significant injury. Cholestasis usually peaks from

Figure 11-19. **A.** Hepatic transection completed for removal of left lateral segments (S2 and S3). Bile ducts to segments 2 and 3 divided; vascular structures still intact. **B.** Implantation of the donor left lobe. (Reproduced with permission from Gruessner RWG, Benedetti E: Living Donor Organ Transplantation. New York, NY: McGraw-Hill Education; 2008.)

postoperative day 7 to 12. The INR should improve shortly after reperfusion.

In 3% to 4% of patients undergoing a liver transplant, the graft does not function for any identifiable reason, a condition termed primary nonfunction; in such cases, a retransplant is the only option. Some studies suggest that a peak AST level of 5000 IU/L may be predictive of primary nonfunction.¹⁴⁹⁻¹⁵¹ Factors associated with primary nonfunction include donor macrosteatosis, prolonged cold and warm ischemic times, and prolonged donor hospital stay.¹⁵¹

Complications

Vascular complications occur in about 8% to 12% of recipients and include thrombosis, stenosis, and pseudoaneurysm formation.

The most common vascular complication is hepatic artery thrombosis. Initial reviews suggest that its incidence is between 1.6% and 4%¹⁵²; the mortality rate is 50%, even after definitive therapy.¹⁵³ Early presentation can be quite dramatic, with fulminant hepatic necrosis, primary nonfunction, transaminitis, or fever. Late presentation, however, can be asymptomatic or subtle, with cholangitis, bile leak, mild transaminitis, hepatic abscesses, or failure to thrive. Diagnostic imaging with

ultrasound has more than 90% sensitivity and specificity. If hepatic artery thrombosis is identified, urgent reexploration is needed. A thrombectomy or revision of an anastomosis may be successful, but with significant hepatic necrosis, a retransplant is necessary.

Thrombosis of the portal vein is very uncommon. Signs of early thrombosis include liver dysfunction, ascites, and variceal bleeding. Upon diagnosis, an operative thrombectomy should be attempted.

Biliary complications remain the “Achilles’ heel” of liver transplantation, affecting 10% to 35% of these organ recipients. Signs include fever and abdominal pain, with bilious drainage from surgical drains. Diagnosis is made with cholangiography.

Complications manifest themselves as leaks or strictures. Leaks require a reoperation and surgical correction, whereas strictures can most often be managed with radiologic or endoscopic interventions. Two common reconstructions are choledochostomy and choledochojejunostomy. Some centers also routinely use T-tube stents or internal stents. Consensus has not been reached as to which reconstruction technique is superior. Early infectious complications are often associated with initial graft function and pretransplant risk factors. Intra-abdominal infections should raise concerns of a possible bile leak. Fungal infections are often associated with poor graft function. Given the immunosuppressed and compromised state of liver recipients, early infectious complications can be devastating.

The types of opportunistic infections that occur in liver transplant recipients are similar to those that occur in other types of solid organ transplant recipients and are due to suppression of cell-mediated immunity by chronic immunosuppressive drug administration.

Acute rejection occurs in approximately 20% of liver recipients. The first line of treatment is with a high dose of a corticosteroid, which is usually effective; if not, antilymphocyte therapy is initiated. Rejection of the liver (unlike other transplanted organs) does not adversely affect patient or graft survival rates. Maintenance immunosuppression consists of a corticosteroid, tacrolimus, and mycophenolate.

INTESTINE AND MULTIVISCERAL TRANSPLANTATION

After the introduction of long-term total parenteral nutrition (TPN) in the late 1970s and the early success of liver, kidney, and heart transplants, the first attempts at intestine transplants were made. Over the first two decades, the results were dismal. But the introduction of the immunosuppressive drug tacrolimus in the late 1980s led to significant improvement in graft and patient survival rates. Nonetheless, intestine transplants remain the least frequently performed of all transplants, with the lowest graft survival rates.

The main obstacle is the high immunogenicity of the intestine, caused by its abundant lymphoid tissue. High levels of immunosuppression are needed, yet the rejection rate is still high. The microbial colonization of the intestine confers the risk of translocation of pathogenic microorganisms into the recipient’s circulation, causing severe systemic infections. Through the first decade of the 21st century, the survival of patients on long-term TPN was superior to the survival of intestine transplant recipients, so a transplant was considered only as rescue therapy for patients with life-threatening TPN-related complications.

Over the last several years, improvements in surgical techniques, in perioperative and postoperative care, and particularly in immunosuppressive protocols have led to significantly better patient and graft survival rates posttransplant.¹⁵⁴ Recent data indicate that survival rates after an intestine transplant often are better than, or at least similar to, survival rates among patients receiving chronic TPN in the home setting with improved quality of life in selected patients.¹⁵⁵ Today, an intestine or multivisceral transplant is recognized as a feasible treatment.

Indications and Recipient Selection

An intestine transplant is indicated for patients with irreversible intestine failure in combination with TPN failure. The definition of intestine failure does not specify the exact length of the remaining intestine. Intestine failure is typically multifactorial. Variables include what part of the small intestine is absent, whether or not the ileocecal valve is present, whether or not the patient underwent an ostomy, and how long the remaining colon is. TPN failure is defined as significant biochemical or pathologic evidence of liver injury, loss of central vein access with thrombosis of at least two central veins, frequent indwelling catheter infection or a single episode of fungal infection, and recurrent episodes of severe dehydration despite IV fluid supplementation.

Indications for a transplant differ between the adult and pediatric population. The leading causes of intestine failure are summarized in Table 11-7. The disease involvement of organs other than the intestine dictates the extent of the operation required. Liver failure is often seen in patients on long-term TPN. If pathologic or biochemical evidence of severe liver damage is combined with signs of portal hypertension, then a combined liver-intestine transplant is the treatment of choice. However, a multivisceral transplant (liver, pancreas, stomach, duodenum, and/or small intestine) might be necessary among children who suffer diffuse intestinal dysmotility syndromes and adults who develop diffuse portomesenteric thrombosis, extensive intra-abdominal desmoid disease encasing the main visceral vascular structures with concurrent short gut syndrome, or massive abdominal trauma.

Table 11-7

Leading causes of intestine failure

CHILDREN	ADULTS
Gastroschisis	Visceral ischemia secondary to SMA/SMV thrombosis
Midgut volvulus	Crohn's disease
Intestinal atresia	Trauma
Necrotizing enterocolitis	Mesenteric desmoid tumors
Microvillus involution disease	Radiation enteritis
Hirschsprung's disease	Massive resection secondary to tumors
Crohn's disease	Chronic intestinal pseudo-obstruction
Pseudo-obstruction	Autoimmune enteropathy

SMA = superior mesenteric artery; SMV = superior mesenteric vein

Surgical Procedure

For both the donor and recipient surgery, the key decision is which organs will be transplanted.¹⁵⁶ For an isolated intestine transplant, the blood supply is based on the arterial inflow from the SMA and on the venous outflow from the superior mesenteric vein (SMV). Both vessels are isolated at the root of the mesentery.

For a combined liver-intestine transplant, the blood supply is based on the arterial inflow from the celiac axis and SMA, which are procured en bloc with an aortic patch. The liver, duodenum, pancreas, and small intestine—because of their close anatomic relationship—are procured en bloc. If the hepatoduodenal ligament is left intact, no biliary reconstruction is necessary, which virtually eliminates the risk of postoperative biliary complications.¹⁵⁷ Because the entire splanchnic system drains into the liver, venous drainage is achieved by anastomosis of the hepatic veins to the recipient's vena cava.

For both an isolated intestine transplant and a combined liver-intestine transplant, the proximal transection of the GI tract occurs at the first portion of the duodenum. For a multivisceral transplant, the stomach is part of the graft; hence, the transection of the GI tract occurs at the distal esophagus. Figures 11-20 to 11-22 show these three main types of transplants.

The vast majority of intestine transplants use a deceased donor organ. However, advances in surgical techniques have made the use of living donors a feasible alternative for either an isolated intestine transplant or a combined liver-intestine transplant. With a living donor, the donor operation is slightly different: for an isolated intestine transplant, 150 to 200 cm of the donor's ileum, on a vascular pedicle comprising the ileocolic artery and vein, are used¹⁵⁸ (Fig. 11-23); for a combined liver-intestine transplant, performed almost exclusively for pediatric recipients, segments II and III of the donor's liver are used, in addition to the intestine (Fig. 11-24).

Figure 11-20. Isolated intestine transplant.

Figure 11-21. Combined liver-intestine transplant.

Figure 11-22. Multivisceral transplant.

A

B

Figure 11-23. **A.** Donor operation. About 180 to 200 cm of distal ileum on a vascular pedicle comprising the ileocolic artery and vein are removed. **B.** Recipient operation. The donor's ileocolic artery and vein (or the terminal branches of the donor's superior mesenteric artery and vein) are anastomosed end-to-side to the recipient's infrarenal aorta and vena cava. (Reproduced with permission from Gruessner RWG, Benedetti E: Living Donor Organ Transplantation. New York, NY: McGraw-Hill Education; 2008.)

Figure 11-24. Recipient operation. For a combined living donor liver-intestine transplant in a pediatric recipient, liver segments 2 and 3 are implanted in standard fashion (the donor's left hepatic vein to the recipient's vena cava, the donor's left hepatic artery to the recipient's proper or common hepatic artery, the donor's left portal vein branch to the recipient's portal vein trunk). The donor's ileocolic artery and vein are anastomosed to the recipient's infra-renal aorta and cava. In the recipient, a duodenum-to-donor ileum anastomosis and a distal Bishop-Coop ileostomy are constructed to reestablish bowel continuity. A very short Roux-en-Y loop (10 to 20 cm) is anastomosed to the donor's bile duct(s). (Reproduced with permission from Gruessner RWG, Benedetti E: Living Donor Organ Transplantation. New York, NY: McGraw-Hill Education; 2008.)

Similarly, the recipient operation also varies by the organs transplanted. Generally, the recipient's infrarenal aorta is used to achieve the arterial inflow to the graft. For an isolated intestine transplant, venous drainage is achieved via systemic or portomesenteric drainage; for a combined liver-intestine transplant or a multivisceral transplant, venous drainage is achieved via the hepatic veins. Systemic venous drainage, given its lesser technical difficulty, is preferred over portomesenteric drainage. The diversion of splanchnic flow into the systemic venous circulation can cause several metabolic abnormalities, but no hard evidence shows any negative impact clinically on the recipient.

After the organs are perfused, the continuity of the recipient's GI tract is restored, which includes the placement of a gastrostomy or jejunostomy feeding tube and an ileostomy. In the early postoperative period, the ileostomy enables regular endoscopic surveillance and biopsy of the intestinal mucosa. Once the recipient recovers, the ileostomy can be taken down.

The last, but often the most difficult, part of the recipient operation is abdominal wall closure. It is especially

challenging in intestine transplant recipients because they have usually undergone multiple previous procedures, resulting in many scars, ostomies, feeding tubes, and the loss of abdominal domain. To provide sufficient coverage of the transplanted organs, the use of prosthetic mesh often is necessary.

Postoperative Care

Initial postoperative care for intestine transplant recipients does not significantly differ from that for other organ transplant recipients. In the intensive care unit, each recipient's cardiovascular, pulmonary, and renal function is closely monitored; aggressive resuscitation with fluid, electrolytes, and blood products is performed. Broad-spectrum antibiotics are an integral component of care.

Of all solid organ transplants, intestine transplants have the highest rate of rejection. With intestine transplants, no serologic marker of rejection is available, so frequent biopsies and histologic evaluation of the intestinal mucosa are of utmost importance. Rejection leads to structural damage of the intestinal mucosa. Translocation of endoluminal pathogens into the circulation can cause systemic infections.

Thanks to the introduction of new immunosuppressive protocols, the rejection rates and the overall patient and graft survival rates have improved significantly. Variations between the protocols exist, but the general concept is to induce immunosuppression with polyclonal T-cell antibody and high doses of a corticosteroid, followed by maintenance doses of corticosteroids and the calcineurin inhibitor tacrolimus.

Immediately, posttransplant, recipients are maintained on TPN. Enteral nutrition is initiated as early as possible, but it is advanced very cautiously. It can take several weeks for the transplanted intestine to achieve structural integrity and functionality and for the recipient to tolerate the full strength of tube feeds.

Despite all the recent advances, the complication rate posttransplant remains high. The most common complications include intra-abdominal abscesses, enteric leaks, intra-abdominal sepsis, the need for a reoperation, graft thrombosis, life-threatening bleeding, and central line problems. Immunosuppression-specific complications include rejection, PTLD, graft-versus-host disease (GVHD), infections, and malignancies. Tailoring the recipient's immunosuppression plays a critical role in preventing these complications: a low level of immunosuppression leads to graft rejection, but too much confers a high risk of infectious complications, PTLD, and, less commonly, GVHD—all of which are associated with a significantly increased risk of graft failure and mortality.

The long-term results of intestine transplants have improved significantly, even though they still remain inferior to the results of other abdominal organ transplants.^{159,160}

HEART AND LUNG TRANSPLANTATION

History

The first successful heterotopic heart transplant, in an animal model, was performed by Carrel and Guthrie in 1905.¹⁶¹ Subsequent progress with cardiopulmonary bypass and immunologic modulation facilitated the first successful adult human heart transplant, performed by Christiaan Barnard in 1967 in Cape Town, South Africa.¹⁶² However, it was Norman Shumway at Stanford who persisted with heart transplants, in the face of disappointing patient outcomes at a number of early centers.

Thanks to the diligence of Shumway and colleagues in perfecting heart transplant techniques, along with the development, by Caves, of endomyocardial biopsy as a method of allograft rejection surveillance, human heart transplants began to reappear in the 1980s as a viable solution to end-stage heart failure. By 1981, the introduction of cyclosporin A finally created the necessary clinical immunologic modulation necessary to make long-term survival of heart recipients a reality.¹⁶¹

Lung transplants have a similar history. In the 1950s, Metras in France and Hardin and Kittle in the United States performed canine lung transplants, demonstrating that meticulous anastomotic technique could produce normal pulmonary pressures. Hardy performed the first human lung transplant in 1963, although the patient lived only 18 days. The first successful long-term lung transplant was performed in 1983 in Toronto. These early lung recipients, however, were plagued by infection, rejection, and, most significantly, bronchial anastomotic dehiscence. Cooper and colleagues soon determined that the high-dose corticosteroids used for immunosuppression were responsible for the frequent occurrence of dehiscence. The combination of high-dose corticosteroids and ischemic donor bronchi was deadly to lung recipients. Cooper, Morgan, and colleagues showed that the bronchial anastomosis could be protected by wrapping it with a vascular omental pedicle, which not only provided neovascularity but also offered a buttress against any partial dehiscence.¹⁶³

Once cyclosporine became available for lung recipients, corticosteroid doses could be quickly tapered and stopped; cyclosporine poses no danger to the integrity of the bronchial anastomosis. In fact, the introduction of cyclosporine allowed the success of the first combined heart-lung transplant at Stanford in 1981 (after unsuccessful attempts by Cooley in 1969, Lillehei in 1970, and Barnard in 1981, all of whom used only high-dose corticosteroids for immunosuppression). The 1980s marked the start of the modern age of thoracic transplants.

Heart Transplants

Indications. The most common diagnosis leading to a heart transplant is ischemic dilated cardiomyopathy, which stems from coronary artery disease, followed by idiopathic dilated myopathy and congenital heart disease. About 3000 patients are added to the waiting list each year.

Evaluation. Pretransplant, both candidates and potential donors are evaluated to ensure their suitability for the procedure. Transplant candidates undergo echocardiography, right and left heart catheterization, evaluation for any undiagnosed malignancies, laboratory testing to assess the function of other organs (such as the liver, kidneys, and endocrine system), a dental examination, psychosocial evaluation, and appropriate screening (such as mammography, colonoscopy, and prostate-specific antigen testing). Once the evaluation is complete, the selection committee determines, at a multidisciplinary conference, whether or not a heart transplant is needed and is likely to be successful. Transplant candidates who meet all of the center's criteria are added to the waiting list, according to the UNOS criteria, which are based on health status.

Once a potential deceased donor is identified, the surgeon reviews the status report and screening examination results. The donor is initially matched to the recipient per the recipient's status on the UNOS waiting list, the size match, and the blood type. Results of the donor's serologic testing, echocardiography,

Figure 11-25. A donor's heart brought forward for anastomosis.

chest X-ray, hemodynamic testing, and possibly coronary artery evaluation are assessed, in order to determine whether or not the donor's heart can withstand up to 4 hours of cold ischemic time during procurement, transport, and surgery.

Procedure. Heart transplants are most often performed orthotopically (Fig. 11-25). The recipient's native heart is removed, leaving the superior vena cava, the IVC, the left atrial cuff, the aorta, and the pulmonary artery in situ, in order to allow for anastomosis of the donor's heart. Usually the left atrial cuff is anastomosed first, providing left heart inflow. Right heart inflow is achieved using a bicaval technique, by directly sewing the donor's superior vena cava and IVC to the recipient's venae cavae or by creating an anastomosis of the right atrium to a right atrial cuff. The donor's main pulmonary artery is connected to the recipient's pulmonary artery, and finally, the aortic anastomosis is completed (Fig. 11-26).

Once the cross-clamp is removed, the heart is allowed to receive circulation from the recipient and begins to function normally. Inotropic support with isoproterenol, dobutamine, or epinephrine is often required for 3 to 5 days, in order to support recovery from the cold ischemia.¹⁶⁴

On rare occasions, a heterotopic or "piggyback" heart can be transplanted, leaving the native heart in place. But this scenario is becoming very uncommon with the increasing use of mechanical circulatory support for single-ventricle failure.

Posttransplant Care. Patient survival rates for heart recipients differ slightly after primary transplants vs. retransplants. In 2016, 3209 heart transplants were performed in the United States. New, active listings increased 57% since 2005. Overall 1-year survival for patients who underwent heart transplant in 2009 to 2011 was 90.1%, 3-year survival was 83.5%, and 5-year

Figure 11-26. Suture lines for bicaval anastomosis (a), biatrial anastomosis (b), aortic anastomosis (c), and pulmonary artery anastomosis (d).

survival was 78.3%, and the most common cause of death within the first year after transplant was infection.¹⁶⁵ An increasing number of heart recipients have now survived more than 15 to 20 years with their first graft, especially those with no significant history of either cellular or antibody-mediated rejection.

Heart recipients must be monitored for both early and late complications. Early complications include primary graft dysfunction, acute cellular or antibody-mediated rejection, right heart failure secondary to pulmonary hypertension, and infection. Hemodynamic values are monitored to assess early graft function; pharmacologic and sometimes mechanical support is instituted if needed.

The goal of immunosuppression is to prevent rejection, which is assessed by immunosuppressive levels and, early on, by endomyocardial biopsy. Both T-cell-mediated (cellular) and B-cell-mediated (antibody-mediated) rejection are monitored. Most of the immunosuppression used is aimed at T cells; however, if the recipient has many preformed antibodies or develops donor-specific antibodies, other strategies (such as plasmapheresis or rituximab) are used to reduce the antibody load. Immunosuppressive regimens can vary by center, but most often consist of three categories of medications: a calcineurin inhibitor (usually tacrolimus or cyclosporine), an antiproliferative agent (MMF or AZA), and a corticosteroid (prednisone). Other immunosuppressive agents can be used, depending on the needs of individual recipients.

Recipients are also assessed for any infections, with visual inspection of wound healing and with monitoring of the complete blood count and cultures as needed. Other common early sequelae include drug-induced nephrotoxicity, glucose intolerance, hypertension, hyperlipidemia, osteoporosis, malignancies, and biliary disease.

Late complications include acquired transplant vasculopathy, progressive renal failure, and, most commonly, malignancies, especially skin cancer and PTLD. Accelerated coronary artery disease is the third most common cause of death posttransplant (after infections and acute rejection) and the most common cause after the first year. Coronary artery disease can begin to develop as early as 1 year posttransplant. Its pathogenesis is

unknown, but it is believed to be immunologic. Because of these late complications, most transplant centers continue to perform screening tests and recipient examinations at least annually after the first year.

Lung Transplants

Indications. The indications for a lung transplant include congenital disease, emphysema, COPD, cystic fibrosis, idiopathic pulmonary fibrosis, primary pulmonary hypertension, α_1 -antitrypsin deficiency, and the need for a retransplant after primary graft failure. Each year in the United States, about 1600 patients are added to the waiting list; nearly a third of them have COPD and/or emphysema. The next most common diagnosis among patients on the waiting list is cystic fibrosis. A lung allocation score (LAS) was instituted in 2005. The average lung transplant candidate requires oxygen (often 4 L/min or more at rest) and has an extensively compromised quality of life, as documented by the results of pulmonary function and 6-minute walk tests.

Evaluation. Evaluation for a lung transplant is very similar to evaluation for a heart transplant, except that lung transplant candidates undergo more extensive pulmonary function testing, a 6-minute walk test, chest computed tomography, ventilation-perfusion (V-Q) scanning, and arterial blood gas assessment. In addition, all lung transplant candidates must have adequate cardiac function and must meet psychosocial requirements.

Potential lung donors are also screened for blood type and size match. Larger lungs are accepted for COPD patients; smaller lungs are chosen for the restricted chest cavity of fibrotic patients. Donors should have a partial pressure of oxygen in arterial blood (PaO_2) value >300 mmHg on a fraction of inspired oxygen (FiO_2) of 100% and a positive end-expiratory pressure (PEEP) value of 5. Ideally, donors will have normal chest X-ray results, but exceptions for isolated abnormalities that will not affect subsequent graft function can be made. Living donors can donate a single lobe to a smaller recipient, such as a child. Single-lung transplants are common in many centers and can serve to increase the availability of lungs for multiple recipients. Newer concepts, such as “lung in the box” extracorporeal lung perfusion and stem cell technologies, may further improve the availability of donor lungs by optimizing the use of otherwise marginal grafts.

Procedure. Lung transplants can be done either as (a) single-lung transplants (to either side via thoracotomy) or as (b) sequential bilateral-lung transplants (via bilateral thoracotomies or via a single clamshell incision that divides the sternum; Fig. 11-27). They can be done absent extracorporeal mechanical cardiopulmonary perfusion (bypass), with the lung with the worst function (as predicted by preoperative ventilation and perfusion scanning) transplanted first. Despite careful surgical technique and excellent anesthesia, the poor pulmonary reserve of some lung recipients may require the institution of cardiopulmonary bypass to complete the transplant. Bypass is initiated through the chest by direct cardiac cannulation or peripherally via the femoral vessels.

Once the thoracotomy is made, a recipient pneumonectomy is performed with care, in order to avoid injury to the phrenic or recurrent laryngeal nerves. The pulmonary veins and main pulmonary artery are encircled outside the pericardium. At this point, once the main pulmonary vessels are occluded, the need for cardiopulmonary bypass can be assessed.

Figure 11-27. Clamshell incision. Bronchial anastomosis with ligated pulmonary arteries and veins.

The vessels and bronchus are ligated; the donor's lung is prepared and brought to the table wrapped in cold iced gauze, in order to extend the cold preservation time. The bronchial anastomosis (Fig. 11-28) is performed first and then covered with peribronchial tissue or pericardium. The pulmonary artery and, finally, the vein are anastomosed. The lung is then de-aired before the final anastomotic suture is tightened, with gentle lung insufflation. All clamps are removed, and the lung is aerated. At least two chest tubes are left in place. After the transplant is complete, a bronchoscopy is performed to clear the airway of blood and secretions.

Posttransplant Care. Patient survival rates for lung recipients vary significantly after primary vs. redo transplants. After primary transplants, the patient survival rates at 1, 3, and 5 years

Figure 11-28. Bronchial anastomosis.

are 83%, 62%, and 46%, respectively; after retransplants, the rates are 64%, 38%, and 28%.

Postoperative care of lung recipients can be very labor-intensive. These patients require meticulous ventilator management, in order to maintain F_{iO_2} at a minimum and to keep P_{aO_2} at 70 mmHg. Most patients are extubated within the first 24 to 48 hours. Recipients can require multiple bronchoscopies for both airway management and surveillance biopsies. Diuretics are used generously to counteract any positive fluid balance from the operation and to help with pulmonary recovery.

Early complications include technical complications, graft dysfunction, infections, and rejection. Technical complications often involve stenosis of one or more anastomoses leading to graft dysfunction. Bronchoscopy, V-Q scanning, echocardiography, and radiologic imaging are useful in identifying the causes of graft dysfunction. In up to 20% of recipients, primary early graft dysfunction can occur with no obvious cause. Such dysfunction may be due to some pathology from the donor, perhaps an unknown aspiration, infection, or contusion; or it could result from poor graft preservation at the time of organ procurement. In the intensive care unit, aggressive ventilator and pharmacologic management can help, but recipients can nonetheless progress to the need for mechanical support in the form of ECMO. Infections are treated with appropriate antibiotics, which can be challenging in patients with cystic fibrosis and a history of multidrug-resistant organisms. Rejection is monitored by biopsies and treated as needed.

Late complications include airway complications, such as strictures and, rarely, dehiscence, bronchiolitis obliterans, and malignancies. Strictures are treated with bronchoscopic dilation and intervention. Bronchiolitis obliterans often is a sequela of chronic rejection, but can be due to aspiration, chronic infections, or various other causes. In recipients with a progressive fall in their forced expiratory volume in 1 second (FEV_1), bronchiolitis obliterans is suspected. All recipients should be taught to perform microspirometry at home as a screening tool post-transplant. Biopsies are performed to confirm the diagnosis of any complication and, if possible, the cause. Despite aggressive screening and treatment, more than 50% of recipients will develop graft dysfunction. Most if not all of the sequelae of chronic immunosuppression that occur in lung transplant recipients are similar to those occurring in other groups of solid organ transplants.

Heart-Lung Transplants

Every year in the United States, 30 to 50 patients are added to the list of patients waiting to receive a simultaneous heart-lung transplant. The most common diagnosis is idiopathic pulmonary fibrosis, followed by primary pulmonary hypertension. Heart-lung candidates are often younger than their single-organ counterparts. The patient survival rates at 1, 3, and 5 years are 66%, 48%, and 39%, respectively. Often, lung complications ultimately lead to graft failure. The immunosuppression is the same as that for single thoracic organ recipients, with emphasis on weaning the patient off corticosteroids as early as possible.

XENOTRANSPLANTS

Xenotransplants (i.e., cross-species transplants of organs, tissues, or cells) have immense, yet untapped, potential to solve the critical shortage of available grafts. A primary hurdle is the formidable immunologic barrier between species, especially

with vascularized whole organs.¹⁶¹⁻¹⁷⁰ Other problems include the potential risk of transmitting infections (known as zoonoses or xenoses) and the ethical problems of using animals for widespread human transplants, even though great progress has been made in the past few years in efforts to overcome these problems.¹⁶⁶⁻¹⁷²

Pigs are generally accepted as the most likely donor species for xenotransplants into human beings.¹⁷³ Pigs would also be easier to raise on a large-scale basis. Guidelines for raising pigs in specialized facilities designated as pathogen-free have been established; in anticipation of clinical trials, such facilities have already been created and populated.^{171,172}

The immunologic barrier in pig-to-human xenotransplants is highly complex, but generally involves four subtypes of rejection.¹⁶⁶ The first is hyperacute rejection (HAR), which is mediated by the presence of natural (preformed) xenoantibodies in humans. These antibodies bind to antigens found mainly on the vascular endothelial cells of porcine donor organs, leading to complement activation, intravascular coagulation, and rapid graft ischemia soon after the transplant. The second subtype is acute humoral xenograft rejection (AHXR), a delayed form of antibody-mediated rejection seen in pig-to-nonhuman-primate transplants after steps to prevent HAR—steps such as depletion of antipig antibodies or complement from nonhuman primates' serum. Alternative names for AHXR include acute vascular rejection or delayed xenograft rejection. The third subtype is an acute cellular rejection process (similar to the classic T-cell-mediated acute rejection seen in allograft recipients). The fourth subtype is chronic rejection in grafts that survive for more than a few weeks (similar to the chronic rejection seen in long-surviving allograft recipients, with features of chronic vasculopathy).

Many different options are being tested to overcome this immunologic barrier, including the genetic engineering of pigs, the use of agents to inhibit platelet aggregation and complement activation, and the administration of powerful immunosuppressive drugs.¹⁶⁶⁻¹⁷³

During the first decade of the 21st century, the field of whole-organ xenotransplantation progressed significantly, thanks to the increasing availability of genetically engineered pigs and new immunosuppressive protocols. At a recent symposium organized by the International Xenotransplantation Association, data presented demonstrated extended survival time of porcine solid organs in nonhuman primates: from about 30 days to an average of 60 days and even up to 250 days (depending on the model).^{166,169,174,175} However, clinical application is still limited by thrombotic microangiopathy and consumptive coagulopathy; novel methods to prevent those complications will be required for further progress.

Cellular xenotransplants have made great strides and are currently in the early stages of clinical trials. Porcine islet xenotransplants are the most advanced form; five independent groups have now demonstrated survival and function of porcine islets in nonhuman primates for more than 100 days.^{166,175-181} For the clinical trials, cost-benefit models have been developed, and the regulatory framework has been established.^{170-172,178} One trial of particular interest involves transplanting encapsulated porcine islets without immunosuppression.¹⁷⁹ Early results are encouraging. But the efficacy of that approach may be limited until further genetic engineering enables proper oxygenation and nourishment of islet grafts, thereby supporting their viability and function.

The future of xenotransplantation is exciting. Continued active research will focus on further genetic engineering of pigs, newer immunosuppressive drugs, and tissue engineering approaches that will minimize or eliminate the need for immunosuppression. Given recent progress, routine clinical application of cellular xenotransplants is likely within the next decade.

BACKGROUND

Patient harm due to medical mistakes can be catastrophic, resulting in high-profile consequences for the patient, surgeon, and institution. A single error can even destroy a surgeon's career. While mistakes are inherent to human nature, it is becoming more recognized that many mistakes are preventable.

1▶ Patient safety is a science that promotes the use of evidence-based medicine and local wisdom to minimize the impact of human error on quality patient care. Wrong-site/wrong-procedure surgeries, retained sponges, unchecked blood transfusions, mismatched organ transplants, and overlooked allergies are all examples of potentially catastrophic events that can be prevented by implementing safer hospital systems. This chapter provides an overview of the modern-day field of patient safety by reviewing key measures of safety and quality, components of culture, interventions and tools, assessment methods, risk management strategies, and a selected review of common complications in surgery.

Medical Care Gone Wrong

2▶ Today, there are more medications, diagnoses, procedures, and handoffs performed than ever in the history of medicine. Moreover, overtreatment is now an endemic problem in some areas of healthcare. With more medical care being delivered, there are naturally more opportunities for things to go wrong. In fact, harm may be associated with complexity. The Commonwealth Fund reported that the United States leads the world in medical

errors, observing that 34% of patients with health problems in the United States report experiencing medical, medication, or test errors—the highest rate of any nation, and an analysis suggests that the problem of medical care gone wrong, i.e., medical errors including systems errors, may rank as the third leading cause of death in the United States.¹

Medical error is defined as an unintended act (either of omission or commission) or one that does not achieve its intended outcome, the failure of a planned action to be completed as intended (an error of execution) or the use of a wrong plan to achieve an aim (an error of planning), and a deviation from the process of care, which may or may not cause harm to the patient. Medical error can occur at the individual provider level or at the system level. An expanding taxonomy is maturing to better categorize the types of factors and events that are avoidable. The role of error may be complex; error can sometimes tragically end the life of a thriving person with a long life expectancy, or it can also accelerate an imminent death.

The most commonly cited report on the incidence of deaths due to medical error, the 1999 Institute of Medicine (IOM) report, describes an incidence of 44,000 to 98,000 deaths annually.² However, this estimate by the IOM was not based on primary research conducted by the IOM; rather, it was based on two older studies conducted in 1984 and 1992. Both studies were small and limited. In 2013, after compiling more recent evidence from multiple sources, James estimated an incidence range of 210,000 to 400,000 deaths a year associated with

Key Points

- 1▶ Medical error ranks as the third leading cause of death in the United States when defined to include system errors.
- 2▶ One form of medical error is unnecessary or excessive medical care, which represents 21% of medical care administered in the United States.
- 3▶ New peer-comparison metrics evaluate appropriateness of surgical care by measuring a physician’s practice pattern among all the physician’s patients benchmarked to the physician’s peers.
- 4▶ Judicious opioid prescribing upon discharge after surgery is critical given the magnitude of the opioid crisis.
- 5▶ The structure-process-outcome framework within the context of an organization’s culture helps to clarify how risks and hazards embedded within the organization’s structure may potentially lead to error and injure or harm patients.
- 6▶ Poor communication contributes to approximately 60% of the sentinel events reported to The Joint Commission.
- 7▶ Operating room briefings are team discussions of critical issues and potential hazards that can improve the safety of the operation and have been shown to improve operating room culture and decrease operating room delays.
- 8▶ National Quality Forum surgical “never events” include retained surgical items, wrong-site surgery, and death on the day of surgery of a normal healthy patient (American Society of Anesthesiologists Class 1).
- 9▶ The most important determinant of malpractice claims against a surgeon is patient rapport, not undertesting.

medical errors among hospital patients.³ Any point estimate in this range would rank the problem of dying from “medical care gone wrong” as the third leading cause of death in the United States. In caring for patients and considering the risks of tests and procedures done for borderline indications, it is important to consider the magnitude of the problem of patients dying from the care they receive rather than from the disease or injury that brought them to care.

Human error is inevitable. But while we cannot eliminate human error, we can better measure the problem to design safer systems mitigating its frequency, visibility, and consequences. Hospitals should consider the magnitude of the problem of medical error as a barrier to achieving safe, highly-reliable medical care. Investigating errors to learn from them can guide local changes to prevent future events. The strategy to rein in the

endemic problem of death from medical care should include three areas: (a) make errors less frequent (by following principles that take human limitations into account); (b) make errors more visible when they occur so that their effects can be intercepted; and (c) have remedies at hand when errors affect a patient. This multitier approach necessitates guidance from reliable data.

Unnecessary Medical Care

Increasingly preventable complications and complications from unnecessary procedures are considered to be forms of medical error. Unnecessary medical care accounts for an estimated \$210 billion in excess spending each year, according to the National Academy of Medicine. The issue represents a significant opportunity to make improve patient safety and lower healthcare

Figure 12-1. Causes of death in the United States 2013. (Reproduced with permission from Makary MA, Daniel M. Medical error—the third leading cause of death in the US, *BMJ*. 2016 May 3;353:i2139.)

costs. In a Johns Hopkins study, surveying over 2000 physicians in the United States, unnecessary medical care was reported to be common.⁴ On average, these authors reported that 21% of medical care is unnecessary. Breaking the problem down by type of medical care, the doctors reported that 22% of prescription medications, 25% of medical tests, and 11% of procedures are unnecessary. These perceptions by U.S. physicians validate previous estimates of the National Academy of Medicine that suggest that one-third of healthcare spending is wasteful and does not result in better health. Addressing avoidable medical and surgical care is a topic gaining increasing recognition in healthcare.

3► One example of overtreatment in surgical care is opioid over-prescribing.⁵ In the United States in 2015 alone, clinicians handed out 249 million opioid prescriptions, almost one for every American adult. And in 2016, the United States produced 14 billion opioid pills (40 for every American citizen). With the exception of pain specialists treating patients with pain syndromes, surgeons are the most common prescribers of opioids. Judicious opioid prescribing is important because of the addictive potential of these medications. Moreover, many patients can recover comfortably after hospital discharge with nonopioid or nonaddictive pain regimens.

THE SCIENCE OF PATIENT SAFETY

Medicine is considered a high-risk system with a high error rate, but these two characteristics are not always correlated. Other high-risk industries have managed to maintain an impeccably low error rate. For example, one of the highest risk systems in existence today, the U.S. Navy's nuclear submarine program, has an unmatched safety record.

Much of the credit for their safety record is due to the culture of the nuclear submarine program, with its insistence on individual ownership, responsibility, attention to detail, professionalism, moral integrity, and mutual respect.⁶ These characteristics have created the cultural context necessary for high-quality communications under high-risk, high-stress conditions. Each reactor operator is aware of what is going on at all times and is responsible for understanding the implications and possible consequences of any action. Communication flows freely between crewmen and officers, and information about any mistakes that occur are dispersed rapidly through the entire system so that other workers can learn how to prevent similar mistakes in the future.

High Reliability Organizations

The nuclear submarine program is an example of an organization that has achieved the distinction of being considered a "high reliability organization." High reliability organization theory recognizes that there are certain high-risk industries and organizations that have achieved very low accident and error rates compared to what would be expected given the inherent risks involved in their daily operations. Other high reliability industries and organizations include aircraft carrier flight decks, nuclear power plants, and the Federal Aviation Administration's air traffic control system. In fact, one reason why nuclear power plants have such an excellent reliability record may be that their operators are often former naval submarine officers whose previous experience and training within one highly reliable organization are easily transferable to other organizations.⁷

One of the assumptions underlying the science of high reliability organizations is that humans who operate and manage

complex systems are themselves not sufficiently complex to sense and anticipate the problems generated by the system.⁷ This introduces another important idea undergirding the science of patient safety: the concept of normal accident theory. Instead of attributing accidents to individual error, this theory states that accidents are intrinsic to high-volume activities and even inevitable in some settings. Accidents should not be used merely to identify and punish the person at fault, but should be seen as a systems problem and addressed at a broader level. As Ruchlin states, even the "best people can make the worst errors as a result of latent conditions."⁷

High-risk systems, as defined by Perrow in 1984⁸:

- Have the potential to create a catastrophe, loosely defined as an event leading to loss of human or animal life, despoiling of the environment, or some other situation that gives rise to the sense of "dread."
- Are complex, in that they have large numbers of highly interdependent subsystems with many possible combinations that are nonlinear and poorly understood.
- Are tightly coupled, so that any perturbation in the system is transmitted rapidly between subsystems with little attenuation.

However, high reliability organization theory suggests that proper oversight of people, processes, and technology can handle complex and hazardous activities and keep error rates acceptably low.⁷ Studies of multiple high reliability organizations show that they share the following common characteristics:

- People are supportive of one another.
- People trust one another.
- People have friendly, open relationships emphasizing credibility and attentiveness.
- The work environment is resilient and emphasizes creativity and goal achievement, providing strong feelings of credibility and personal trust.

Developing these characteristics is an important step toward achieving a low error rate in any organization. For this reason, safety culture is a measure used by hospitals nationwide to improve outcomes and is increasingly recognized as a metric of hospital quality.

The Conceptual Model

The Donabedian model of measuring quality identifies three main types of improvements: changes to organizational structure, changes in organizational processes, and changes in outcomes.⁹ *Structure* refers to the physical and organizational tools, equipment, and policies that improve safety. Structural measures ask, "Do the right tools, equipment, and policies exist?" *Process* is the application of these tools, equipment, and policies/procedures to patients (good practices and evidence-based medicine). Process measures ask, "Are the right tools, policies, and equipment being used?" *Outcome* is the result on patients. Outcome measures ask, "How often are patients harmed?" In this model, structure (how care is organized) plus process (what we do) influences patient outcomes (the results achieved).¹⁰

The structure, process, and outcome components of quality measurement all occur within the context of an organization's overall *culture*. The local culture impacts all aspects of the delivery of care because it affects how front-line personnel

Table 12-1

Types of medical error

Adverse event

- Injury caused by medical management rather than the underlying condition of the patient
- Prolongs hospitalization, produces a disability at discharge, or both
- Classified as preventable or unpreventable

Negligence

- Care that falls below a recognized standard of care
- Standard of care is considered to be care a reasonable physician of similar knowledge, training, and experience would use in similar circumstances

Near miss

- An error that does not result in patient harm
- Analysis of near misses provides the opportunity to identify and remedy system failures before the occurrence of harm

Sentinel event

- An unexpected occurrence involving death or serious physical or psychological injury
- The injury involves loss of limb or function
- This type of event requires immediate investigation and response
- Other examples
 - Hemolytic transfusion reaction involving administration of blood or blood products having major blood group incompatibilities
 - Wrong-site, wrong-procedure, or wrong-patient surgery
 - A medication error or other treatment-related error resulting in death
 - Unintentional retention of a foreign body in a patient after surgery

Reproduced with permission from Makary M: General Surgery Review. Washington, DC: Ladner-Drysdale; 2008.

understand and deliver safe patient care. In fact, culture (collective attitudes and beliefs of caregivers) is increasingly being recognized to be the fourth measurable component to the structure-process-outcome model. This recognition is based

Case 12-1 Systems change resulting from medical error

Libby Zion was an 18-year-old woman who died after being admitted to the New York Hospital with fever and agitation on the evening of October 4, 1984. Her father, Sidney Zion, a lawyer and columnist for the *N.Y. Daily News*, was convinced that his daughter's death was due to inadequate staffing and overworked physicians at the hospital and was determined to bring about changes to prevent other patients from suffering as a result of the teaching hospital system. Due to his efforts to publicize the circumstances surrounding his daughter's death, Manhattan District Attorney Robert Morgenthau agreed to let a grand jury consider murder charges. Although the hospital was not indicted, in May 1986, a grand jury issued a report strongly criticizing "the supervision of interns and junior residents at a hospital in NY County."

As a result, New York State Health Commissioner David Axelrod convened a panel of experts headed by Bertrand M. Bell, a primary care physician at Albert Einstein College of Medicine who had long been critical of the lack of supervision of physicians-in-training, to evaluate the training and supervision of doctors in New York State. The Bell Commission recommended that residents work no more than 80 hours per week and no more than 24 consecutive hours per shift, and that a senior physician needed to be physically present in the hospital at all times. These recommendations were adopted by New York State in 1989. In 2003, the Accreditation Council on Graduate Medical Education followed by mandating that all residency training programs adhere to the reduced work hour schedule.

on growing evidence that local culture is linked to a variety of important clinical outcomes.¹⁰ For any new patient safety initiative to be deemed successful, any change in structure or process must lead to a corresponding positive change in patient outcomes.¹¹

CREATING A CULTURE OF SAFETY

Culture is to an organization what personality is to the individual—a hidden, yet unifying theme that provides meaning, direction, and mobilization.⁷ Organizations with effective safety cultures share a constant commitment to safety as a top-level priority that permeates the entire organization. These organizations frequently share the following characteristics¹²:

- An acknowledgment of the high-risk, error-prone nature of an organization's activities
- A nonpunitive environment where individuals are able to report errors or close calls without fear of punishment or retaliation
- An expectation of collaboration across ranks to seek solutions to vulnerabilities
- A willingness on the part of the organization to direct resources to address safety concerns

Traditional surgical culture stands almost in direct opposition to the values upheld by organizations with effective safety cultures for several reasons. Surgeons are less likely to acknowledge their propensity to make mistakes or to admit these mistakes to others.¹³ Surgeons tend to minimize the effect of stress on their ability to make decisions.¹⁴ The surgical culture, especially in the operating room (OR), is traditionally rife with hierarchy. Intimidation of other OR personnel by surgeons was historically accepted as the norm. This can prevent nurses and other OR staff from pointing out potential errors or

Case 12-2 High-profile sentinel event

On December 3, 1994, Betsy Lehman, a *Boston Globe* health columnist, died as a result of receiving four times the intended dose of chemotherapy for breast cancer. Remarkably, 2 days later, Maureen Bateman, a teacher being treated for cancer, also received a chemotherapy overdose and suffered irreversible heart damage. After investigating the medication errors, the prescribing doctor, three druggists, and 15 nurses were disciplined by state regulators. The hospital was sued by the two women's families and by one of the doctors disciplined.

As a result of this widely publicized event, the Dana-Farber Cancer Institute invested more than \$11 million to overhaul their safety programs, including providing new training for their employees and giving doctors more time to meet with patients. The hospital adopted a full disclosure policy so that patients would be informed anytime a mistake had affected their care. Dana-Farber also started a patient committee providing advice and feedback on ways to improve care at the hospital.

mistakes. Moreover, this culture is not limited to the OR. In the intensive care unit (ICU), when compared to physicians, nurses reported more difficulty speaking up, disagreements were not appropriately resolved, and decisions were made without adequate input.¹⁵ In addition, the field of medicine strongly values professional autonomy, which frequently promotes individualism over cooperation, often to the detriment of patient care.¹⁶ Finally, patient safety, although often viewed as important, is seldom promoted from an organizational priority to an organizational value. Organizations often do not feel the need to devote resources to overhauling their patient safety systems as long as they perceive their existing processes to be adequate. It often takes a high-profile sentinel event to motivate leaders to commit the necessary time and resources to improving patient safety within their organization, as exemplified by the Dana-Farber Institute in the aftermath of Betsy Lehman's death (Case 12-2).

Assessing an Organization's Safety Culture

Efforts to foster cultural change within an organization with regard to patient safety have been limited in the past by the inability to measure the impact of any given intervention. However, studies have shown that employee attitudes about culture are associated with error reduction behaviors in aviation and with patient outcomes in ICUs. The Safety Attitudes Questionnaire (SAQ) is a validated survey instrument that can be used to measure culture in a healthcare setting.⁹ Adapted from two safety tools used in aviation, the Flight Management Attitudes Questionnaire and its predecessor, the Cockpit Management Attitudes Questionnaire, the SAQ consists of a series of questions measuring six domains: teamwork climate, safety climate, job satisfaction, perception of management, stress recognition, and working conditions.

The safety climate scale portion of the questionnaire consists of the following seven items:

- I am encouraged by my colleagues to report any patient safety concerns I may have.
- The culture in this clinical area makes it easy to learn from the mistakes of others.
- Medical errors are handled appropriately in this clinical area.

- I know the proper channels to direct questions regarding patient safety in this clinical area.
- I receive appropriate feedback about my performance.
- I would feel safe being treated here as a patient.
- In this clinical area, it is not difficult to discuss mistakes.

Although perceptions of teamwork climate can differ as a function of one's role in the OR, perceptions of safety climate are relatively consistent across OR providers in a given hospital. Validated in over 500 hospitals, the SAQ is used to establish benchmark safety culture scores by healthcare worker type, department, and hospital. Using this survey, hospitals can compare culture between different types of healthcare workers within a department as well as culture between departments throughout the institution. Scores can be compared to those of other participating institutions to compare safety climates. This allows hospitals to participate with one another to implement programs to improve safety culture. In addition, scores are used to evaluate the effectiveness of safety interventions by comparing the SAQ safety climate scores after implementation to baseline scores.

Strong teamwork is at the core of any effective organization and is a key element to ensuring patient safety in the OR. Teamwork is dependent on the underlying culture and patterns of communication. The ability for all team members, to "speak up" about patient safety concerns is one of the most important elements of creating a culture of patient safety.

TEAMWORK AND COMMUNICATION

According to The Joint Commission, communication breakdown is one of the top three root causes of sentinel events such as wrong-site surgery (Fig. 12-2). Poor communication contributed to over 60% of sentinel events reported to The Joint Commission in 2011.¹⁷ Good communication is an essential component of

6► teamwork and is especially important in the OR, one of the most complex work environments in healthcare.

Within the realm of patient care, there are enormous amounts of information being exchanged between healthcare providers on a daily basis. Much of this information, if prioritized correctly, has the potential to prevent unintended medical errors and serious harm to patients. The importance of good communication in preventing medical errors is undeniable; however, it is difficult to achieve. The traditional surgical hierarchy can prevent OR personnel from sharing important patient data and expressing safety concerns. One perioperative field study showed a 30% rate of communication failure in the OR, with 36% of these breakdowns having a substantial impact on patient safety.¹⁸

In addition to overcoming the cultural barrier to better teamwork and communication, the prospective study by Christian and associates of patient safety in the OR demonstrated that the standard workflow of the OR itself presents many opportunities for the loss or degradation of critical information.¹⁹ Hand-offs of patient care from the OR to other locations or providers are particularly prone to information loss, which has been demonstrated in other clinical settings. Hand-offs and auxiliary tasks, such as surgical sponge and instrument counts, frequently take place during critical portions of the case and place competing demands on provider attention from primary patient-centered activities. Communication between the surgeon and pathologist also is vulnerable because the communication often occurs through secondary messengers such as nurses or technicians. This information loss can lead to delays, overuse of

Figure 12-2. Root causes of sentinel events 2004 to 2012. (Data from *The Joint Commission, 2012.*)

staff and resources, uncertainty in clinical decision making and planning, and oversights in patient preparation.

Measuring Teamwork

Research in commercial aviation has demonstrated a strong correlation between better teamwork and improved safety performance. Cockpit crew members' reluctance to question a captain's judgment has been identified as a root cause of aviation accidents. Good attitudes about teamwork are associated with error-reduction behaviors in aviation, improved patient outcomes in ICUs, and decreased nurse turnover in the OR. It is also associated with higher job satisfaction ratings and less sick time taken from work.

The SAQ can be used to measure teamwork and provide benchmarks for departments or hospitals seeking to measure and improve their teamwork climate.²⁰ The SAQ teamwork scores are responsive to interventions that aim to improve teamwork among operating teams, such as the implementation of ICU checklists, executive walk rounds, and preoperative briefing team discussions. The communication and collaboration sections of the SAQ reflect OR caregiver views on teamwork and can be used to distinguish meaningful interventions from impractical and ineffective programs.

In a survey of OR personnel across 60 hospitals, the SAQ identified substantial differences in the perception of teamwork in the OR depending on one's role. Physicians frequently rated the teamwork of others as good, while nurses at the same institutions perceived teamwork as poor (Fig. 12-3). Similar

Figure 12-3. Differences in teamwork perceptions between surgeons and operating room (OR) nurses. (Reproduced with permission from Makary MA, Sexton JB, Freischlag JA, et al. *Operating room teamwork among physicians and nurses: teamwork in the eye of the beholder*, J Am Coll Surg. 2006 May;202(5):746-752.)

discrepancies have been found in ICUs. These discrepancies can be attributed to differences in the communication skills that are valued by surgeons and nurses. For example, nurses describe good collaboration as having their input respected, while physicians describe good collaboration as having nurses who can anticipate their needs and follow instructions. Efforts to improve the communication that takes place between physicians and nurses can directly improve the perception of teamwork and collaboration by the OR team (Table 12-2). Empowering well-respected surgeons to promote principles of teamwork and communication can go a long way toward transforming attitudinal and behavioral changes in fellow physicians as well as other members of the surgical team. Surgeons are increasingly encouraging the respectful and timely voicing of concerns of OR personnel.

COMMUNICATION TOOLS

High reliability organizations such as aviation frequently use tools such as prompts, checks, standard operating protocols, and communication interventions such as team briefings and debriefings. These tools identify and mitigate hazards and allow an organization to complete tasks more efficiently. They also foster a culture of open communication and speaking up if a team member senses a safety concern. Safety checks and standardized team discussions serve as prompts to help “engineer out” human error, providing quality assurance and improving information flow. They also can prevent errors related to omissions, which are more likely to occur when there is information overload, multiple steps in a process, repetitions in steps, and planned departures from routine processes, and when there are other interruptions and distractions present while the process is being executed. These same interventions have been shown to improve patient safety in ORs and ICUs.^{21,22}

Operating Room Briefings (A Surgical Checklist)

Preoperative briefings and checklists, when used appropriately, help to facilitate transfer of information between team members (Table 12-3). A briefing, or checklist, is any preprocedure discussion of requirements, needs, and special issues of the procedure. Briefings often are locally adapted to the specific needs of the specialty. They have been associated with an improved safety culture, including increased awareness of wrong-site/wrong-procedure errors, early reporting of equipment problems, reduced operational costs and fewer unexpected delays. In one study, 30.9% of OR personnel reported a delay before the

Table 12-2

Percentage of operating room caregivers reporting a high or very high level of collaboration with other members of the operating room team

CAREGIVER POSITION PERFORMING RATING	CAREGIVER POSITION BEING RATED			
	SURGEON	ANESTHESIOLOGIST	NURSE	CRNA
Surgeon	85	84	88	87
Anesthesiologist	70	96	89	92
Nurse	48	63	81	68
CRNA	58	75	76	93

The best teamwork scores were recorded by anesthesiologists when they rated their teamwork with other anesthesiologists (“high” or “very high” 96% of the time). The lowest teamwork ratings were recorded by nurses when they rated their teamwork with surgeons (“high” or “very high” 48% of the time). CRNA = certified registered nurse anesthetist.

institution of OR briefings, and only 23.3% reported delays after briefings were instituted.²³ OR briefings are increasingly being used to ensure evidence-based measures are used, such as the appropriate administration of preoperative antibiotics and deep vein thrombosis (DVT) prophylaxis. Briefings allow personnel to discuss potential problems, before they become a “near miss” or cause actual harm.

Operating Room Debriefings

Postprocedural debriefings improve patient safety by allowing for discussion and reflection on causes for errors and critical incidents that occurred during the case. Errors or critical incidents are regarded as learning opportunities rather than cause for punishment. During the debriefing, the team also can discuss what went well during the case and designate a point person to follow up on any proposed actions that result from the discussion. In addition, most debriefings include a verification of the sponge, needle, and instrument counts and confirmation of the correct labeling of the surgical specimen.

Errors in surgical specimen labeling have not received as much attention as incorrect sponge or instrument counts as an indicator of the quality of communication in the OR. However, an error in communication or during the hand-off process increases the risk of mislabeling a surgical specimen before its arrival in a pathology laboratory. In one study, this type of identification error occurred in 4.3 per 1000 surgical specimens, which implies an annualized rate of occurrence of 182 mislabeled specimens per year (Fig. 12-5).²⁴ Errors involving specimen identification can result in delays in care, the need for an

additional biopsy or therapy, failure to use appropriate therapy, or therapy administered to the wrong body site, side, or patient. These system failures can lead to significant harm to the patient, costs to the institution, and distrust by a community. Given the frequency of occurrence and the feasibility and validity of measuring them, mislabeled surgical specimens may serve as a useful indicator of patient safety and should be included in any postprocedural debriefing checklist.

Sign Outs

In healthcare, information frequently passes to covering providers without prioritizing potential concerns. This makes sign outs a very vulnerable process of care, which can lead to catastrophic events.

The term *sign out* can refer to either the verbal or written communication of patient information to familiarize oncoming physicians about patients who will be under their care. Sign outs should occur whenever a patient’s care setting or provider is changing. When performed well, sign outs help to ensure the transfer of pertinent information. However, previous studies have shown the hand-off process to be variable, unstructured, and prone to error. Common categories of communication failure during sign outs include content omissions, such as failure to mention active medical problems, and failures in the actual communication process, such as leaving illegible or unclear notes (Case 12-3).²⁵ These failures lead to confusion and uncertainty by the covering physician during patient care decisions, resulting in the delivery of inefficient and suboptimal care.

The use of more structured verbal communication such as the Situational Debriefing Model, otherwise known as *SBAR* (situation, background, assessment, and recommendation), used by the U.S. Navy, can be applied to healthcare to improve the communication of critical information in a timely and orderly fashion.²⁵ In addition, all sign outs should begin with the statement, “In this patient, I am most concerned about . . .” to signal to the healthcare provider on the receiving end the most important safety concerns regarding that specific patient.

Implementation

Tools such as checklists, sign outs, briefings, and debriefings improve communication between healthcare providers and create a safer patient environment (Fig. 12-6). Although their use in healthcare is still highly variable, specialties that

have incorporated them, such as intensive care and anesthesia, have made impressive strides in patient safety. Currently, communication breakdowns, information loss, hand off, multiple competing tasks, and high workload are considered “annoying but accepted features” of the perioperative environment.²⁰ As physician attitudes toward errors, stress, and teamwork in medicine become more favorable toward the common goals of reducing error and improving teamwork and communication, medicine will likely achieve many of the milestones in safety that high-reliability industries such as aviation have already accomplished.

COMPREHENSIVE UNIT-BASED SAFETY PROGRAM

As medical care and hospitals continue to expand, the care that is provided to patients is becoming more fragmented. This fragmentation makes communication more difficult and opportunities for medical errors more common. These problems require common sense solutions, often necessitating a change in the way that care is delivered on the local level. Unit-based meetings to discuss processes that are potentially dangerous for patients can quickly bring danger areas out into the open. These meetings

Figure 12-5. Incidence of identification errors observed per 1000 specimens (n = 21,351). (Reproduced with permission from Makary MA, Epstein J, Pronovost PJ, et al. *Surgical specimen identification errors: a new measure of quality in surgical care*, *Surgery*. 2007 Apr;141(4):450-455.)

Case 12-3 Inadequate sign out leading to medical error

Josie King was an 18-month-old child who was admitted to Johns Hopkins Hospital in January of 2001 for first- and second-degree burns. She spent 10 days in the pediatric intensive care unit and was well on her way to recovery. She was transferred to an intermediate care floor with the expectation that she would be sent home in a few days.

The following week, her central line was removed, but nurses would not allow Josie to drink anything by mouth. Around 1 PM the next day, a nurse came to Josie’s bedside with a syringe of methadone. Although Josie’s mother told the nurse that there was no order for narcotics, the nurse insisted that the orders had been changed and administered the drug. Josie’s heart stopped, and her eyes became fixed. She was moved to the pediatric intensive care unit and placed on life support. Two days later, on February 22, 2001, she died from severe dehydration.

After her death, Josie’s parents, Sorrel and Jay King, were motivated to work with leaders at Johns Hopkins to ensure that no other family would have to endure the death of a child due to medical error. They later funded the Josie King Patient Safety Program and an academic scholarship in the field of safety.

should be held on a regular basis and bring together a multidisciplinary team of physicians, nurses, technicians, social workers, and other staff who can each voice their concerns about safety hazards in their area. This enables all aspects of patient care to be addressed and improved continuously, thereby streamlining and improving patient care.²⁶

The implementation of the Comprehensive Unit-based Safety Program (CUSP) involves measurement of a unit’s safety culture prior to starting the program and inclusion of hospital management from the start. Having management involved allows for more efficient allocation of resources and allows them to better understand the problems faced by front-line providers. Once CUSP is in place, changes can be made using local

wisdom to advance patient care.²⁶ The impact of changes made using CUSP can be measured using both patient outcomes and safety culture data.

Implementation of CUSP has been associated with improved patient outcomes, including decreased surgical site infections. In a 2-year study of colorectal patients, where the first year was pre-CUSP implementation and the second year was post-CUSP implementation, there was a 33% decrease in the surgical site infection rate after CUSP.²⁷ In this study, the CUSP group met monthly and came up with a list of interventions based on their experience with these cases, including standardization of skin preparation and warming of patients in the preanesthesia area. This study showed that CUSP can be highly effective in ameliorating patient harm and improving patient care.

MEASURING QUALITY IN SURGERY

Despite the newfound focus on patient safety in surgery and the number of initiatives being undertaken by many organizations to improve their safety culture, there are few tools to actually measure whether these efforts are effective in reducing the number of errors. Several agencies and private groups have developed criteria to evaluate quality and safety within hospitals.

Practice Pattern Measures

New quality measures in healthcare focus on the appropriateness of medical care.²⁸ These appropriateness indicators are doctor-defined and specialty-specific so they are smart and fair. One of the first of these new appropriateness metrics is the average number of tissue blocks a skin cancer (Mohs) surgeon will use to surgically remove a skin cancer. The American College of Mohs Surgeons formalized and endorsed the surgeon metric: average number of blocks a surgeon requires to remove a standardized skin cancer. In a report describing the national distribution of surgeons by their mean number of blocks per case, the national average was found to be 1.7 blocks per surgeon. Statistical outlier surgeons had an average four or more blocks per patient. Boundaries of normal variation was determined by expert physician leaders to define an acceptable range and an

Figure 12-6. Impact of operating room briefings on teamwork and communication.

unacceptable range (greater than two standard deviations from the national norm). The American College of Mohs Surgeons sent letters to outliers, letting them know where they stand, and offered coaching and retraining help. The new Mohs surgery metric demonstrates the opportunity to reduce unwarranted clinical variation and lower healthcare costs by simply using clinical wisdom and the power of peer-comparison.

Appropriateness measures approach quality differently than traditional quality measures and rely on expert physicians to define the metric and set boundaries of reasonable versus unsafe variation in an individual physician's practice pattern relative to his or her peers nationally. This concept is being applied to utilization rates of minimally invasive surgery in candidate patients as well as rates of physical therapy utilization before elective spine surgery for chronic pain.

Agency for Healthcare Research and Quality Patient Safety Indicators

The Agency for Healthcare Research and Quality (AHRQ) was created in 1989 as a Public Health Service agency in the Department of Health and Human Services. Its mission is to improve the quality, safety, efficiency, and effectiveness of healthcare for all Americans. Nearly 80% of the AHRQ's budget is awarded as grants and contracts to researchers at universities and other research institutions across the country. The AHRQ sponsors and conducts research that provides evidence-based information on healthcare outcomes, quality, cost, use, and access. It has advocated the use of readily available hospital inpatient administrative data to measure healthcare quality. The information helps healthcare decision makers make more informed decisions and improve the quality of healthcare services.²⁹

One of the major contributions of the AHRQ is a set of Patient Safety Indicators (PSIs), initially released in 2003 and revised in 2010. PSIs are a tool to help health system leaders identify potential adverse events occurring during hospitalization. Developed after a comprehensive literature review, analysis of International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes, review by a clinician panel, implementation of risk adjustment, and empirical analyses, these 27 indicators provide information on potential in-hospital complications and adverse events following surgeries, procedures, and childbirth (Table 12-4).

Provider-level indicators provide a measure of the potentially preventable complications for patients who received their initial care and the complication of care within the same hospitalization. They include only those cases where a secondary diagnosis code flags a potentially preventable complication. Area-level indicators capture all cases of the potentially preventable complications that occur in a given area (e.g., metropolitan area or county), either during their initial hospitalization or resulting in subsequent hospitalization.³⁰

Currently, PSIs are considered indicators, not definitive measures, of patient safety concerns. They can identify potential safety problems that merit further investigation. They also can be used to better prioritize and evaluate local and national initiatives, and even as benchmarks for tracking progress in patient safety. In the future, further growth in electronic health data will make administrative data-based tools like the PSIs more useful.³¹

The Surgical Care Improvement Project Measures

The Surgical Care Improvement Project (SCIP) was established in 2003 by a national partnership of organizations committed

Table 12-4

Agency for Healthcare Research and Quality patient safety indicators

Provider-level patient safety indicators

- Complications of anesthesia
- Death in low mortality diagnosis-related groups
- Decubitus ulcer
- Failure to rescue
- Foreign body left in during procedure
- Iatrogenic pneumothorax
- Selected infections due to medical care
- Postoperative hip fracture
- Postoperative hemorrhage or hematoma
- Postoperative physiologic and metabolic derangements
- Postoperative respiratory failure
- Postoperative pulmonary embolism or deep vein thrombosis
- Postoperative sepsis
- Postoperative wound dehiscence in abdominopelvic surgical patients
- Accidental puncture and laceration
- Transfusion reaction
- Birth trauma—injury to neonate
- Obstetric trauma—vaginal delivery with instrument
- Obstetric trauma—vaginal delivery without instrument
- Obstetric trauma—cesarean delivery

Area-level patient safety indicators

- Foreign body left in during procedure
- Iatrogenic pneumothorax
- Selected infections due to medical care
- Postoperative wound dehiscence in abdominopelvic surgical patients
- Accidental puncture and laceration
- Transfusion reaction
- Postoperative hemorrhage or hematoma

to improving surgical care by reducing surgical complications. The steering committee is comprised of groups such as the Centers for Medicare & Medicaid Services, the American Hospital Association, Centers for Disease Control and Prevention (CDC), Institute for Healthcare Improvement, The Joint Commission, and others.

The incidence of postoperative complications ranges from 6% for patients undergoing noncardiac surgery to more than 30% for patients undergoing high-risk surgery. Common postoperative complications include surgical site infections (SSIs), myocardial infarction, postoperative pneumonia, and thromboembolic complications. Patients who experience postoperative complications have increased hospital length of stay (3 to 11 days longer than those without complications), increased hospital costs (ranging from \$1398 for an infectious complication to \$18,310 for a thromboembolic event), and increased mortality (median patient survival decreases by up to 69%).³²

Despite well-established evidence that many of these adverse events are preventable, failure to comply with standards

Table 12-5

The Surgical Care Improvement Project measures**Process of care performance measures**

Infection

- Prophylactic antibiotic received within 1 h before surgical incision
- Prophylactic antibiotic selection for surgical patients
- Prophylactic antibiotics discontinued within 24 h after surgery end time (48 h for cardiac patients)
- Cardiac surgery patients with controlled 6 A.M. postoperative serum glucose
- Surgery patients with appropriate hair removal
- Colorectal surgery patients with immediate postoperative normothermia

Venous thromboembolism

- Surgery patients with recommended venous thromboembolism prophylaxis ordered
- Surgery patients who received appropriate venous thromboembolism prophylaxis within 24 h before surgery to 24 h after surgery

Cardiac events

- Surgery patients on a β -blocker prior to arrival who received a β -blocker during the perioperative period

Proposed outcome measures

Infection

- Postoperative wound infection diagnosed during index hospitalization

Venous thromboembolism

- Intra- or postoperative pulmonary embolism diagnosed during index hospitalization and within 30 d of surgery
- Intra- or postoperative deep vein thrombosis diagnosed during index hospitalization and within 30 d of surgery

Cardiac events

- Intra- or postoperative acute myocardial infarction diagnosed during index hospitalization and within 30 d of surgery

Global measures

- Mortality within 30 d of surgery
- Readmission within 30 d of surgery

Data from The Joint Commission, 2012.

of care known to prevent them results in unnecessary harm to a large number of patients. SCIP has identified three broad areas within surgery where potential complications have a high incidence and cost and there is a significant opportunity for prevention: SSIs, venous thromboembolism, and adverse cardiac events. The SCIP measures aim to reduce the incidence of these events during the perioperative period by advocating the use of proven process and outcome measures. These process and outcome measures are detailed in Table 12-5.

SSIs account for 14% to 16% of all hospital-acquired infections and are a common complication of care, occurring in 2% to 5% of patients after clean extra-abdominal operations and up to 20% of patients undergoing intra-abdominal procedures. By implementing steps to reduce SSIs, hospitals could recognize a savings of \$3152 and reduction in extended length of stay by 7 days on each patient developing an infection.³³

Adverse cardiac events occur in 2% to 5% of patients undergoing noncardiac surgery and as many as 34% of patients undergoing vascular surgery. Certain perioperative cardiac

events, such as myocardial infarction, are associated with a mortality rate of 40% to 70% per event, prolonged hospitalization, and higher costs. Appropriately administered β -blockers reduce perioperative ischemia, especially in at-risk patients. It has been found that nearly half of the fatal cardiac events could be preventable with β -blocker therapy.³³

DVT occurs after approximately 25% of all major surgical procedures performed without prophylaxis, and pulmonary embolism (PE) occurs after 7%. Despite the well-established efficacy and safety of preventive measures, studies show that prophylaxis often is underused or used inappropriately. Both low-dose unfractionated heparin and low molecular weight heparin have similar efficacy in DVT and PE prevention. Prophylaxis using low-dose unfractionated heparin has been shown to reduce the incidence of fatal PEs by 50%.³³

The SCIP effort provides an infrastructure and guidelines for data collection and quality improvement on a national scale. By achieving high levels of compliance with evidence-based practices to reduce SSIs, venous thromboembolism events, and perioperative cardiac complications, the potential number of lives saved in the Medicare patient population alone exceeds 13,000 annually.³²

National Surgical Quality Improvement Program

The National Surgical Quality Improvement Program (NSQIP) is a measurement program that allows hospitals to sample their rates of postoperative events and compare them to similar hospitals. Created by the Veterans Health Administration (VA) in 1991, NSQIP has been credited with measuring and improving morbidity and mortality outcomes at the VA, reducing 30-day mortality rate after major surgery by 31%, and 30-day postoperative morbidity by 45% in its first decade.³⁴ Beta testing at 18 non-VA sites from 2001 to 2004 demonstrated the feasibility and utility of the program in the private sector. The program was subsequently expanded to the private sector in 2004 when the American College of Surgeons endorsed the program and encouraged hospital participation to measure and evaluate outcomes on a large scale. A study of 118 hospitals participating in NSQIP between 2005 to 2007 showed that 82% of hospitals decreased their complication rates and there was a decrease in morbidity of 11% and mortality of 17% annually per hospital.³⁵ Currently, over 400 private-sector U.S. hospitals participate in the program.

NSQIP uses a risk-adjusted ratio of the observed to expected outcome (focusing primarily on 30-day morbidity and mortality) to compare the performance of participating hospitals with their peers. The data the program has compiled also can be used to conduct observational studies using prospectively collected information on more than 1.5 million patients and operations. The expansion of NSQIP to the private sector has helped shift the focus from merely preventing the provider errors and sentinel events highlighted by the IOM publication “To Err Is Human” to the larger goal of preventing all adverse postoperative outcomes.

Several insights about patient safety have arisen as a result of NSQIP. First, safety is indistinguishable from overall quality of surgical care and should not be addressed separately. Defining quality in terms of keeping a patient safe from adverse outcomes allows the NSQIP data to be used to assess and improve quality of care by making improvements in patient safety. In other words, prevention of errors is synonymous with the reduction of adverse outcomes and can be used as a reliable quality measure. Second, during an episode of surgical care, adverse

outcomes, and hence, patient safety, are primarily determined by the quality of the systems of care. Errors in hospitals with higher than expected observed to expected outcomes ratios are more likely to be from system errors than from provider incompetence. This underscores the importance of adequate communication, coordination, and teamwork in achieving quality surgical care. Finally, reliable comparative outcomes data are imperative for the identification of system problems. Risk-adjusted rates of adverse outcomes must be compared with those at peer institutions to appreciate more subtle system errors that lead to adverse outcomes to prompt changes in the quality of an institution's processes and structures.

The Leapfrog Group

One of the largest efforts to standardize evidence-based medicine in the United States is led by The Leapfrog Group, an alliance of large public and private healthcare purchasers representing more than 37 million individuals across the United States. This healthcare consortium was founded in 2000 with the aim to exert their combined leverage toward improving nationwide standards of healthcare quality, optimizing patient outcomes, and ultimately lowering healthcare costs. The Leapfrog Group's strategy to achieve these goals is through providing patient referral, financial incentives, and public recognition for hospitals that practice or implement evidence-based healthcare standards.

The healthcare quality and safety practices (leaps) that Leapfrog initially identified to measure healthcare standards were hospital use of computerized physician order entry systems, 24-hour ICU physician staffing, and evidence-based hospital referral (EBHR) standards for five high-risk operations.³⁶ In 2010, after the National Quality Forum (NQF) released its updated Safe Practices for Better Healthcare, Leapfrog added a safe practices leap, which includes eight practices from the NQF report.³⁷

Leapfrog collects data on these practices through administration of an ongoing, voluntary, web-based hospital quality and safety survey. This survey is conducted in 41 regions that cover over half of the U.S. population and 62% of all hospital beds in the country. In 2011, more than 1200 urban, suburban, and rural hospitals participated in the survey. Leapfrog asks for information on eight high-risk conditions or procedures, including coronary artery bypass graft, percutaneous coronary intervention, abdominal aortic aneurysm (AAA) repair, pancreatic resection, and esophagectomy. These procedures were chosen because evidence exists that adherence to certain process measures can dramatically improve the outcomes of these procedures. In addition, more than 100 studies also have demonstrated that better results are obtained at high-volume hospitals when undergoing cardiovascular surgery, major cancer resections, and other high-risk procedures. Hospitals fulfilling the EBHR Safety Standard are expected to meet the hospital and surgeon volume criteria shown in Table 12-6. Hospitals that do not meet these criteria but adhere to the Leapfrog-endorsed process measures for coronary artery bypass graft surgery, percutaneous coronary intervention, AAA repair, and care for high-risk neonates, receive partial credit toward fulfilling the EBHR Safety Standard. Leapfrog purchasers work to recognize and reward hospitals that provide care for their enrollees who meet EBHR standards.³⁵

In a recent study, Brooke and associates analyzed whether achieving Leapfrog's established evidence-based standards for AAA repair, including meeting targets for case volume and

Table 12-6

Recommended annual volumes: hospitals and surgeons

1. Coronary artery bypass graft	≥450/100
2. Percutaneous coronary intervention	≥400/75
3. Abdominal aortic aneurysm repair	≥50/22
4. Aortic valve replacement	≥120/22
5. Pancreatic resection	≥11/2
6. Esophagectomy	≥13/2
7. Bariatric surgery	>100/20

perioperative β -blocker usage, correlated with improved patient outcomes over time.³⁶ After controlling for differences in hospital and patient characteristics, hospitals that implemented a policy for perioperative β -blocker usage had an estimated 51% reduction in mortality following open AAA repair cases. Among 111 California hospitals in which endovascular AAA repair was performed, in-hospital mortality was reduced by an estimated 61% over time among hospitals meeting Leapfrog case volume standards, although this result was not statistically significant. These results suggest that hospital compliance with Leapfrog standards for elective AAA repair is an effective means to help improve in-hospital mortality outcomes over time and support further efforts aimed at standardizing patient referral to hospitals that comply with evidence-based medicine standards for other surgical procedures.

The newest effort of the Leapfrog group is to promote transparency of hospital outcomes using a safety scorecard. This information can be viewed at www.hospitalsafetygrade.org.

World Health Organization "Safe Surgery Saves Lives" Initiative

In October 2004, the WHO launched a global initiative to strengthen healthcare safety and monitoring systems by creating the World Alliance for Patient Safety. As part of the group's efforts to improve patient safety, the alliance implemented a series of safety campaigns that brought together experts in specific problem areas through individual Global Patient Safety Challenges. The second Global Patient Safety Challenge focuses on improving the safety of surgical care. The main goal of the campaign, called *Safe Surgery Saves Lives*, is to reduce surgical deaths and complications through the universal adaptation of a comprehensive perioperative surgical safety checklist in ORs worldwide (Fig. 12-4). In addition to the checklist, the WHO defined a set of uniform measures for national and international surveillance of surgical care to better assess the quantity and quality of surgical care being delivered worldwide.³⁸ At the population level, metrics include the number of surgeon, anesthesia, and nurse providers per capita, the number of ORs per capita, and overall surgical case volumes and mortality rates. At the hospital level, metrics include safety improvement structures and a surgical "Apgar score," a validated method of prognosticating patient outcomes based on intraoperative events (i.e., hypotension, tachycardia, blood loss).³⁹

National Quality Forum

The National Quality Forum (NQF) is a coalition of healthcare organizations that has worked to develop and implement a national strategy for healthcare quality measurement and

Table 12-7

Surgical “never events”

- Surgery performed on the wrong body part
- Surgery performed on the wrong patient
- Wrong surgical procedure performed on a patient
- Unintended retention of a foreign object in a patient after surgery or other procedure
- Intraoperative or immediately postoperative death in an ASA Class 1 patient

ASA = American Society of Anesthesiologists.

reporting. Their mission is to improve the quality of American healthcare by setting national priorities and goals for performance improvement, endorsing national consensus standards for measuring and publicly reporting on performance, and promoting the attainment of national goals through education and outreach programs.

One of the major contributions of the NQF is the development of a list of Serious Reportable Events, which are frequently referred to as “never events.”⁴⁰ According to the NQF, “never events” are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility. Examples of never events include surgery performed on the wrong body part; a foreign body left in a patient after surgery; a mismatched blood transfusion; a major medication error; a severe pressure ulcer acquired in the hospital; and preventable postoperative deaths. Criteria for inclusion as a never event are listed in Table 12-7. The event must be:

- Unambiguous (i.e., the event must be clearly identifiable and measurable, and thus feasible to include in a reporting system);
- Usually preventable, with the recognition that some events are not always avoidable, given the complexity of healthcare;
- Serious, resulting in death or loss of a body part, disability, or more than transient loss of a body function; and
- Any one of the following:
 - Adverse, and/or
 - Indicative of a problem in a healthcare facility’s safety systems, and/or
 - Important for public credibility or public accountability.

These events are not a reasonable medical risk of undergoing surgery that the patient must accept but medical errors that should never happen (Case 12-4). The occurrence of any of these events signals that an organization’s patient safety culture or processes have defects that need to be evaluated and corrected (Table 12-8).

“NEVER EVENTS” IN SURGERY

Never events are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility.⁴⁰ Despite widespread agreement that surgical never events are preventable and despite several national and local programs being launched to decrease them, never

Case 12-4 Surgical “never event”

In 2002, Mike Hurewitz, a reporter for *The Times Union* of Albany, suddenly began vomiting blood 3 days after donating part of his liver to his brother while recovering on a hospital floor in which 34 patients were being cared for by one first-year resident. He aspirated and died immediately with no other physician available to assist the overworked first-year resident.

Recognized for its advances in the field of liver transplantation, at the time, Mount Sinai Hospital was performing more adult-to-adult live-donor operations than any other hospital in the country. But the program was shut down by this event. Mount Sinai was held accountable for inadequate care and was banned from performing any live-donor adult liver transplants for more than 1 year. Of the 92 complaints investigated by the state, 75 were filed against the liver transplant unit, with 62 involving patient deaths. The state concluded that most of the 33 serious violations exhibited by the hospital occurred within the liver transplant unit.

As a result of the investigation, Mount Sinai revamped many of the procedures within its transplant unit. Among the changes, first-year residents no longer staffed the transplant service, two healthcare practitioners physically present in the hospital oversaw the transplant unit at all times, and any page coming from the transplant unit had to be answered within 5 minutes of the initial call. In addition, nurses monitored patients’ vital signs more closely after surgery, transplant surgeons were required to make postoperative visits to both organ donor and recipient, and each registered nurse was assigned to four patients, rather than six or seven. The death also led New York to become the first state to develop guidelines for treating live organ donors. Finally, Mike Hurewitz’s widow became a patient safety advocate, urging stricter controls on live donor programs.

events are still a significant problem. A study from Mehtsun and colleagues showed that from October 1990 to October 2010, nationwide there were 9744 paid malpractice claims for never events. Of these, mortality was reported in 6.6%, permanent injury in 33%, and temporary injury in 59%. The cost of the never events totaled \$1.3 billion. Also, of physicians who were named in a surgical never event claim, 12.4% were named in a future never events claim.⁴¹ Another study in 2010 by The Joint Commission found that wrong-site surgery occurs 40 times per week nationwide.⁴² Future directions for decreasing these problems include public reporting of never events by hospitals to increase hospital accountability, more formal training in teamwork, and CUSP programs in hospitals that have higher rates of never events to help elucidate the root cause.

Retained Surgical Items

A retained surgical item refers to any surgical item found to be inside a patient after he or she has left the OR, thus requiring a second operation to remove the item.⁴³ Estimates of retained foreign bodies in surgical procedures range from one case per 8000 to 18,000 operations, corresponding to one case or more each year for a typical large hospital or approximately 1500 cases per year in the United States.⁴⁴ This estimate is based on an analysis of malpractice claims and is likely to underestimate the true incidence. The risk of having a retained surgical item increases during emergency surgery, when there are unplanned changes in

Table 12-8

Four patient events that advanced the modern field of patient safety

PATIENT	INSTITUTION	YEAR	EVENT	ROOT CAUSE	OUTCOME
Libby Zion	New York Hospital, New York, NY	1984	Missed allergy to Demerol	Physician fatigue	Bell Commission shortened resident work hours
Betsy Lehman	Dana-Farber Cancer Institute, Boston, MA	1994	Chemotherapy overdose	Lack of medication checks and triggers	Fired doctor, three pharmacists, 15 nurses; overhauled safety program
Josie King	Johns Hopkins Hospital, Baltimore, MD	2001	Severe dehydration	Poor communication	Increased safety research funding
Mike Hurewitz	Mt. Sinai Hospital, New York, NY	2002	Inadequate postoperative care	Inadequate supervision	Transplant program shut down until better patient safety safeguards implemented

procedure (due to new diagnoses encountered in the OR), and in patients with higher body mass index (Table 12-9).⁴⁴

The most common retained surgical item is a surgical sponge, but other items, such as surgical instruments and needles, can also be inadvertently left inside a patient during an operation. Retained surgical sponges are commonly discovered as an incidental finding on a routine postoperative radiograph, but also have been discovered in patients presenting with a mass or abdominal pain. Patients with sponges that were originally left in an intracavitary position (such as inside the chest or abdomen) also can present with complications such as abscess, erosion through the skin, fistula formation, bowel obstruction, hematuria, or the development of a new, tumor-like lesion.

Retained surgical needles usually are discovered incidentally, and reports of retained needles are uncommon. Retained surgical needles have not been reported to cause injury in the same way that nonsurgical needles (e.g., sewing needles, hypodermic needles) have been reported to perforate bowel or lodge in vessels and migrate. However, there have been reports of chronic pelvic pain and ocular irritation caused by retained surgical needles. A study of plain abdominal radiographs in pigs has demonstrated that medium- to large-size needles can easily be detected. The decision to remove these retained needles depends on symptoms and patient preference. Needles smaller than 13 mm have been found to be undetectable on plain radiograph in several studies, have not been shown to cause injury to vessels or visceral organs, and can probably be left alone.

Although the actual incidence of retained surgical instruments is unknown, they are retained with far less frequency than surgical sponges. The initial presentation of a retained surgical instrument is most commonly pain in the surgical site or the

sensation of a mass of fullness after a surgical procedure that leads to the discovery of a metallic object on a radiographic study. Commonly retained instruments include the malleable and “FISH” instrument that are used to protect the viscera when closing abdominal surgery.

A retained surgical foreign body should be included in the differential diagnosis of any postoperative patient who presents with pain, infection, a palpable mass, or a radiopaque structure on imaging. The diagnosis can usually be made using a computed tomographic (CT) scan, and this is often the only test needed. If a retained surgical item is identified in the setting of an acute clinical presentation, the treatment usually is removal of the item. However, if the attempt to remove the retained surgical item can potentially cause more harm than the item itself, as in the case of a needle or a small part of a surgical item, then removal is occasionally not recommended. Retained surgical sponges should always be removed.

The American College of Surgeons and the Association of Perioperative Registered Nurses, in addition to The Joint Commission, have issued guidelines to try to prevent the occurrence of retained surgical items. Current recommendations include the use of standard counting procedures, performing a thorough wound exploration before closing a surgical site, and using only X-ray–detectable items in the surgical wound. These organizations also strongly endorse the completion of a postoperative debriefing after every operation. An X-ray at the completion of an operation is encouraged if there is any concern for a foreign body based on confusion regarding the counts by even a single member of the OR team or in the presence of a risk factor.

Surgical Counts

The benefit of performing surgical counts to prevent the occurrence of retained surgical items is controversial. The increased risk of a retained surgical item during emergency surgery in the study by Gawande and colleagues appeared to be related to bypassing the surgical count in many of these cases.⁴⁴ However, in another study, the “falsely correct count,” in which a count is performed and declared correct when it is actually incorrect, occurred in 21% to 100% of cases in which a retained surgical item was found.⁴⁵ This type of count was the most common circumstance encountered in all retained surgical item cases, which suggests that performing a surgical count in and of itself does not prevent this error from taking place. The counting protocol also imposes significant demands on the nursing staff and

Table 12-9

Risk factors for retained surgical sponges

- Emergency surgery
- Unplanned changes in procedure
- Patient with higher body mass index
- Multiple surgeons involved in same operation
- Multiple procedures performed on same patient
- Involvement of multiple operating room nurses/staff members
- Case duration covers multiple nursing “shifts”

distracts them from focusing on other primarily patient-centered tasks, often during critical portions of the case.¹⁹

A retained surgical item can occur even in the presence of a known incorrect count. This event is usually a result of poor communication in which a surgeon will dismiss the incorrect count and/or fail to obtain a radiograph before the patient leaves the OR. Having stronger institutional policies in place in case of an incorrect count (such as requiring a mandatory radiograph while the patient is still in the OR) can avoid conflict among caregivers and mitigate the likelihood of a retained surgical item occurring as a result of a known incorrect count.

Although there is no single tool to prevent all errors, the development of multiple lines of defense to prevent retained surgical items and universally standardizing and adhering to OR safety protocols by all members of the surgical team will help reduce the incidence of this never event.⁴⁵ Surgeons should take the lead in the prevention of retained surgical items by avoiding the use of small or nonradiologically detectable sponges in large cavities, performing a thorough wound inspection before closing any surgical incision, and having a vested interest in the counting procedure performed by nursing staff. The value of routine radiography to prevent a retained surgical item in emergency cases or when major procedures involving multiple surgical teams are being performed is becoming more apparent.

The widely accepted legal doctrine when a foreign body is erroneously left in a patient is that the mere presence of the item in the plaintiff's body indicates that the patient did not receive proper surgical care. The characteristics of the surgeon and their style, bedside manner, honesty, and confidence demonstrated in the management of the case can go a long way in averting a lawsuit or mitigating damages.

Wrong-Site Surgery

Wrong-site surgery is any surgical procedure performed on the wrong patient, wrong body part, wrong side of the body, or wrong level of a correctly identified anatomic site. It is difficult to determine the true incidence of wrong-site surgery for several reasons. First, there is no standard definition for what constitutes wrong-site surgery among various healthcare organizations. Another factor is that wrong-site surgery is underreported by healthcare providers. Finally, the total number of potential opportunities for each type of wrong-site error is unknown. However, various studies show incidences ranging from 1 in 112,994 cases to 1 in 15,500 cases.⁴⁶ The Washington University School of Medicine suggests a rate of 1 in 17,000 operations, which adds up to approximately 4000 wrong-site surgeries in the United States each year. If these numbers are correct, wrong-site surgery is the third most frequent life-threatening medical error in the United States.⁴⁷

Several states now require mandatory reporting of all wrong-site surgery events, including near misses. These data provide some insight into the number of actual errors compared to the number of potential opportunities to perform wrong-site surgery. Of the 427 reports of wrong-site surgery submitted from June 2004 through December 2006 to the Pennsylvania Patient Safety Reporting System, more than 40% of the errors actually reached the patient, and nearly 20% involved completion of a wrong-site procedure.⁴⁶

The risk of performing wrong-site surgery increases when there are multiple surgeons involved in the same operation or multiple procedures are performed on the same patient, especially if the procedures are scheduled or performed on different

areas of the body.⁴⁷ Time pressure, emergency surgery, abnormal patient anatomy, and morbid obesity are also thought to be risk factors. Communication errors are the root cause in more than 70% of the wrong-site surgeries reported to The Joint Commission.⁴⁶ Other risk factors include receiving an incomplete preoperative assessment; having inadequate procedures in place to verify the correct surgical site; or having an organizational culture that lacks teamwork or reveres the surgeon as someone whose judgment should never be questioned.

There is a one in four chance that surgeons who work on symmetric anatomic structures will be involved in a wrong-site error sometime during their careers.⁴⁷ The specialties most commonly involved in reporting wrong-site surgeries according to The Joint Commission are orthopedic/podiatric surgery (41%); general surgery (20%); neurosurgery (14%); urology (11%); and maxillofacial, cardiovascular, otolaryngology, and ophthalmology (14%).⁴⁶ Most errors involved symmetric anatomic structures: lower extremities (30%), head/neck (24%), and genital/urinary/pelvic/groin (21%).⁴² Although orthopedic surgery is the most frequently involved, this may be due to the higher volume of cases performed as well as the increased opportunity for lateralization errors inherent in the specialty. In addition, because the American Academy of Orthopaedic Surgeons has historically tried as a professional organization to reduce wrong-site operations, orthopedic surgeons may be more likely to report these events when they do occur.⁴⁷

The Joint Commission Universal Protocol to Ensure Correct Surgery

The movement to eliminate wrong-site surgery began among professional orthopedic societies in the mid-1990s, when both the Canadian Orthopaedic Association and the American Academy of Orthopaedic Surgeons issued position statements and embarked on educational campaigns to prevent the occurrence of wrong-site surgery within their specialty.⁴⁷ Other organizations that issued position statements advocating for the elimination of wrong-site surgery include the North American Spine Society, the American Academy of Ophthalmology, the Association of Perioperative Registered Nurses, and the American College of Surgeons. After issuing a review of wrong-site surgery in their Sentinel Event Alert in 1998, The Joint Commission made the elimination of wrong-site surgery one of their first National Patient Safety Goals in 2003 and adopted a universal protocol for preventing wrong-site, wrong-procedure, and wrong-person surgery in 2004. The protocol has been endorsed by more than 50 professional associations and organizations.

A preoperative "time-out" or "pause for the cause" to confirm the patient, procedure, and site to be operated on before incision was recommended by The Joint Commission and is now mandatory for all ORs in the United States. Elements of the protocol include the following:

- Verifying the patient's identity
- Marking the surgical site
- Using a preoperative site verification process such as a checklist
- Confirming the availability of appropriate documents and studies before the start of a procedure
- Taking a brief time-out immediately before skin incision, in which all members of the surgical team actively communicate and provide oral verification of the patient's identity, surgical site, surgical procedure, administration of preoperative

- medications, and presence of appropriate medical records, imaging studies, and equipment
- Monitoring compliance with protocol recommendations

Focusing on individual process components of the universal protocol, such as surgical site marking or the time-out, is not enough to prevent wrong-site surgery. Over a 30-month period in Pennsylvania, 21 wrong-site errors occurred despite the proper use of time-out procedures, with 12 of these errors resulting in complete wrong-site procedures. During the same period, correct site markings failed to prevent another 16 wrong-site surgeries, of which six were not recognized until after the procedure had been completed.⁴⁷

Site verification begins with the initial patient encounter by the surgeon, continues throughout the preoperative verification process and during multiple critical points in the OR, and requires the active participation of the entire operating team, especially the surgeon and anesthesia provider. Based on a recent review of malpractice claims, two-thirds of wrong-site operations could have been prevented by a site-verification protocol.⁴⁸

Despite the proliferation of wrong-site protocols in the last decade, their effectiveness is difficult to measure as the incidence of wrong-site surgery is too rare to measure as a rate. Interestingly, the number of sentinel events reported to The Joint Commission has not changed significantly since the widespread implementation of the Universal Protocol in 2004.⁴⁷ This could be due to an increase in reporting rather than an actual increase in the incidence of wrong-site surgery.

The legal treatment of wrong-site surgery is similar to that of surgical items erroneously left in a patient: the mere fact that it occurred indicates that the patient did not receive proper surgical care. A malpractice claim may lead to a settlement or award on verdict in the six- or seven-figure range in 2011 U.S. dollars.⁴¹

Ultimately, the occurrence of retained surgical items or wrong-site surgery is a reflection of the quality of professional communication between caregivers and the degree of teamwork among the members of the operating team. In addition to standardizing procedures like the surgical count, instituting mandatory postoperative radiographs in the presence of a known miscount, and reforming the processes of patient identification and site verification, organizations should also strive to create a culture of safety, create independent and redundant checks for key processes, and create a system in which caregivers can learn from their mistakes (Table 12-10).⁴⁹

TRANSPARENCY IN HEALTHCARE

Despite a large increase in data being collected about patient safety and harm, much of it is not available to the public or other hospitals. This lack of transparency allows some hospitals to continue to practice outdated medicine and, in some cases, puts patients at a higher risk of serious complications. In a study by Mark Chassin, the health commissioner of New York State, having hospitals publicly disclose their mortality rates for coronary artery bypass graft (CABG) procedures resulted in a 41% decline in mortality from CABGs statewide.⁵⁰ In this study, when CABG mortality data were initially made public, there was a wide range in cardiac surgery-related mortality from 1% to 18%, depending on the hospital; the standard of care is 2%. The reasons for higher mortality in the poorly performing

Table 12-10

Best practices for operating room safety

- Conduct The Joint Commission Universal Protocol (“time-out”) to prevent wrong-site surgery.
- Perform an operating room briefing (checklist) to identify and mitigate hazards early.
- Promote a culture of speaking up about safety concerns.
- Use a screening X-ray to detect foreign bodies in high-risk cases.
- Begin patient sign-outs with the most likely immediate safety hazard.

Data from Michaels RK, Makary MA, Dahab Y, et al. Achieving the National Quality Forum’s “Never Events”: Prevention of wrong site, wrong procedure, and wrong patient operations, *Ann Surg.* 2007 Apr;245(4):526-532.

hospitals ranged from poor communication between care teams to one rogue surgeon operating when the surgeon should not have been. The consequence of making this data transparent was that the hospitals held multidisciplinary, CUSP-like meetings, where as a team they decided on the measures to implement for improvement. Through this, over the next year, most hospitals decreased their mortality rate to below 2%. Even the hospital that had an 18% mortality rate decreased it to 7% within 3 years and 1.7% over the next several years.

Transparency in healthcare is becoming central to the healthcare quality discussion. A new SCIP core measure is publishing practitioner performance, and all Leapfrog survey results are published online where other hospitals and the public can see them. Additionally, different large medical societies, including the Society for Thoracic Surgery (STS), are encouraging and rewarding practitioners and hospitals that are transparent with their outcomes. Making hospital outcomes transparent makes hospitals accountable to the public for their outcomes and, in the case of New York, caused a radical improvement in the quality of care provided to patients. It also empowers patients by making them better informed about which hospital they choose for their care, which will further incentivize hospitals to improve.

Public Reporting and Patient Assessment of Care

The epiphany moment in contemporary healthcare created by the Institute of Medicine report² generated far-reaching effects. One important aspect has been development of a variety of initiatives focused on the generation, endorsement, and reporting of numerous measures related to the safety and quality of healthcare—primarily process and outcomes measures. However, the science of measure development is slow paced and, unfortunately, has difficulty evolving at the same pace of change as clinical medicine or healthcare delivery systems.

Given the strong interest for improved knowledge and information by consumers of healthcare, the trend toward public reporting has rapidly gained momentum and outpaced reporting from the measurement science community. This has subsequently created occasional confusion and uncertainty in the marketplace—simply because the generation of public reports are not necessarily always based upon solid scientific data or evidence. The resulting net effect can be creation of a premature focus by organizations and providers on achieving success within influential public reporting venues (e.g., U.S. News Best Hospitals) and uncertainty by patients on what are optimal healthcare information resources.

Ideally centered on the public good, federal government sponsored healthcare payment plans are also focused upon measurement and reporting within the industry. One such initiative funded and overseen by the Agency for Healthcare Research and Quality (AHRQ) is the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) program.⁵¹ AHRQ works closely with a consortium of public and private research organizations to develop and maintain the HCAHPS surveys, but they do not administer any of the surveys to patients or require use of the surveys. The intent of the HCAHPS initiative is to provide a standardized survey instrument and data collection methodology for measuring patients' perspectives on hospital care (Fig. 12-7).

While many hospitals have collected information on patient satisfaction, prior to HCAHPS there was no national standard for collecting or publicly reporting patients' perspectives of care information that would enable valid comparisons to be made across all hospitals. Three broad goals have shaped the HCAHPS Survey. First, the survey is designed to produce comparable data on the patient's perspective on care that allows objective and meaningful comparisons between hospitals on domains that are important to consumers. Second, public reporting of the survey results is designed to create incentives for hospitals to improve their quality of care. Hospitals frequently distribute the results of HCAHPS surveys of individual services or physicians to incentivize corrective steps and improve patients' perceptions of their care. Third, public reporting will serve to enhance public accountability in healthcare by increasing the transparency of the quality of hospital care provided in return for the public investment (www.hcahpsonline.org).

HCAHPS scores are now directly tied to a hospital's CMS reimbursement by federal law, and survey results account for 25% of the value-based purchasing score—directly impacting a hospital's Medicare payments.⁵² In May 2005, the National Quality Forum (NQF), an organization established to standardize healthcare quality measurement and reporting, formally endorsed the HCAHPS Hospital Survey. The NQF endorsement represents the consensus of many healthcare providers, consumer groups, professional associations, purchasers, federal agencies, and research and quality organizations (www.qualityforum.org).

While the American College of Surgeons and other professional societies continue to develop and implement scientifically based healthcare measures, the escalating prevalence of less robust measures developed outside of scientific communities will also continue to expand. The patient population, provider organizations, payer organization, and the surgical community will necessarily need to find the balance of developing and utilizing valid patient-based information for decision-making.

RISK MANAGEMENT

Between one-half to two-thirds of hospital-wide adverse events are attributable to surgical care. Most surgical errors occur in the OR and are technical in nature. Surgical complications and adverse outcomes have previously been linked to lack of surgeon specialization, low hospital volume, communication breakdowns, fatigue, surgical residents and trainees, and numerous other factors.⁵³

However, poor surgical outcomes are not necessarily correlated with a surgeon's level of experience in performing a certain procedure. In one study, three-fourths of the technical errors that occurred in a review of malpractice claims data involved fully trained and experienced surgeons operating within their

area of expertise, and 84% occurred in routine operations that do not require advanced training. Rather than surgeon expertise, these errors likely occurred due to situations complicated by patient comorbidity, complex anatomy, repeat surgery, or equipment problems (Table 12-11). Because these errors occurred during routine operations, previous suggestions to limit the performance of high-complexity operations using selective referral, regionalization, or limitation of privileging may not actually be effective in reducing the incidence of technical error among surgical patients.⁵³

In any event, although there has been much emphasis on reducing the prevalence of surgical technical errors as a way of improving surgical care, a technical error in the OR may not be the most important indicator of whether a surgeon will be sued by a patient. Recent studies point to the importance of a surgeon's communication skills in averting malpractice litigation. In the American College of Surgeons' Closed Claims Study, although intraoperative organ injuries occurred in 40% of patients, a surgical technical misadventure was the most deficient component of care in only 12% of patients. In fact, communication and practice pattern violations were the most common deficiency in care for one third of patients in the Closed Claims Study who received the expected standard of surgical care.⁵⁴

The Importance of Communication in Managing Risk

The manner and tone in which a physician communicates is potentially more important to avoiding a malpractice claim than the actual content of the dialogue. For example, a physician relating to a patient in a "negative" manner may trigger litigious feelings when there is a bad result, whereas a physician relating in a "positive" manner may not. Expressions of dominance, in which the voice tone is deep, loud, moderately fast, unaccented, and clearly articulated, may communicate a lack of empathy and understanding for the patient, whereas concern or anxiety in the surgeon's voice is often positively related to expressing concern and empathy. General and orthopedic surgeons whose tone of voice was judged to be more dominant were more likely to have been sued than those who sounded less dominant.⁵⁵

When significant medical errors do occur, physicians have an ethical and professional responsibility to immediately disclose them to patients. Failure to disclose errors to patients undermines public confidence in medicine and can create legal liability related to fraud. Physicians' fear of litigation represents a major barrier to error disclosure. However, when handled appropriately, immediate disclosure of errors frequently leads to improved patient rapport, improved satisfaction, and fewer malpractice claims.⁵⁶ In fact, rapport is the most important factor in determining whether a lawsuit is filed against a physician.

In 1987, the Department of Veterans Affairs Hospital in Lexington, Kentucky, implemented the nation's first formal apology and medical error full disclosure program, which called for the hospital and its doctors to work with patients and their families to settle a case. As a result, the hospital improved from having one of the highest malpractice claims totals in the VA system to being ranked among the lowest quartile of a comparative group of similar hospitals for settlement and litigation costs over a 7-year period. Its average payout in 2005 was \$16,000 per settlement vs the national VA average of \$98,000 per settlement, and only two lawsuits went to trial during a

Table 12-11

Common causes of lawsuits in surgery

- Positional nerve injury
- Common bile duct injury
- Failure to diagnose or delayed diagnosis
- Failure to treat, delayed treatment, or wrong treatment
- Inadequate documentation
- Inappropriate surgical indication
- Failure to call a specialist
- Cases resulting in amputation/limb loss

10-year period. As a result of the success of this program, the Department of Veteran Affairs expanded the program to all VA hospitals nationwide in October 2005. This model also was replicated at the University of Michigan Health System with similar results. Its full-disclosure program cut the number of pending lawsuits by one half and reduced litigation costs per case from \$65,000 to \$35,000, saving the hospital approximately \$2 million in defense litigation bills each year. In addition, University of Michigan's doctors, patients, and lawyers are happier with this system. The cultural shift toward honesty and openness also has led to the improvement of systems and processes to reduce medical errors, especially repeat medical errors.⁵⁷

With regard to risk management, the importance of good communication by surgeons and other care providers cannot be overemphasized. Whether alerting other members of the care team about a patient's needs, openly discussing concerns the patient and/or family might have, or disclosing the cause of a medical error, open communication with all parties involved can reduce anger and mistrust of the medical system; the frequency, morbidity, and mortality of preventable adverse events; and the likelihood of litigation.

COMPLICATIONS

Despite the increased focus on improving patient safety and minimizing medical errors, it is impossible to eliminate human error entirely. Individual errors in judgment or technique can cause minor or major complications during or after a surgical procedure. Although these types of errors may not be quantified as easily as wrong-site surgery or a retained surgical item, they can still lead to surgical complications that prolong the course of illness, lengthen hospital stay, and increase morbidity and mortality rates. In addition to technical and management errors, patient comorbidities also increase the risk of complications. The recognition and management of complications is a critical component of surgical care.

Robotic Surgery

Surgical advancements would not exist without intellectual curiosity, innovation, and technical developments; robotic surgery is a prime example of such an advance. With these advancements, however, errors and complications appear to be an inevitable and recognized risk by institutions and stakeholders due to unforeseen risks inherent in the new technology and the failure or delay of achieving expertise with a new device or technology. Although the reward for adopting new advances may be notoriety, increased patient referrals, improved patient satisfaction, decreased pain, and possibly decreased length of stay, the risks of adopting new technologies and methods become apparent only after widespread use.

Multiple surgical specialties have begun or continue to develop their experiences using robotic surgery from general surgery procedures such as inguinal hernia repairs to pancreaticoduodenectomies to complex thoracic, urologic and ear, nose, and throat procedures. When robotic surgery goes awry, however, the complications can be serious. The MAUDE (Manufacturer and User Facility Device Experience) is an open access database where mandatory and voluntary adverse events are collected. As it relates to robotic surgery, some important information has been elucidated. Device failures (electrocautery, instrument malfunctions), make up roughly half of the complications. A retrospective study over the past 14 years in the United States documented over 10,000 robotic device-related complications that have occurred, of which 98% were reported by the manufacturers and distributors, and 2% were voluntary reports by hospitals and physicians. The data revealed that 1535 adverse events (14.4%) led to significant negative patient experiences (1391 injuries and 144 deaths). Additionally, the absolute number of reports increased 32 times since 2006, while in the same time period, the number of cases performed has only increased tenfold.⁵⁸ Despite the large number of reports contained within this database, the extent to which it is a true representation of the complications associated with robotic surgery is uncertain due to the lack of comprehensive and mandatory reporting.⁵⁹

Despite the numbers and trends reported from this database, few prospective, controlled trials exist that examine the risks and benefits of robotic surgery with those of open and laparoscopic surgery. The data from 5 to 10 years ago may also be misleading as the approved use of robotic surgery continues to expand to additional specialties. The more recent adoption of robotic surgery by specialties such as gynecologic surgery, for example, appears to be accompanied by a disproportionately high rate of morbidity and mortality in robotically assisted procedures.⁵⁹ Teaching institutions are producing a newer generation of robotic surgeons who will continue important advances in surgery and identify those patients who would benefit most from this type of approach. The challenge for the surgical community is to develop robust and effective training programs to allow trainees and practicing surgeons to acquire the skills necessary to perform robotic procedures with the highest degree of safety. This need replicates the development of skill acquisition processes that reversed the high number of bile duct injuries after the introduction of laparoscopic cholecystectomy and suggests that validated curricula and the use of robotic simulation applications will be crucial to achieve these goals (see Chapter 53, Skills and Simulation).

Complications in Minor Procedures

When performing procedures such as central line insertion or arterial line insertion, one should consider the necessity of the access, the use of less invasive or lower risk alternatives such as PICC line insertion instead of central line insertion, and non-invasive cardiac monitoring instead of arterial line insertion. While these alternatives may not be reliable substitutes in all patients, considering less invasive procedures can reduce the problem of avoidable harm.

Central Venous Access Catheters. Complications of central venous access catheters are common. Improvements in ultrasound technology and mass education surrounding the use and techniques in ultrasonography have led to increased employment and enthusiasm for its use in central venous catheter placement. Numerous institutions have mandated the use of ultrasound for placement of all central venous lines. In addition, many subclavian catheters have been alternatively placed at the internal jugular position due to a perceived benefit of decreasing the complication of pneumothorax. This theoretical benefit may be offset by an increase in line infections as the neck is a difficult site to keep clean and the dressing intact. Steps to decrease complications include:

- Ensure that central venous access is indicated.
- Experienced personnel should insert the catheter or should supervise the insertion.
- Use proper positioning and sterile technique.
- Ultrasound is recommended for internal jugular vein insertion.
- All central venous catheters should be assessed on a daily basis and should be exchanged only for specific indications (not as a matter of routine).
- All central catheters should be removed as soon as possible.

Common complications of central venous access include the following.

Pneumothorax Occurrence rates from both subclavian and internal jugular vein approaches are 1% to 6%. Prevention requires proper positioning of the patient and correct insertion technique. A postprocedure chest X-ray is recommended to confirm the presence or absence of a pneumothorax, regardless

of whether a pneumothorax is suspected. Recent reports have questioned whether a chest X-ray is required when the line is placed and confirmed under ultrasound guidance. Pneumothorax rates are higher among inexperienced providers and underweight patients but occur with experienced operators as well. If the patient is stable, and the pneumothorax is small (<15%), close expectant observation may be adequate. If the patient is symptomatic, a thoracostomy tube should be placed. Occasionally, pneumothorax will occur as late as 48 to 72 hours after central venous access attempts. This usually creates sufficient compromise that a tube thoracostomy is required.

Arrhythmias Arrhythmias can result from myocardial irritability secondary to guidewire placement and usually resolve when the catheter or guidewire is withdrawn from the right heart. Prevention requires electrocardiogram (ECG) monitoring whenever possible during catheter insertion and rapid recognition when a new arrhythmia occurs.

Arterial Puncture Inadvertent puncture or laceration of an adjacent artery with bleeding can occur, but the majority will resolve with direct pressure on or near the arterial injury site. Rarely will angiography, stent placement, or surgery be required to repair the puncture site, but close observation and a chest X-ray are indicated. Ultrasound-guided insertion has not mitigated this complication, but it may decrease the incidence of arterial puncture. Ultrasound use has also been shown to decrease the number of attempts and the time it takes to complete insertion.

Lost Guidewire A guidewire or catheter that inadvertently migrates further into the vascular space away from the insertion site can be readily retrieved with interventional angiography techniques. A prompt chest X-ray and close monitoring of the patient until retrieval are indicated.

Air Embolus Although estimated to occur in only 0.2% to 1% of patients, an air embolism can be dramatic and fatal. If an embolus is suspected, the patient should immediately be placed into a left lateral decubitus Trendelenburg position so the entrapped air can be stabilized within the right ventricle. Auscultation over the precordium may reveal a “crunching” sound, but a portable chest X-ray will help confirm the diagnosis. Aspiration via a central venous line accessing the heart may decrease the volume of gas in the right side of the heart and minimize the amount traversing into the pulmonary circulation. Subsequent recovery of intracardiac and intrapulmonary air may require open surgical or angiographic techniques. Treatment may prove futile if the air bolus is larger than 50 mL, however.

Pulmonary Artery Rupture Flow-directed, pulmonary artery (Swan-Ganz) catheters can cause pulmonary artery rupture due to excessive advancement of the catheter into the pulmonary circulation. There usually is a sentinel bleed with coughing noted when a pulmonary artery catheter balloon is inflated, followed by uncontrolled hemoptysis. Reinflation of the catheter balloon is the initial step in management, followed by immediate airway intubation with mechanical ventilation, an urgent portable chest X-ray, and notification of the OR that an emergent thoracotomy may be required. If there is no further bleeding after the balloon is reinflated, the X-ray shows no significant consolidation of lung fields from ongoing bleeding, and the patient is easily ventilated, then a conservative nonoperative approach may be considered. However, more typically a pulmonary angiogram with angioembolization or vascular stenting is required. Hemodynamically unstable patients rarely survive because of the time needed to initiate and perform interventional procedures or a

thoracotomy and to identify the ruptured branch of the pulmonary artery.

Central Venous Line Infection The CDC reports mortality rates of 12% to 25% when a central venous line infection becomes systemic, with a cost of approximately \$25,000 per episode.⁶⁰⁻⁶² The CDC does not recommend routine central line changes, but when the clinical suspicion of infection is high, the site of venous access must be changed. Nearly 15% of hospitalized patients will acquire central venous line sepsis. In many instances, once an infection is recognized as central line sepsis, removing the line is adequate. *Staphylococcus aureus* infections, however, present a unique problem because of the potential for metastatic seeding of bacterial emboli. The required treatment is 4 to 6 weeks of tailored antibiotic therapy. Using a checklist when inserting central venous catheters has been shown to significantly decrease rates of line infections.⁶³ Following a checklist strategy and close monitoring of catheters has resulted in significant reductions in infection rates for numerous institutions, and many are now reporting zero annual infection rates.

Arterial Lines. Arterial lines are placed to facilitate arterial blood gas sampling and hemodynamic monitoring. The use of ultrasound to assist in placement of these catheters has become commonplace and markedly reduces the number of attempts and time for insertion completion.

Arterial access requires a sterile Seldinger technique, and a variety of arteries are used, including the radial, femoral, brachial, axillary, dorsalis pedis, or superficial temporal arteries. Although complications occur less than 1% of the time, they can be catastrophic. Complications include thrombosis, bleeding, hematoma, arterial spasm (nonthrombotic pulselessness), and infection. Thrombosis or embolization of an extremity arterial catheter can result in the loss of a digit, hand, or foot, and the risk is nearly the same for both femoral and radial cannulation. Thrombosis with distal tissue ischemia is treated with anticoagulation, but occasionally surgical intervention is required. Pseudoaneurysms and arteriovenous fistulae can also occur.

Endoscopy and Bronchoscopy. The principal risk of gastrointestinal (GI) endoscopy is perforation. Perforations occur in 1 in 10,000 patients with endoscopy alone but have a higher incidence rate when biopsies are performed (up to 10%). This increased risk is due to complications of intubating a GI diverticulum (either esophageal or colonic) or from the presence of weakened or inflamed tissue in the intestinal wall (e.g., diverticulitis, glucocorticoid use, or inflammatory bowel disease).

Patients will usually complain of diffuse abdominal pain shortly after the procedure and then progress with worsening abdominal discomfort and peritonitis on examination. In obtunded or elderly patients, a change in clinical status may be delayed for 24 to 48 hours. Radiologic studies to look for free intraperitoneal air, retroperitoneal air, or a pneumothorax are diagnostic. Open or laparoscopic exploration locates the perforation and allows repair and local decontamination of the surrounding tissues.

The occasional patient who may be a candidate for nonoperative management is one in whom perforation arises during an elective, bowel-prepped endoscopy and who does not have significant pain or clinical signs of infection. These patients must be closely observed in a monitored setting and must be on strict dietary restriction and broad-spectrum antibiotics.

Complications of bronchoscopy include bronchial plugging, hypoxemia, pneumothorax, lobar collapse, and bleeding.

When diagnosed in a timely fashion, they are rarely life-threatening. Bleeding usually resolves spontaneously and rarely requires surgery but may require repeat endoscopy for thermocoagulation or fibrin glue application. The presence of a pneumothorax necessitates placement of a thoracostomy tube when significant deoxygenation occurs or the pulmonary mechanics are compromised. Lobar collapse or mucous plugging usually responds to aggressive pulmonary toilet but occasionally requires repeat bronchoscopy. If biopsies have been performed, the risk for these complications increases.

Tracheostomy. Tracheostomy facilitates weaning from a ventilator, may decrease length of ICU or hospital stay, and improves pulmonary toilet. Tracheostomies are performed open, percutaneously, with or without bronchoscopy, and with or without Doppler guidance. The advantages of percutaneous tracheostomy include efficiency and cost containment over open tracheostomy. A recent literature review examining early (<3–7 days) vs late (>14 days) tracheostomy after endotracheal intubation demonstrates little difference in outcomes but does demonstrate greater patient comfort in those patients with tracheostomy than those with an endotracheal tube. Complications and outcomes between the two different methods remain largely equivalent.

Recent studies do not support obtaining a routine chest X-ray after percutaneous or open tracheostomy.^{64,65} However, significant lobar collapse can occur from copious tracheal secretions or mechanical obstruction. The most dramatic complication of tracheostomy is tracheoinnominate artery fistula (TIAF) (Fig. 12-8).^{66,67} This occurs rarely (~0.3%) but carries a 50% to 80% mortality rate. TIAFs can occur as early as 2 days or as late as 2 months after tracheostomy. A sentinel bleed occurs in 50% of TIAF cases, followed by a large-volume bleed. Should a TIAF be suspected, the patient should be transported immediately to the OR for fiberoptic evaluation. If needed, remove the tracheostomy and place a finger through the tracheostomy site to apply direct pressure anteriorly for compression of the innominate artery while preparation for a more definitive approach is organized.

Percutaneous Endogastrostomy. A misplaced percutaneous endogastrostomy (PEG) tube may lead to intra-abdominal sepsis with peritonitis and/or an abdominal wall abscess with necrotizing fasciitis. As in other minor procedures, the initial placement technique must be fastidious to avoid complications.

Figure 12-8. This illustration depicts improper positioning of the percutaneous needle. It is possible to access the innominate artery via the trachea, thus placing the patient at risk for early tracheoinnominate artery fistula.

Endoscopic transillumination of the abdomen from within the stomach has been proposed to decrease the risk for error, but this is without supporting evidence. Inadvertent colotomies, intraperitoneal placement of the tube and subsequent leakage of tube feeds with peritonitis, and abdominal wall abscesses require surgery to correct the complications and to replace the PEG with an alternate feeding tube, usually a jejunostomy.

A dislodged or prematurely removed PEG tube should be replaced as early as possible after dislodgment because the gastrostomy site closes rapidly. A contrast X-ray (sinogram) should be performed to confirm the tube's intragastric position before feeding. If there is uncertainty of the tube location, conversion to an open tube placement procedure is required.

Tube Thoracostomy. Chest tube insertion is performed for pneumothorax, hemothorax, pleural effusions, or empyema. In most patients, a chest tube can be easily placed with a combination of local analgesia and light conscious sedation. Common complications include inadequate analgesia or sedation, incomplete penetration of the pleura with formation of a subcutaneous tube track, lacerations to the lung or diaphragm, intraperitoneal placement of the tube through the diaphragm, and bleeding. Additional problems include slippage of the tube out of position or mechanical problems related to the drainage system. In patients with bullous disease, there can be significant intrapleural scarring, and it can be easy to mistakenly place the chest tube into bullae. All of these complications can be avoided with proper initial insertion techniques, plus a daily review of the drainage system and follow-up radiographs. Tube removal can create a residual pneumothorax if the patient does not maintain positive intrapleural pressure by Valsalva maneuver during tube removal and dressing application.

Complications of Angiography. Intramural dissection of a cannulated artery can lead to complications such as ischemic stroke from a carotid artery dissection or occlusion, mesenteric ischemia from dissection of the superior mesenteric artery, or a more innocuous finding of “blue toe syndrome” from a dissected artery in a peripheral limb. Invasive or noninvasive imaging studies confirm the suspected problem. The severity of ischemia and extent of dissection determine if anticoagulation therapy or urgent surgical exploration is indicated.

Bleeding from a vascular access site usually is obvious, but may not be visible when the blood loss is tracking into the retroperitoneal tissue planes after femoral artery cannulation. These patients can present with hemorrhagic shock; an abdominal-pelvic CT scan delineates the extent of bleeding along the retroperitoneum. Initial management is direct compression at the access site and resuscitation as indicated. Urgent surgical exploration may be required to control the bleeding site and evacuate larger hematomas.

Renal complications of angiography occur in 1% to 2% of patients. Contrast nephropathy is a temporary and preventable complication of radiologic studies such as CT, angiography, and/or venography. Intravenous (IV) hydration before and after the procedure is the most efficient method for preventing contrast nephropathy. Nonionic contrast also may be of benefit in higher-risk patients. Close communication between providers is often required to resolve the priorities in care as well as to balance the risks versus benefits of renal protection when managing patients in need of angiographic procedures.

Complications of Biopsies. Lymph node biopsies have direct and indirect complications that include bleeding, infection,

lymph leakage, and seromas. Measures to prevent direct complications include proper surgical hemostasis, proper skin preparation, and a single preoperative dose of antibiotic to cover skin flora 30 to 60 minutes before incision. Bleeding at a biopsy site usually can be controlled with direct pressure. Infection at a biopsy site will appear 5 to 10 days postoperatively and may require opening of the wound to drain the infection. Seromas or lymphatic leaks resolve with aspiration of seromas and the application of pressure dressings but may require repeated treatments or even placement of a vacuum drain.

Organ System Complications

Neurologic System. Neurologic complications that occur after surgery include motor or sensory deficits and mental status changes. Peripheral motor and sensory deficits are often due to neurapraxia secondary to improper positioning and/or padding during operations. Treatment is largely clinical observation, and the majority of deficits resolve spontaneously within 1 to 3 months.

Direct injury to nerves during a surgical intervention is a well-known complication of several specific operations, including superficial parotidectomy (facial nerve), carotid endarterectomy (hypoglossal nerve), thyroidectomy (recurrent laryngeal nerve), prostatectomy (nervi erigentes), inguinal herniorrhaphy (ilioinguinal nerve), and mastectomy (long thoracic and thoracodorsal nerves). The nerve injury may be a stretch injury or an unintentionally severed nerve. In addition to loss of function, severed nerves can result in a painful neuroma that may require subsequent surgery.

Mental status changes in the postoperative patient can have numerous causes (Table 12-12). Mental status changes must be continually assessed. A noncontrast CT scan should be used early to detect new or evolving intracranial causes.

Atherosclerotic disease increases the risk for intraoperative and postoperative stroke (cerebrovascular accident). Postoperatively, hypotension and hypoxemia are the most likely causes of a cerebrovascular accident. Neurologic consultation should be obtained immediately to confirm the diagnosis. Management is largely supportive and includes adequate intravascular volume replacement plus optimal oxygen delivery. Advents in interventional radiology by radiologists and vascular and neurologic

surgeons have proven successful alternatives in patients requiring diagnostic and therapeutic care in the immediate and acute postoperative period. Catheter-directed therapy with anticoagulants such as the kinases and tissue plasminogen activator (tPA) has potential benefit in postoperative thrombosis where reoperation carries significant risk. In addition, endoluminal stents with drug-eluting stents (DESs) or non-DESs have been used with some degree of success. DESs do require systemic antiplatelet therapy due to the alternative coagulation pathway. Duration of antiplatelet therapy of 1 year is routine.

Eyes, Ears, and Nose. Corneal abrasions are unusual, but are due to inadequate protection of the eyes during anesthesia. Overlooked contact lenses in patients occasionally cause conjunctivitis.

Persistent epistaxis can occur after nasogastric tube placement or removal, and nasal packing is the best treatment option if prolonged persistent direct pressure on the external nares fails. Anterior and posterior nasal gauze packing with balloon tamponade, angioembolization, and fibrin glue placement may be required in refractory cases. The use of antibiotics for posterior packing is controversial.

External otitis and otitis media occasionally occur postoperatively. Patients complain of ear pain or decreased hearing, and treatment includes topical antibiotics and nasal decongestion for symptomatic improvement.

Ototoxicity due to aminoglycoside administration occurs in up to 10% of patients and is often irreversible. Vancomycin-related ototoxicity occurs about 3% of the time when used alone, and as often as 6% when used with other ototoxic agents.⁶⁸

Vascular Problems of the Neck. Complications of carotid endarterectomy include central or regional neurologic deficits or bleeding with an expanding neck hematoma. An acute change in mental status or the presence of localized neurologic deficit requires an immediate return to the OR. An expanding hematoma may warrant emergent airway intubation and subsequent transfer to the OR for control of hemorrhage. Intraoperative anticoagulation with heparin during carotid surgery makes bleeding a postoperative risk. Other complications include arteriovenous fistulae, pseudoaneurysms, and infection, all of which are treated surgically.

Table 12-12

Common causes of mental status changes

ELECTROLYTE IMBALANCE	TOXINS	TRAUMA	METABOLIC	MEDICATIONS
Sodium	Ethanol	Closed head injury	Thyrotoxicosis	Aspirin
Magnesium	Methanol	Pain	Adrenal insufficiency	β-Blockers
Calcium	Venoms and poisons	Shock	Hypoxemia	Narcotics
Inflammation	Ethylene glycol	Psychiatric	Acidosis	Antiemetics
Sepsis	Carbon monoxide	Dementia	Severe anemia	MAOIs
AIDS		Depression	Hyperammonemia	TCA
Cerebral abscess		ICU psychosis	Poor glycemic control	Amphetamines
Meningitis		Schizophrenia	Hypothermia	Antiarrhythmics
Fever/hyperpyrexia			Hyperthermia	Corticosteroids, anabolic steroids

AIDS = acquired immunodeficiency syndrome; ICU = intensive care unit; MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant.

Intraoperative hypotension during manipulation of the carotid bifurcation can occur and is related to increased tone from baroreceptors that reflexively cause bradycardia. Should hypotension occur when manipulating the carotid bifurcation, an injection of 1% lidocaine solution around this structure should attenuate this reflexive response.

The most common delayed complication following carotid endarterectomy remains myocardial infarction. The possibility of a postoperative myocardial infarction should be considered as a cause of labile blood pressure and arrhythmias in high-risk patients.

Thyroid and Parathyroid Glands. Surgery of the thyroid and parathyroid glands can result in hypocalcemia in the immediate postoperative period. Manifestations include ECG changes (shortened P-R interval), muscle spasm (tetany, Chvostek's sign, and Trousseau's sign), paresthesias, and laryngospasm. Treatment includes calcium gluconate infusion and, if tetany ensues, chemical paralysis with intubation. Maintenance treatment is thyroid hormone replacement (after thyroidectomy) in addition to calcium carbonate and vitamin D.

Recurrent laryngeal nerve (RLN) injury occurs in less than 5% of patients. Of those with injury, approximately 10% are permanent. Dissection near the inferior thyroid artery is a common area for RLN injury. At the conclusion of the operation, if there is suspicion of an RLN injury, direct laryngoscopy is diagnostic. The cord on the affected side will be in the paramedian position. With bilateral RLN injury, the chance of a successful extubation is poor. If paralysis of the cords is not permanent, function may return 1 to 2 months after injury. Permanent RLN injury can be treated by various techniques to stent the cords in a position of function.

Superior laryngeal nerve injury is less debilitating, as the common symptom is loss of projection of the voice. The glottic aperture is asymmetrical on direct laryngoscopy, and management is limited to clinical observation.

Respiratory System. Surgical complications that put the respiratory system in jeopardy are not confined to technical errors. Malnutrition, inadequate pain control, inadequate mechanical ventilation, inadequate pulmonary toilet, and aspiration can cause serious pulmonary problems.

Pneumothorax can occur from central line insertion during anesthesia or from a diaphragmatic injury during an abdominal procedure. Hypotension, hypoxemia, and tracheal deviation away from the affected side may be present. A tension pneumothorax can cause complete cardiovascular collapse. Treatment is by needle thoracostomy, followed by tube thoracostomy. The chest tube is inserted at the fifth intercostal space in the anterior axillary line. The anterior chest wall is up to 1 cm thicker than the lateral chest wall, so needle decompression is more effective in the lateral position. Attempted prehospital needle decompression in the traditional anterior position results in only 50% needle entry into the thoracic cavity.

Hemothoraces should be evacuated completely. Delay in evacuation of a hemothorax leaves the patient at risk for empyema and entrapped lung. If evacuation is incomplete with tube thoracostomy, video-assisted thoracoscopy or open evacuation and pleurodesis may be required.

Pulmonary atelectasis results in a loss of functional residual capacity (FRC) of the lung and can predispose to pneumonia. Poor pain control in the postoperative period contributes to poor inspiratory effort and collapse of the lower lobes in

particular. The prevention of atelectasis is facilitated by sitting the patient up as much as possible, early ambulation, and adequate pain control. An increase in FRC by 700 mL or more can be accomplished by sitting patients up to greater than 45°. For mechanically ventilated patients, simply placing the head of the bed at 30° to 45° elevation and delivering adequate tidal volumes (8–10 mL/kg) improves pulmonary outcomes.⁶⁹

Patients with inadequate pulmonary toilet are at increased risk for bronchial plugging and lobar collapse. Patients with copious and tenacious secretions develop these plugs most often, but foreign bodies in the bronchus can be the cause of lobar collapse as well. The diagnosis of bronchial plugging is based on chest X-ray and clinical suspicion with acute pulmonary decompensation with increased work of breathing and hypoxemia. Fiberoptic bronchoscopy can be useful to clear mucous plugs and secretions.

Aspiration complications include pneumonitis and pneumonia. The treatment of pneumonitis is similar to that for acute respiratory distress syndrome (see later in this section) and includes oxygenation with general supportive care. Antibiotics are not indicated. Hospitalized patients who develop aspiration pneumonitis have a mortality rate as high as 70% to 80%. Early, aggressive, and repeated bronchoscopy for suctioning of aspirated material from the tracheobronchial tree will help minimize the inflammatory reaction of pneumonitis and facilitate improved pulmonary toilet. Forced diuresis to overcome anasarca and over-resuscitation remains controversial and unsubstantiated. Complications of forced diuresis include electrolyte disturbances, replacement of those electrolytes, metabolic alkalosis, hypotension, and acute kidney injury.

Pneumonia is the second most common nosocomial infection and is the most common infection in ventilated patients. Ventilator-associated pneumonia (VAP) occurs in 15% to 40% of ventilated ICU patients, with a probability rate of 5% per day, up to 70% at 30 days. The 30-day mortality rate of nosocomial pneumonia can be as high as 40% and depends on the microorganisms involved and the timeliness of initiating appropriate antimicrobials. Protocol-driven approaches for prevention and treatment of VAP are recognized as beneficial in managing these difficult infectious complications.

Once the diagnosis of pneumonia is suspected (an abnormal chest X-ray, fever, productive cough with purulent sputum, and no other obvious fever sources), it is invariably necessary to initially begin treatment with broad-spectrum antibiotics until proper identification, colony count ($\geq 100,000$ colony-forming units [CFU]), and sensitivity of the microorganisms are determined. The spectrum of antibiotic coverage should be narrowed as soon as the culture sensitivities are determined. Double-coverage antibiotic strategy for the two pathogens, *Pseudomonas* and *Acinetobacter* spp., may be appropriate if the local prevalence of these particularly virulent organisms is high. One of the most helpful tools in treating pneumonia and other infections is the tracking of a medical center's antibiogram every 6 to 12 months.⁷⁰

Epidural analgesia decreases the risk of perioperative pneumonia. This method of pain control improves pulmonary toilet and the early return of bowel function; both have a significant impact on the potential for aspiration and for acquiring pneumonia. The routine use of epidural analgesia results in a lower incidence of pneumonia than patient-controlled analgesia.⁷¹

Acute lung injury (ALI) was a diagnosis applied to patients with similar findings to those with acute respiratory distress

syndrome (ARDS). The Berlin definition of ARDS developed by the American-European Consensus Conference of 2012 not only simplifies the definition of ARDS but also eliminates the term ALI from critical care vernacular. ARDS is now classified by partial pressure of oxygen in arterial blood (P_{aO_2})/fraction of inspired oxygen (F_{iO_2}) ratios as mild (300–201 mmHg), moderate (200–101 mmHg), and severe (<100 mmHg). Elements of modification of the definition include the following: <7 days of onset; removal of pulmonary artery occlusion pressure; and clinical judgment for characterizing hydrostatic pulmonary edema is acceptable, unless risk factors for ARDS have been eliminated, in which case objective analysis is necessary.⁷²⁻⁷⁵

The definition of ARDS traditionally included five criteria (Table 12-13). The multicenter ARDS Research Network (ARDSnet) research trial demonstrated improved clinical outcomes for ARDS patients ventilated at tidal volumes of only 5 to 7 mL/kg.⁷⁶ This strategy is no longer prescribed solely for patients with ARDS but is also recommended for patients with normal pulmonary physiology who are intubated for reasons other than acute respiratory failure. The beneficial effects of positive end-expiratory pressure (PEEP) for ARDS were confirmed in this study as well. The maintenance of PEEP during ventilatory support is determined based on blood gas analysis, pulmonary mechanics, and requirements for supplemental oxygen. As gas exchange improves with resolving ARDS, the initial step in decreasing ventilatory support should be to decrease the levels of supplemental oxygen first, and then to slowly bring the PEEP levels back down to minimal levels.⁷⁷ This is done to minimize the potential for recurrent alveolar collapse and a worsening gas exchange.

Not all patients can be weaned easily from mechanical ventilation. When the respiratory muscle energy demands are not balanced or there is an ongoing active disease state external to the lungs, patients may require prolonged ventilatory support. Protocol-driven ventilator weaning strategies are successful and have become part of the standard of care. The use of a weaning protocol for patients on mechanical ventilation greater than 48 hours reduces the incidence of VAP and the overall length of time on mechanical ventilation. Unfortunately, there is still no reliable way of predicting which patient will be successfully extubated after a weaning program, and the decision for extubation is based on a combination of clinical parameters and measured pulmonary mechanics.⁷⁸ The Tobin Index (frequency [breaths per minute]/tidal volume [L]), also known as the *rapid shallow breathing index*, is perhaps the best negative predictive instrument.⁷⁹ If the result equals less than 105, then

there is nearly a 70% chance the patient will pass extubation. If the score is greater than 105, the patient has an approximately 80% chance of failing extubation. Other parameters such as the negative inspiratory force, minute ventilation, and respiratory rate are used, but individually these have no better predictive value than the rapid shallow breathing index.⁸⁰

Malnutrition and poor nutritional support may adversely affect the respiratory system. The respiratory quotient (RQ), or respiratory exchange ratio, is the ratio of the rate of carbon dioxide (CO_2) produced to the rate of oxygen uptake ($RQ = V_{CO_2}/\dot{V}O_2$). Lipids, carbohydrates, and protein have differing effects on CO_2 production. Patients consuming a diet of mostly carbohydrates have an RQ of 1 or greater. The RQ for a diet of mostly lipids is closer to 0.7, and that for a diet of mostly protein is closer to 0.8. Ideally, an RQ of 0.75 to 0.85 suggests adequate balance and composition of nutrient intake. An excess of carbohydrate may negatively affect ventilator weaning because of the abnormal RQ due to higher CO_2 production and altered pulmonary gas exchange.

Although not without risk, tracheostomy decreases the pulmonary dead space and provides for improved pulmonary toilet. When performed before the tenth day of ventilatory support, tracheostomy may decrease the incidence of VAP, the overall length of ventilator time, and the number of ICU patient days.

The occurrence of PE is probably underdiagnosed. Its etiology is thought to stem from DVT. This concept, however, has recently been questioned by Spaniolas et al.⁸¹ The diagnosis of PE is made when a high degree of clinical suspicion for PE leads to imaging techniques such as ventilation–perfusion nuclear scans or CT pulmonary angiogram. Clinical findings include elevated central venous pressure, hypoxemia, shortness of breath, hypocarbia secondary to tachypnea, and right heart strain on ECG. Ventilation–perfusion nuclear scans are often indeterminate in patients who have an abnormal chest X-ray and are less sensitive than a CT angiogram or pulmonary angiogram for diagnosing PE. The pulmonary angiogram remains the gold standard for diagnosing PE, but spiral CT angiogram has become an alternative method because of its relative ease of use and reasonable rates of diagnostic accuracy. For cases without clinical contraindications to therapeutic anticoagulation, patients should be empirically started on heparin infusion until the imaging studies are completed if the suspicion of a PE is high.

Sequential compression devices on the lower extremities and low-dose subcutaneous heparin or low molecular weight heparinoid administration are routinely used to prevent DVT and, by inference, the risk of PE. Neurosurgical and orthopedic patients have higher rates of PE, as do obese patients and those at prolonged bed rest.

When anticoagulation is contraindicated, or when a known clot exists in the inferior vena cava (IVC), decreasing the risk for PE includes insertion of an IVC filter. The Greenfield filter has been most widely studied, and it has a failure rate of less than 4%. Newer devices include those with nitinol wire that expands with body temperature and retrievable filters. Retrievable filters, however, must be considered as permanent. In most studies, the actual retrievable rate only reached about 20%. Some studies recognize the benefit of automated reminders and diligence of outlying patient follow-up, where higher retrieval rates have been achieved.⁸² Patients with spinal cord injury and multiple long-bone or pelvic fractures frequently receive IVC filters, and

Table 12-13

Inclusion criteria for the acute respiratory distress syndrome

Acute onset
Predisposing condition
P_{aO_2} : F_{iO_2} <200 (regardless of positive end-expiratory pressure)
Bilateral infiltrates
Pulmonary artery occlusion pressure <18 mmHg
No clinical evidence of right heart failure

F_{iO_2} = fraction of inspired oxygen; P_{aO_2} = partial pressure of arterial oxygen.

there appears to be a low, but not insignificant, long-term complication rate with their use. However, IVC filters do not prevent PEs that originate from DVTs of the upper extremities.

Cardiac System. Arrhythmias are often seen preoperatively in elderly patients but may occur postoperatively in any age group. Atrial fibrillation is the most common arrhythmia⁸³ and occurs between postoperative days 3 to 5 in high-risk patients. This is typically when patients begin to mobilize their interstitial fluid into the vascular fluid space. Contemporary evidence suggests that rate control is more important than rhythm control for atrial fibrillation.^{84,85} The first-line treatment includes β -blockade and/or calcium channel blockade. β -Blockade must be used judiciously because hypotension, as well as withdrawal from β -blockade with rebound hypertension, is possible. Calcium channel blockers are an option if β -blockers are not tolerated by the patient, but caution must be exercised in those with a history of congestive heart failure. Although digoxin is still a standby medication, it has limitations due to the need for optimal dosing levels. Cardioversion may be required if patients become hemodynamically unstable and the rhythm cannot be controlled.

Ventricular arrhythmias and other tachyarrhythmias may occur in surgical patients as well. Similar to atrial rhythm problems, these are best controlled with β -blockade, but the use of other antiarrhythmics or cardioversion may be required if patients become hemodynamically unstable.

Cardiac ischemia is a cause of postoperative mortality. Acute myocardial infarction (AMI) can present insidiously, or it can be more dramatic with the classic presentation of shortness of breath, severe angina, and sudden cardiogenic shock. The workup to rule out an AMI includes an ECG and cardiac enzyme measurements. The patient should be transferred to a monitored (telemetry) floor. Morphine, supplemental oxygen, nitroglycerine, and aspirin (MONA) are the initial therapeutic maneuvers for those being investigated for AMI.

Gastrointestinal System. Surgery of the esophagus is potentially complicated because of its anatomic location and blood supply. Nutritional support strategies should be considered for esophageal resection patients to maximize the potential for survival. The two primary types of esophageal resection performed are the transhiatal resection and the transthoracic (Ivor-Lewis) resection.⁸⁶ The transhiatal resection has the advantage that a formal thoracotomy incision is avoided. However, dissection of the esophagus is blind, and anastomotic leaks occur more than with other resections. However, when a leak does occur, simple opening of the cervical incision and draining the leak is all that is usually required.

The transthoracic Ivor-Lewis resection includes an esophageal anastomosis performed in the chest near the level of the azygos vein. These have lower leak rates, but the leaks that do occur result in mediastinitis and can be difficult to control. The reported mortality is about 50% with an anastomotic leak, and the overall mortality of the procedure is about 5%, which is similar to transhiatal resection.

Postoperative ileus is related to dysfunction of the neural reflex axis of the intestine. Excessive narcotic use may delay return of bowel function. Epidural anesthesia results in better pain control, and there is an earlier return of bowel function and a shorter length of hospital stay. The limited use of nasogastric tubes and the initiation of early postoperative feeding are associated with an earlier return of bowel function.⁸⁷ The

use of chewing gum and other oral stimulants to minimize ileus remains controversial.

Pharmacologic agents commonly used to stimulate bowel function include metoclopramide and erythromycin. Metoclopramide's action is limited to the stomach and duodenum, and it may help primarily with gastroparesis. Erythromycin is a motilin agonist that works throughout the stomach and bowel. Several studies demonstrate significant benefit from the administration of erythromycin in those suffering from an ileus.⁸⁸ Alvimopan, a newer agent and a μ -opioid receptor antagonist, has shown some promise in many studies for earlier return of gut function and subsequent reduction in length of stay.^{89,90} Neostigmine has been used in refractory pan-ileus patients (Ogilvie's syndrome) with some degree of success. It is recommended for patients receiving this type of therapy to be in a monitored unit.⁹¹

Small bowel obstruction occurs in less than 1% of early postoperative patients. When it does occur, adhesions are usually the cause. Internal and external hernias, technical errors, and infections or abscesses are also causative. Hyaluronidase is a mucolytic enzyme that degrades connective tissue, and the use of a methylcellulose form of hyaluronidase, Septrafilm®, has been shown to result in a 50% decrease in adhesion formation in some patients.^{92,93} This may translate into a lower occurrence of postoperative bowel obstruction, but has yet to be proven.

Fistulae are the abnormal communication of one structure to an adjacent structure or compartment and are associated with extensive morbidity and mortality. Common causes for fistula formation are summarized in the mnemonic FRIENDS (*Foreign body, Radiation, Ischemia/Inflammation/Infection, Epithelialization of a tract, Neoplasia, Distal obstruction, and Steroid use*). Postoperatively, they are most often caused by infection or obstruction leading to an anastomotic leak. The cause of the fistula must be recognized early, and treatment may include non-operative management with observation and nutritional support, or a delayed operative management strategy that also includes nutritional support and wound care.

Gastrointestinal (GI) bleeding can occur perioperatively (Table 12-14). Technical errors such as a poorly tied suture, a nonhemostatic staple line, or a missed injury can all lead to

Table 12-14

Common causes of upper and lower gastrointestinal (GI) hemorrhage

UPPER GI BLEED	LOWER GI BLEED
Erosive esophagitis	Angiodysplasia
Gastric varices	Radiation proctitis
Esophageal varices	Hemangioma
Dieulafoy's lesion	Diverticulosis
Aortoduodenal fistula	Neoplastic diseases
Mallory-Weiss tear	Trauma
Peptic ulcer disease	Vasculitis
Trauma	Hemorrhoids
Neoplastic disease	Aortoenteric fistula Intussusception Ischemic colitis Inflammatory bowel disease Postprocedure bleeding

postoperative intestinal bleeding.^{94,95} The source of bleeding is in the upper GI tract about 85% of the time and is usually detected and treated endoscopically. Surgical control of intestinal bleeding is required in up to 40% of patients.⁹⁶

When patients in the ICU have a major bleed from stress gastritis, the mortality risk is as high as 50%. It is important to keep the gastric pH greater than 4 to decrease the overall risk for stress gastritis in patients mechanically ventilated for 48 hours or greater and patients who are coagulopathic.⁹⁷ Proton pump inhibitors, H₂-receptor antagonists, and intragastric antacid installation are all effective measures. However, patients who are not mechanically ventilated or who do not have a history of gastritis or peptic ulcer disease should not be placed on gastritis prophylaxis postoperatively because it carries a higher risk of causing pneumonia.

Hepatobiliary-Pancreatic System. Complications involving the hepatobiliary system are usually due to technical errors. Laparoscopic cholecystectomy has become the standard of care for cholecystectomy, but common bile duct injury remains a nemesis of this approach. Intraoperative cholangiography has not been shown to decrease the incidence of common bile duct injuries because the injury to the bile duct usually occurs before the cholangiogram.^{98,99} Early recognition and immediate repair of an injury are important because delayed bile duct leaks often require a more complex repair.

Ischemic injury due to devascularization of the common bile duct has a delayed presentation days to weeks after an operation. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates a stenotic, smooth common bile duct, and liver function studies are elevated. The recommended treatment is a Roux-en-Y hepaticojejunostomy.

A bile leak due to an unrecognized injury to the ducts may present after cholecystectomy as a biloma. These patients may present with abdominal pain and hyperbilirubinemia. The diagnosis of a biliary leak can be confirmed by CT scan, ERCP, or radionuclide scan. Once a leak is confirmed, a retrograde biliary stent and external drainage are the treatment of choice.

Hyperbilirubinemia in the surgical patient can be a complex problem. Cholestasis makes up the majority of causes for hyperbilirubinemia, but other mechanisms of hyperbilirubinemia include reabsorption of blood (e.g., hematoma from trauma), decreased bile excretion (e.g., sepsis), increased unconjugated bilirubin due to hemolysis, hyperthyroidism, and impaired excretion due to congenital abnormalities or acquired disease. Errors in surgery that cause hyperbilirubinemia largely involve missed or iatrogenic injuries.

The presence of cirrhosis predisposes to postoperative complications. Abdominal or hepatobiliary surgery is problematic in the cirrhotic patient. Ascites leak in the postoperative period can be an issue when any abdominal operation has been performed. Maintaining proper intravascular oncotic pressure in the immediate postoperative period can be difficult, and resuscitation should be maintained with crystalloid solutions. Prevention of renal failure and the management of the hepatorenal syndrome can be difficult, as the demands of fluid resuscitation and altered glomerular filtration become competitive. Spironolactone with other diuretic agents may be helpful in the postoperative care. These patients often have a labile course, and bleeding complications due to coagulopathy are common. The operative mortality in cirrhotic patients is 10% for Child class A, 30% for Child class B, and 82% for Child class C patients.¹⁰⁰

Pyogenic liver abscess occurs in less than 0.5% of adult admissions, due to retained necrotic liver tissue, occult intestinal perforations, benign or malignant hepatobiliary obstruction, sepsis, and hepatic arterial occlusion. The treatment is long-term antibiotics with percutaneous drainage of large abscesses.

Pancreatitis can occur following injection of contrast during cholangiography and after endoscopic cholangiopancreatography (ERCP). These episodes range from a mild elevation in amylase and lipase with abdominal pain, to a fulminant course of pancreatitis with necrosis requiring surgical debridement. The incidence of post-ERCP pancreatitis has been shown to be reduced by the administration of rectal indomethacin.¹⁰¹ Studies are underway to determine whether the prophylactic use of pancreatic duct stenting in patients at high risk for post-ERCP pancreatitis can be avoided with the use of rectal indomethacin.

Traumatic injuries to the pancreas can occur during surgical procedures on the kidneys, GI tract, and spleen most commonly. Treatment involves serial CT scans and percutaneous drainage to manage infected fluid and abscess collections; sterile collections should not be drained because drain placement can introduce infection. A pancreatic fistula may respond to antisecretory therapy with a somatostatin analogue. Management of these fistulae initially includes ERCP with or without pancreatic stenting, percutaneous drainage of any fistula fluid collections, total parenteral nutrition (TPN) with bowel rest, and repeated CT scans. The majority of pancreatic fistulae will eventually heal spontaneously.

Renal System. Renal failure can be classified as prerenal failure, intrinsic renal failure, and postrenal failure. Postrenal failure, or obstructive renal failure, should always be considered when low urine output (oliguria) or anuria occurs. The most common cause is a misplaced or clogged urinary catheter. Other, less common causes to consider are unintentional ligation or transection of ureters during a difficult surgical dissection (e.g., colon resection for diverticular disease) or a large retroperitoneal hematoma (e.g., ruptured aortic aneurysm).

Oliguria is initially evaluated by flushing the urinary catheter using sterile technique. Urine electrolytes should also be measured (Table 12-15). A hemoglobin and hematocrit level should be checked immediately. Patients in compensated shock from acute blood loss may manifest anemia and end-organ malperfusion as oliguria.

Acute tubular necrosis (ATN) carries a mortality risk of 25% to 50% due to the many complications that can cause, or result from, this insult. When ATN is due to poor inflow (prerenal failure), the remedy begins with IV administration of crystalloid or colloid fluids as needed. If cardiac insufficiency is the problem, the optimization of vascular volume is achieved first, followed by inotropic agents, as needed. Intrinsic renal failure

Table 12-15

Urinary electrolytes associated with acute renal failure and their possible etiologies

	FE _{Na}	OSMOLARITY	UR _{Na}	ETIOLOGY
Prerenal	<1	>500	<20	CHF, cirrhosis
Intrinsic failure	>1	<350	>40	Sepsis, shock

CHF = congestive heart failure; FE_{Na} = fractional excretion of sodium; UR_{Na} = urinary excretion of sodium.

and subsequent ATN are often the result of direct renal toxins. Aminoglycosides, vancomycin, and furosemide, among other commonly used agents, contribute directly to nephrotoxicity. Contrast-induced nephropathy usually leads to a subtle or transient rise in creatinine. In patients who are volume depleted or have poor cardiac function, contrast nephropathy may permanently impair renal function.¹⁰²⁻¹⁰⁵

The treatment of renal failure due to myoglobinuria has shifted away from the use of sodium bicarbonate for alkalinizing the urine, to merely maintaining brisk urine output of 100 mL per hour with crystalloid fluid infusion. Mannitol and furosemide are not recommended. Patients who do not respond to resuscitation are at risk for needing renal replacement therapy. Fortunately, most of these patients eventually recover from their renal dysfunction.

Musculoskeletal System. A compartment syndrome can develop in any compartment of the body. Compartment syndrome of the extremities generally occurs after a closed fracture. The injury alone may predispose the patient to compartment syndrome, but aggressive fluid resuscitation can exacerbate the problem. Pain with passive motion is the hallmark of compartment syndrome, and the anterior compartment of the leg is usually the first compartment to be involved. Confirmation of the diagnosis is obtained by direct pressure measurement of the individual compartments. If the pressures are greater than 20 to 25 mmHg in any of the compartments, then a four-compartment fasciotomy is considered. Compartment syndrome can be due to ischemia-reperfusion injury, after an ischemic time of 4 to 6 hours. Renal failure (due to myoglobinuria), tissue loss, and a permanent loss of function are possible results of untreated compartment syndrome.

Decubitus ulcers are preventable complications of prolonged bed rest due to traumatic paralysis, dementia, chemical paralysis, or coma. Unfortunately, they are still occurring despite extensive research and clinical initiatives that demonstrate successful prevention strategies. Ischemic changes in the microcirculation of the skin can be significant after 2 hours of sustained pressure. Routine skin care and turning of the patient help ensure a reduction in skin ulceration. This can be labor intensive, and special mattresses and beds are available to help. The treatment of a decubitus ulcer in the noncoagulopathic patient is surgical debridement. Once the wound bed has a viable granulation base without an excess of fibrinous debris, a vacuum-assisted closure dressing can be applied. Wet to moist dressings with frequent dressing changes is the alternative and is labor intensive. Expensive topical enzyme preparations are also available. If the wounds fail to respond to these measures, soft tissue coverage by flap is considered.

Contractures are the result of muscle disuse. Whether from trauma, amputation, or vascular insufficiency, contractures can be prevented by physical therapy and splinting. If not attended to early, contractures will prolong rehabilitation and may lead to further wounds and wound healing issues. Depending on the functional status of the patient, contracture releases may be required for long-term care.

Hematologic System. The traditional transfusion guideline of maintaining the hematocrit level in all patients at greater than 30% is no longer valid. Only patients with symptomatic anemia, who have significant cardiac disease, or who are critically ill and require increased oxygen-carrying capacity to adequately perfuse end organs require higher levels of hemoglobin. Other

than these select patients, the decision to transfuse should generally not occur until the hemoglobin level falls to 7 mg/dL or the hematocrit reaches 21%.

Transfusion reactions are common complications of blood transfusion. These can be attenuated with a leukocyte filter, but not completely prevented. The manifestations of a transfusion reaction include simple fever, pruritus, chills, muscle rigidity, and renal failure due to myoglobinuria secondary to hemolysis. Discontinuing the transfusion and returning the blood products to the blood bank is an important first step, but administration of antihistamine and possibly steroids may be required to control the reaction symptoms. Severe transfusion reactions are rare but can be fatal.

Infectious complications in blood transfusion range from cytomegalovirus transmission, which is benign in the nontransplant patient, to human immunodeficiency virus (HIV) infection, to passage of the hepatitis viruses (Table 12-16).

Patients on warfarin (Coumadin) who require surgery can have anticoagulation reversal by administration of fresh frozen plasma. Each unit of fresh frozen plasma contains 200 to 250 mL of plasma and includes one unit of coagulation factor per milliliter of plasma.

Thrombocytopenia may require platelet transfusion for a platelet count less than 20,000/mL when invasive procedures are performed, or when platelet counts are low and ongoing bleeding from raw surface areas persists. One unit of platelets will increase the platelet count by 5000 to 7500 per mL in adults. It is important to delineate the cause of the low platelet count. Usually there is a self-limiting or reversible condition such as sepsis. Rarely, it is due to heparin-induced thrombocytopenia I and II. Complications of heparin-induced thrombocytopenia II can be serious because of the diffuse thrombogenic nature of the disorder. Simple precautions to limit this hypercoagulable state include saline solution flushes instead of heparin solutions and limiting the use of heparin-coated catheters. The treatment is anticoagulation with synthetic agents such as argatroban.

For patients with uncontrollable bleeding due to disseminated intravascular coagulopathy (DIC), a potentially useful drug is factor VIIa, but its use should be judicious.¹⁰⁶⁻¹⁰⁹ Originally used in hepatic trauma and obstetric emergencies, this agent was lifesaving in some circumstances. The CONTROL Trial,¹⁰⁹ however, has largely decreased overuse of this agent because investigators demonstrated no benefit over simple factor replacement in severely coagulopathic patients. Factor VIIa use may also be limited due to its potential thrombotic complications. For some situations, the combination of ongoing,

Table 12-16

Rate of viral transmission in blood product transfusions^a

HIV	1:1.9 million
HBV ^b	1:137,000
HCV	1:1 million

^aPost-nucleic acid amplification technology (1999). Earlier rates were erroneously reported higher due to lack of contemporary technology.

^bHBV is reported with pre-nucleic acid amplification technology.

Statistical information is unavailable with postnucleic acid amplification technology at this writing.

Note that bacterial transmission is 50 to 250 times higher than viral transmission per transfusion.

HBV = hepatitis B virus; HCV = hepatitis C virus.

nonsurgical bleeding and renal failure can occasionally be successfully treated with desmopressin.

In addition to classic hemophilia, other inherited coagulation factor deficiencies can be difficult to manage in surgery. When required, transfusion of appropriate replacement products is coordinated with the regional blood bank center before surgery. Other blood dyscrasias seen by surgeons include hypercoagulopathic patients. Those who carry congenital anomalies such as the most common factor V Leiden deficiency, as well as protein C and S deficiencies, are likely to form thromboses if inadequately anticoagulated, and these patients should be managed in consultation with a hematologist.

Abdominal Compartment Syndrome. Multisystem trauma, thermal burns, retroperitoneal injuries, and surgery related to the retroperitoneum are the major initial causative factors that may lead to abdominal compartment syndrome (ACS). Ruptured AAA, major pancreatic injury and resection, or multiple intestinal injuries are also examples of clinical situations in which a large volume of IV fluid resuscitation puts these patients at risk for intra-abdominal hypertension. Manifestations of ACS typically include progressive abdominal distention followed by increased peak airway ventilator pressures, oliguria followed by anuria, and an insidious development of intracranial hypertension.¹¹⁰ These findings are related to elevation of the diaphragm and inadequate venous return from the vena cava or renal veins secondary to the transmitted pressure on the venous system.

Measurement of abdominal pressures is easily accomplished by transducing bladder pressures from the urinary catheter after instilling 100 mL of sterile saline into the urinary bladder.¹¹¹ A pressure greater than 20 mmHg constitutes intra-abdominal hypertension, but the diagnosis of ACS requires intra-abdominal pressure greater than 25 to 30 mmHg, with at least one of the following: compromised respiratory mechanics and ventilation, oliguria or anuria, or increasing intracranial pressures.¹¹²⁻¹¹⁴

The treatment of ACS is to open any recent abdominal incision to release the abdominal fascia or to open the fascia directly if no abdominal incision is present. Immediate improvement in mechanical ventilation pressures, intracranial pressures, and urine output is usually noted. When expectant management for ACS is considered in the OR, the abdominal fascia should be left open and covered under sterile conditions (e.g., a vacuum-assisted open abdominal wound closure system) with plans made for a second-look operation and delayed fascial closure. Patients with intra-abdominal hypertension should be monitored closely with repeated examinations and measurements of bladder pressure, so that any further deterioration is detected and operative management can be initiated. Left untreated, ACS may lead to multiple system end-organ dysfunction or failure and has a high mortality.

Abdominal wall closure should be attempted every 48 to 72 hours until the fascia can be reapproximated. If the abdomen cannot be closed within 5 to 7 days following release of the abdominal fascia, a large incisional hernia is the net result. A variety of surgical options have evolved for prevention and closure of the resultant hernias, but no standard approach has yet evolved.

Wounds, Drains, and Infection

Wound (Surgical Site) Infection. No prospective, randomized, double-blind, controlled studies exist that demonstrate

antibiotics used beyond 24 hours in the perioperative period prevent infections. Prophylactic use of antibiotics should simply not be continued beyond this time. Irrigation of the operative field and the surgical wound with saline solution has shown benefit in controlling wound inoculum.¹¹⁵ Irrigation with an antibiotic-based solution has not demonstrated significant benefit in controlling postoperative infection.

Antibacterial-impregnated polyvinyl placed over the operative wound area for the duration of the surgical procedure has not been shown to decrease the rate of wound infection.¹¹⁶⁻¹²⁰ Although skin preparation with 70% isopropyl alcohol has the best bactericidal effect, it is flammable and could be hazardous when electrocautery is used. The contemporary formulas of chlorhexidine gluconate with isopropyl alcohol remain more advantageous.¹²¹⁻¹²³

There is a difference between wound colonization and infection. Overtreating colonization is just as injurious as undertreating infection. The strict definition of wound (soft tissue) infection is more than 10^5 CFU per gram of tissue. This warrants expeditious and proper antibiotic/antifungal treatment.¹²⁴ Often, however, clinical signs raise enough suspicion that the patient is treated before a confirmatory culture is undertaken. The clinical signs of wound infection include *rubor, tumor, calor, and dolor* (redness, swelling, heat, and pain). Once the diagnosis of wound infection has been established, the most definitive treatment remains open drainage of the wound. The use of antibiotics for wound infection treatment should be limited.¹²⁵⁻¹²⁸

One type of wound dressing/drainage system that has gained popularity is the vacuum-assisted closure dressing. The principle of the system is to decrease local wound edema and to promote healing through the application of a sterile dressing that is then covered and placed under controlled suction for a period of 2 to 4 days at a time. Although costly, the benefits are frequently dramatic and may offset the costs of nursing care, frequent dressing changes, and operative wound debridement.

Drain Management. The four indications for applying a surgical drain are:

- To collapse surgical dead space in areas of redundant tissue (e.g., neck and axilla)
- To provide focused drainage of an abscess or grossly infected surgical site
- To provide early warning notice of a surgical leak (either bowel contents, secretions, urine, air, or blood)—the so-called *sentinel drain*
- To control an established fistula leak

Open drains are often used for large contaminated wounds such as perirectal or perianal fistulas and subcutaneous abscess cavities. They prevent premature closure of an abscess cavity in a contaminated wound. More commonly, surgical sites are drained by closed suction drainage systems, but data do not support closed suction drainage to “protect an anastomosis” or to “control a leak” when placed at the time of surgery. Closed suction devices can exert a negative pressure of 70 to 170 mmHg at the level of the drain; therefore, the presence of this excess suction may call into question whether an anastomosis breaks down on its own or whether the drain creates a suction injury that promotes leakage (Fig. 12-9).¹²⁹

On the other hand, CT- or ultrasound-guided placement of percutaneous drains is now the standard of care for abscesses, loculated infections, and other isolated fluid collections such

A

B

Figure 12-9 This illustration demonstrates typical intraoperative placement of closed suction devices in pancreatic or small bowel surgery, where there may be an anastomosis. At negative pressures of 70 to 170 mmHg, these devices may actually encourage anastomotic leaks and not prevent them or become clogged by them.

as pancreatic leaks. The risk of surgery is far greater than the placement of an image-guided drain.

The use of antibiotics when drains are in place is often unnecessary as the drain provides direct source control. Twenty-four to 48 hours of antibiotic use after drain placement is prophylactic, and after this period, only specific treatment of

positive cultures should be performed to avoid increased drug resistance and superinfection.

Urinary Catheters. Several complications of urinary catheters can occur that lead to an increased length of hospital stay and morbidity. In general, use of urinary catheters should be minimized and every opportunity to expeditiously remove them should be encouraged. If needed, it is recommended that the catheter be inserted its full length up to the hub and that urine flow is established before the balloon is inflated because misplacement of the catheter in the urethra with premature inflation of the balloon can lead to tears and disruption of the urethra.

Enlarged prostatic tissue can make catheter insertion difficult, and a catheter coudeé may be required. If this attempt is also unsuccessful, then a urologic consultation for endoscopic placement of the catheter may be required to prevent harm to the urethra. For patients with urethral strictures, filiform-tipped catheters and followers may be used, but these can potentially cause bladder injury. If endoscopic attempts fail, the patient may require a percutaneously placed suprapubic catheter to obtain decompression of the bladder. Follow-up investigations of these patients are recommended so definitive care of the urethral abnormalities can be pursued.

The most frequent nosocomial infection is urinary tract infection (UTI). These infections are classified into complicated and uncomplicated forms. The uncomplicated type is a UTI that can be treated with outpatient antibiotic therapy. The complicated UTI usually involves a hospitalized patient with an indwelling catheter whose UTI is diagnosed as part of a fever workup. The interpretation of urine culture results of less than 100,000 CFU/mL is controversial. Before treating such a patient, one should change the catheter and then repeat the culture to see if the catheter was simply colonized with organisms. Cultures with more than 100,000 CFU/mL should be treated with the appropriate antibiotics and the catheter changed or removed as soon as possible. Undertreatment or misdiagnosis of a UTI can lead to urosepsis and septic shock.

Recommendations are mixed on the proper way to treat *Candida albicans* fungal bladder infections. Continuous bladder washings with fungicidal solution for 72 hours have been recommended, but this is not always effective. Replacement of the urinary catheter and a course of fluconazole are appropriate treatments, but some infectious disease specialists claim that *C. albicans* in the urine may serve as an indication of fungal infection elsewhere in the body. If this is the case, then screening cultures for other sources of fungal infection should be performed whenever a fungal UTI is found.

Empyema. One of the most debilitating infections is an empyema, or infection of the pleural space. Frequently, an overwhelming pneumonia is the source of an empyema, but a retained hemothorax, systemic sepsis, esophageal perforation from any cause, and infections with a predilection for the lung (e.g., tuberculosis) are potential etiologies as well. The diagnosis is confirmed by chest X-ray or CT scan, followed by aspiration of pleural fluid for bacteriologic analysis. Gram's stain, lactate dehydrogenase, protein, pH, and cell count are obtained, and broad-spectrum antibiotics are initiated while the laboratory studies are performed. Once the specific organisms are confirmed, anti-infective agents are tailored appropriately. Placement of a thoracostomy tube is needed to evacuate and drain the infected pleural fluid, but depending on the specific nidus of infection, video-assisted thoracoscopy may also be

helpful for irrigation and drainage of the infection. Refractory empyemas require specialized surgical approaches.

Abdominal Abscesses. Postsurgical intra-abdominal abscesses can present with vague complaints of intermittent abdominal pain, fever, leukocytosis, and a change in bowel habits. Depending on the type and timing of the original procedure, the clinical assessment of these complaints is sometimes difficult, and a CT scan is usually required. When a fluid collection within the peritoneal cavity is found on CT scan, antibiotics and percutaneous drainage of the collection is the treatment of choice. Initial antibiotic treatment is usually with broad-spectrum antibiotics such as piperacillin-tazobactam or imipenem. Should the patient exhibit signs of peritonitis and/or have free air on X-ray or CT scan, then re-exploration should be considered.

For patients who present primarily (i.e., not postoperatively) with the clinical and radiologic findings of an abscess but are clinically stable, the etiology of the abscess must be determined. A plan for drainage of the abscess and decisions about further diagnostic studies with consideration of the timing of any definitive surgery all need to be balanced. This can be a complex set of decisions, depending on the etiology (e.g., appendicitis or diverticulitis), but if the patient exhibits signs of peritonitis, urgent surgical exploration should be performed.

Necrotizing Fasciitis. Postoperative infections that progress to the fulminant soft tissue infection known as *necrotizing fasciitis* are uncommon. Group A streptococcal (M types 1, 3, 12, and 28) soft tissue infections, as well as infections with *Clostridium perfringens* and *C. septicum*, carry a mortality of 30% to 70%. Septic shock can be present, and patients can become hypotensive less than 6 hours following inoculation. Manifestations of a group A *Streptococcus pyogenes* infection in its most severe form include hypotension, renal insufficiency, coagulopathy, hepatic insufficiency, ARDS, tissue necrosis, and erythematous rash.

These findings constitute a surgical emergency, and the mainstay of treatment remains wide debridement of the necrotic tissue to the level of bleeding, viable tissue. A gray serous fluid at the level of the necrotic tissue is usually noted, and as the infection spreads, thrombosed blood vessels are noted along the tissue planes involved with the infection. Typically, the patient requires serial trips to the OR for wide debridement until the infection is under control. Antibiotics are an important adjunct to surgical debridement, and broad-spectrum coverage should be used because these infections may be polymicrobial (i.e., so-called *mixed-synergistic infections*). *Streptococcus pyogenes* is eradicated with penicillin, and it should still be used as the initial drug of choice.

Systemic Inflammatory Response Syndrome, Sepsis, and Multiple-Organ Dysfunction Syndrome. The systemic inflammatory response syndrome (SIRS) and the multiple-organ dysfunction syndrome (MODS) carry significant mortality risks (Table 12-17). Specific criteria have been established for the diagnosis of SIRS (Table 12-18), but two criteria are not required for the diagnosis of SIRS: lowered blood pressure and blood cultures positive for infection. SIRS is the result of proinflammatory cytokines related to tissue malperfusion or injury. The dominant cytokines implicated in this process include interleukin (IL)-1, IL-6, and tissue necrosis factor (TNF). Other mediators include nitric oxide, inducible macrophage-type nitric oxide synthase, and prostaglandin I₂.

Table 12-17

Mortality associated with patients exhibiting two or more criteria for systemic inflammatory response syndrome (SIRS)

PROGNOSIS	MORTALITY (%)
2 SIRS criteria	5
3 SIRS criteria	10
4 SIRS criteria	15–20

Sepsis is categorized as sepsis, severe sepsis, and septic shock. Sepsis is SIRS plus infection. Severe sepsis is sepsis plus signs of cellular hypoperfusion or end-organ dysfunction. Septic shock is sepsis plus hypotension after adequate fluid resuscitation.

MODS is the culmination of septic shock and multiple end-organ failure.¹³⁰ Usually there is an inciting event (e.g., perforated sigmoid diverticulitis), and as the patient undergoes resuscitation, he or she develops cardiac hypokinesia and oliguric or anuric renal failure, followed by the development of ARDS and eventually septic shock with death.

The international Surviving Sepsis Campaign (www.sccm.org/Documents/SSC-Guidelines.pdf) continues to demonstrate the importance of early recognition and initiation of specific treatment guidelines for optimal management of sepsis. Management of SIRS/MODS includes aggressive global resuscitation and support of end-organ perfusion, correction of the inciting etiology, control of infectious complications, and management of iatrogenic complications.¹³¹⁻¹³³ Drotrecogin- α , or recombinant activated protein C, appears to specifically counteract the cytokine cascade of SIRS/MODS, but its use is still limited.^{134,135} Other adjuncts for supportive therapy include tight glucose control, low tidal volumes in ARDS, vasopressin in septic shock, and steroid replacement therapy.

Nutritional and Metabolic Support Complications

Nutrition-Related Complications. A basic principle is to use enteral feeding whenever possible, but complications can intervene such as aspiration, ileus, and to a lesser extent, sinusitis. There is no difference in aspiration rates when a small-caliber feeding tube is placed postpyloric or if it remains in the stomach. Patients who are fed via nasogastric tubes are at risk for aspiration pneumonia because these large-bore tubes stent open the gastroesophageal junction, creating the possibility of gastric reflux. The use of enteric and gastric feeding tubes obviates

Table 12-18

Inclusion criteria for the systemic inflammatory response syndrome

Temperature >38°C or <36°C (>100.4°F or <96.8°F)
Heart rate >90 beats/min
Respiratory rate >20 breaths/min or PaCO ₂ <32 mmHg
White blood cell count <4000 or >12,000 cells/mm ³ or >10% immature forms

PaCO₂ = partial pressure of arterial carbon dioxide.

complications of TPN, such as pneumothorax, line sepsis, upper extremity DVT, and the related expense. There is growing evidence to support the initiation of enteral feeding in the early postoperative period, before the return of bowel function, where it is usually well tolerated.

In patients who have had any type of nasal intubation who are having high, unexplained fevers, sinusitis must be entertained as a diagnosis. CT scan of the sinuses is warranted, followed by aspiration of sinus contents so the organism(s) are appropriately treated.

Patients who have not been enterally fed for prolonged periods secondary to multiple operations, those who have had enteral feeds interrupted for any other reason, or those with poor enteral access are at risk for the refeeding syndrome, which is characterized by severe hypophosphatemia and respiratory failure. Slow progression of the enteral feeding administration rate can avoid this complication.

Common TPN problems are mostly related to electrolyte abnormalities that may develop. These electrolyte errors include deficits or excesses in sodium, potassium, calcium, magnesium, and phosphate. Acid-base abnormalities can also occur with the improper administration of acetate or bicarbonate solutions.

The most common cause for hypernatremia in hospitalized patients is under-resuscitation, and, conversely, hyponatremia is most often caused by fluid overload. Treatment for hyponatremia is fluid restriction in mild or moderate cases and the administration of hypertonic saline for severe cases. An overly rapid correction of the sodium abnormality may result in central pontine myelinolysis, which results in a severe neurologic deficit. Treatment for hyponatremic patients includes fluid restriction to correct the free water deficit by 50% in the first 24 hours. An overcorrection of hyponatremia can result in severe cerebral edema, a neurologic deficit, or seizures.

Glycemic Control. In 2001, Van den Berghe and colleagues demonstrated that tight glycemic control by insulin infusion is associated with a 50% reduction in mortality in the critical care setting.¹³⁶ This prospective, randomized, controlled trial of 1500 patients had two study arms: the intensive-control arm, where the serum glucose was maintained between 80 and 110 mg/dL with insulin infusion; and the control arm, where patients received an insulin infusion only if blood glucose was greater than 215 mg/dL, but serum glucose was then maintained at 180 to 200 mg/dL.

The tight glycemic control group had an average serum glucose level of 103 mg/dL, and the average glucose level in the control group was 153 mg/dL. Hypoglycemic episodes (glucose <40 mg/dL) occurred in 39 patients in the tightly controlled group, while the control group had episodes in six patients. The overall mortality was reduced from 8% to 4.6%, but the mortality of those patients whose ICU stay lasted longer than 5 days was reduced from 20% to 10%. Secondary findings included an improvement in overall morbidity, a decreased percentage of ventilator days, less renal impairment, and a lower incidence of bloodstream infections. These findings have been corroborated by subsequent similar studies, and the principal benefit appears to be a greatly reduced incidence of nosocomial infections and sepsis. It is not known whether the benefits are due to strict euglycemia, to the anabolic properties of insulin, or both, but the maintenance of strict euglycemia between 140 and 180 mg/dL appears to be a powerful therapeutic strategy.¹³⁶⁻¹³⁸ A number of studies followed this sentinel publication of tight

glycemic control. The NICE-SUGAR¹³⁹ and COITSS¹⁴⁰ trials revisited the Van den Berghe study and found that the glycemic goals found initially to improve outcomes in critically ill patients were now found to be associated with a higher mortality when glucose was kept below 180 mg/dL, due to an increase in incidents of hypoglycemia. When targeted goals of 180 mg/dL are achieved, fewer occurrences of hypoglycemia have been documented, and improved survivorship has been achieved. In addition, some studies find no relationship between glycemic control and improved outcomes. Thus, glycemic control in the critically ill still remains unclear and elusive at best.^{141,142} Part of the difficulty in achieving “tight glycemic control” is the necessity for frequent (every 1–2 hours) blood glucose determinations. When this is performed, glycemic control is enhanced and hypoglycemia is avoided.

Metabolism-Related Complications. “Stress dose steroids” have been advocated for the perioperative treatment of patients on corticosteroid therapy, but recent studies strongly discourage the use of supraphysiologic doses of steroids when patients are on low or maintenance doses (e.g., 5–15 mg) of prednisone daily. Parenteral glucocorticoid treatment need only replicate physiologic replacement steroids in the perioperative period. When patients are on steroid replacement doses equal to or greater than 20 mg per day of prednisone, it may be appropriate to administer additional glucocorticoid doses for no more than 2 perioperative days.¹⁴³⁻¹⁴⁵

Adrenal insufficiency may be present in patients with a baseline serum cortisol less than 20 µg/dL. A rapid provocative test with synthetic adrenocorticotrophic hormone may confirm the diagnosis. After a baseline serum cortisol level is drawn, 250 µg of cosyntropin is administered. At exactly 30 and 60 minutes following the dose of cosyntropin, serum cortisol levels are obtained. There should be an incremental increase in the cortisol level of between 7 and 10 µg/dL for each half hour. If the patient is below these levels, a diagnosis of adrenal insufficiency is made, and glucocorticoid and mineralocorticoid administration is then warranted. Mixed results are common, but the complication of performing major surgery on an adrenally insufficient patient is sudden or profound hypotension that is not responsive to fluid resuscitation.¹³¹

Thyroid hormone abnormalities usually consist of previously undiagnosed thyroid abnormalities. Hypothyroidism and the so-called *sick-euthyroid syndrome* are more commonly recognized in the critical care setting. When surgical patients are not progressing satisfactorily in the perioperative period, screening for thyroid abnormalities should be performed. If the results show mild to moderate hypothyroidism, then thyroid replacement should begin immediately, and thyroid function studies should be monitored closely. All patients should be reassessed after the acute illness has subsided regarding the need for chronic thyroid replacement therapy.

Problems with Thermoregulation

Hypothermia. Hypothermia is defined as a core temperature less than 35°C (95°F) and is divided into subsets of mild (35°C–32°C [95°F–89.6°F]), moderate (32°C–28°C [89.6°F–82.4°F]), and severe (<28°C [$<82.4^{\circ}\text{F}$]) hypothermia. Shivering, the body’s attempt to reverse the effects of hypothermia, occurs between 37°C and 31°C (98.6°F and 87.8°F), but ceases at temperatures below 31°C (87.8°F). Patients who are moderately hypothermic are at higher risk for complications than are those who are more profoundly hypothermic.

Hypothermia creates a coagulopathy that is related to platelet and clotting cascade enzyme dysfunction. This triad of metabolic acidosis, coagulopathy, and hypothermia is commonly found in long operative cases and in patients with blood dyscrasias. The enzymes that contribute to the clotting cascade and platelet activity are most efficient at normal body temperatures; therefore, all measures must be used to reduce heat loss intraoperatively.¹⁴⁶

The most common cardiac abnormality is the development of arrhythmias when body temperature drops below 35°C (95°F). Bradycardia occurs with temperatures below 30°C (86°F). It is well known that hypothermia may induce CO₂ retention, resulting in respiratory acidosis. Renal dysfunction of hypothermia manifests itself as a paradoxical polyuria and is related to an increased glomerular filtration rate, as peripheral vascular constriction creates central shunting of blood. This is potentially perplexing in patients who are undergoing resuscitation for hemodynamic instability because the brisk urine output provides a false sense of an adequate intravascular fluid volume.

Induced peripheral hypothermia for hyperpyrexia due to infection (not to include neurologic or cardiac disease) is likely deleterious and does not appear to be beneficial. Placing cooling blankets on or under the patient or ice packs in the axillae or groin may be effective in cooling the skin, and when this occurs, a subsequent feedback loop triggers the hypothalamus to raise the internally regulated set point, thus raising core temperature even higher. This paradoxical reaction may be why those who feel the need to treat a fever in the ICU by cooling the skin and arguably the core have worse outcomes. Cooling core temperatures can be achieved reliably with catheter-directed therapy with commercially available devices. Whether this is a worthwhile practice or not may be controversial. Poor data exist in support of treating fevers lower than 42°C in any fashion.¹⁴⁷⁻¹⁴⁹

Adult trauma patients who underwent induced hypothermia had poor outcomes in a recent investigation, and thus, this remains a procedure to be avoided. In a similar vein, pediatric patients who were induced did not show any improvement, and therefore, induced hypothermia is not recommended. Complications with induced hypothermia include, but are not limited to, hypokalemia, diuresis, DVT (due to catheter-related vein injury), arrhythmias, shivering, undiagnosed catheter-related bloodstream infection, and bacteremia.¹⁵⁰⁻¹⁵²

Neurologic dysfunction is inconsistent in hypothermia, but a deterioration in reasoning and decision-making skills progresses as body temperature falls, and profound coma (and a flat electroencephalogram) occurs as the temperature drops below 30°C (86°F). The diagnosis of hypothermia is important, so accurate measurement techniques are required to get a true core temperature.

Methods used to warm patients include warm air circulation over the patient and heated IV fluids, as well as more aggressive measures such as bilateral chest tubes with warm solution lavage, intraperitoneal rewarming lavage, and extracorporeal membrane oxygenation. A rate of temperature rise of 2°C to 4°C (3.6°F–7.2°F) per hour is considered adequate, but the most common complication for nonbypass rewarming is arrhythmia with ventricular arrest.

Hyperthermia. Hyperthermia is defined as a core temperature greater than 38.6°C (101.5°F) and has a host of etiologies (Table 12-19).¹⁴⁷ Hyperthermia can be environmentally induced

Table 12-19

Common causes of elevated temperature in surgical patients

HYPERTHERMIA	HYPERPYREXIA
Environmental	Sepsis
Malignant hyperthermia	Infection
Neuroleptic malignant syndrome	Drug reaction
Thyrotoxicosis	Transfusion reaction
Pheochromocytoma	Collagen disorders
Carcinoid syndrome	Factitious syndrome
Iatrogenic	Neoplastic disorders
Central/hypothalamic responses	
Pulmonary embolism	
Adrenal insufficiency	

(e.g., summer heat with inability to dissipate heat or control exposure), iatrogenically induced (e.g., heat lamps and medications), endocrine in origin (e.g., thyrotoxicosis), or neurologically induced (i.e., hypothalamic dysfunction).

Malignant hyperthermia occurs intraoperatively after exposure to agents such as succinylcholine and some halothane-based inhalational anesthetics. The presentation is dramatic, with rapid onset of increased temperature, rigors, and myoglobinuria related to myonecrosis. Medications must be discontinued immediately and dantrolene administered (2.5 mg/kg every 5 minutes) until symptoms subside. Aggressive cooling methods are also implemented, such as an alcohol bath, or packing in ice. In cases of severe malignant hyperthermia, the mortality rate is nearly 30%.^{153,154}

Thyrotoxicosis can occur after surgery due to undiagnosed Graves' disease. Hallmarks of the syndrome include hyperthermia (>40°C [104°F]), anxiety, copious diaphoresis, congestive heart failure (present in about one fourth of episodes), tachycardia (most commonly atrial fibrillation), and hypokalemia (in up to 50% of patients). The treatment of thyrotoxicosis includes glucocorticoids, propylthiouracil, β-blockade, and iodide (Lugol's solution) delivered in an emergent fashion. As the name suggests, these patients are usually toxic and require supportive measures as well. Acetaminophen, the cooling modalities noted in the previous paragraph, and vasoactive agents often are indicated.

INTRODUCTION

The Latin verb *monere*, which means “to warn, or advise” is the origin for the English word *monitor*. In modern medical practice, patients undergo monitoring to detect pathologic variations in physiologic parameters, providing advanced warning of impending deterioration in the status of one or more organ systems. The intended goal of this endeavor is to allow the clinician to take appropriate actions in a timely fashion to prevent or ameliorate the physiologic derangement. Furthermore, physiologic monitoring is used not only to warn, but also to titrate therapeutic interventions, such as fluid resuscitation or the infusion of vasoactive or inotropic drugs. The intensive care unit (ICU) and operating room are the two locations where the most advanced monitoring capabilities are routinely employed in the care of critically ill patients.

In the broadest sense, physiologic monitoring encompasses a spectrum of endeavors, ranging in complexity from the routine and intermittent measurement of the classic vital signs (i.e., temperature, heart rate, arterial blood pressure, and respiratory rate) to the continuous recording of the oxidation state of cytochrome oxidase, the terminal element in the mitochondrial electron transport chain. The ability to assess clinically relevant parameters of tissue and organ status and employ this knowledge to improve patient outcomes represents the “holy grail” of

critical care medicine. Unfortunately, consensus is often lacking regarding the most appropriate parameters to monitor in order to achieve this goal. Furthermore, making an inappropriate therapeutic decision due to inaccurate physiologic data or misinterpretation of good data can lead to a worse outcome than having no data at all. Of the highest importance is the integration of physiologic data obtained from monitoring into a coherent and evidenced-based treatment plan. Current technologies available to assist the clinician in this endeavor are summarized in this chapter. Also presented is a brief look at emerging techniques that may soon enter into clinical practice.

In essence, the goal of hemodynamic monitoring is to ensure that the flow of oxygenated blood through the microcirculation is sufficient to support aerobic metabolism at the cellular level. In general, mammalian cells cannot store oxygen for subsequent use in oxidative metabolism, although a relatively tiny amount is stored in muscle tissue as oxidized myoglobin. Thus, aerobic synthesis of adenosine triphosphate (ATP), the energy “currency” of cells, requires the continuous delivery of oxygen by diffusion from hemoglobin in red blood cells to the oxidative machinery within mitochondria. Delivery of oxygen to mitochondria may be insufficient for several reasons. For example, cardiac output, hemoglobin concentration of blood, or the oxygen content of arterial blood each can be inadequate

Key Points

1▶ The delivery of modern critical care is predicated on the ability to monitor a large number of physiologic variables and formulate evidenced-based therapeutic strategies to manage these variables. Technological advances in monitoring have at least a theoretical risk of exceeding our ability to understand the clinical implications of the derived information. This could result in the use of monitoring data to make inappropriate clinical decisions. Therefore, the implementation of any new monitoring technology must take into account the relevance and accuracy of the data obtained, the risks

to the patient, and the evidence supporting any intervention directed at correcting the detected abnormality.

2▶ The routine use of invasive monitoring devices, specifically the pulmonary artery catheter, must be questioned in light of the available evidence that does not demonstrate a clear benefit to its widespread use in various populations of critically ill patients. The future of physiologic monitoring will be dominated by the application of noninvasive and highly accurate devices which guide evidenced-based therapy.

for independent reasons. Alternatively, despite adequate cardiac output, perfusion of capillary networks can be impaired as a consequence of dysregulation of arteriolar tone, microvascular thrombosis, or obstruction of nutritive vessels by sequestered leukocytes or platelets. Hemodynamic monitoring that does not take into account all of these factors will portray an incomplete and perhaps misleading picture of cellular physiology.

Under normal conditions when the supply of oxygen is plentiful, aerobic metabolism is determined by factors other than the availability of oxygen. These factors include the hormonal milieu and mechanical workload of contractile tissues. However, in pathologic circumstances when oxygen availability is inadequate, oxygen utilization (VO_2) becomes dependent upon oxygen delivery (DO_2). The relationship of VO_2 to DO_2 over a broad range of DO_2 values is commonly represented as two intersecting straight lines (Fig. 13-1). In the region of higher DO_2 values, the slope of the line is approximately equal to zero, indicating that VO_2 is largely independent of DO_2 . In contrast, in the region of low DO_2 values, the slope of the line is nonzero and positive, indicating that VO_2 is supply-dependent. The region where the two lines intersect is called the point of critical oxygen delivery (DO_{2crit}), and represents the transition from supply-independent to supply-dependent oxygen uptake. Below a critical

threshold of oxygen delivery, increased oxygen extraction cannot compensate for the delivery deficit; hence, oxygen consumption begins to decrease. The slope of the supply-dependent region of the plot reflects the maximal oxygen extraction capability of the vascular bed being evaluated.

The subsequent sections will describe the techniques and utility of monitoring various physiologic parameters.

ARTERIAL BLOOD PRESSURE

The pressure exerted by blood in the systemic arterial system, commonly referred to simply as “blood pressure,” is a cardinal parameter measured as part of the hemodynamic monitoring of patients. Extremes in blood pressure are either intrinsically deleterious or are indicative of a serious perturbation in normal physiology. Arterial blood pressure is a complex function of both cardiac output and vascular input impedance. Thus, inexperienced clinicians may assume that the presence of a normal blood pressure is evidence that cardiac output and tissue perfusion are adequate. This assumption is frequently incorrect and is the reason why some critically ill patients may benefit from forms of hemodynamic monitoring in addition to measurement of arterial pressure.

Blood pressure can be determined directly by measuring the pressure within the arterial lumen or indirectly using a cuff around an extremity. When the equipment is properly set up and calibrated, direct intra-arterial monitoring of blood pressure provides accurate and continuous data. Additionally, intra-arterial catheters provide a convenient way to obtain samples of blood for measurements of arterial blood gases and other laboratory studies. Despite these advantages, intra-arterial catheters are invasive devices and occasionally are associated with serious complications.

Noninvasive Measurement of Arterial Blood Pressure

Both manual and automated means for the noninvasive determination of blood pressure use an inflatable sphygmomanometer cuff to increase pressure around an extremity and to detect the presence or absence of arterial pulsations. Several methods exist for this purpose. The time-honored approach is the auscultation of the Korotkoff sounds, which are heard over an artery distal to the cuff as the cuff is deflated from a pressure higher than systolic pressure to one less than diastolic pressure. *Systolic pressure* is defined as the pressure in the cuff when tapping sounds are first audible. *Diastolic pressure* is the pressure in the cuff when audible pulsations first disappear.

Figure 13-1. Graphical representation of the relationship between oxygen utilization (VO_2) and oxygen delivery (DO_2). Under most normal physiologic conditions oxygen utilization does not depend on oxygen delivery, but below the critical value DO_{2crit} oxygen utilization decreases linearly as a function of oxygen delivery, rendering tissues susceptible to ischemic injury.

Another means for pulse detection when measuring blood pressure noninvasively depends upon the detection of oscillations in the pressure within the bladder of the cuff. This approach is simple, and unlike auscultation, can be performed even in a noisy environment (e.g., a busy emergency department or medical helicopter). Unfortunately, this approach is neither accurate nor reliable. Other methods, however, can be used to reliably detect the reappearance of a pulse distal to the cuff and thereby estimate systolic blood pressure. Two excellent and widely available approaches for pulse detection are use of a Doppler stethoscope (reappearance of the pulse produces an audible amplified signal) or a pulse oximeter (reappearance of the pulse is indicated by flashing of a light-emitting diode).

A number of automated devices are capable of repetitively measuring blood pressure noninvasively. Some of these devices measure pressure oscillations in the inflatable bladder encircling the extremity to detect arterial pulsations as pressure in the cuff is gradually lowered from greater than systolic to less than diastolic pressure. Other automated noninvasive devices use a piezoelectric crystal positioned over the brachial artery as a pulse detector. The accuracy of these devices is variable, and often dependent on the size mismatch between the arm circumference and the cuff size.¹ If the cuff is too narrow (relative to the extremity), the measured pressure will be artifactually elevated. Therefore, the width of the cuff should be approximately 40% of its circumference.

Another noninvasive approach for measuring blood pressure relies on a technique called photoplethysmography. This method is capable of providing continuous information, since systolic and diastolic blood pressures are recorded on a beat-to-beat basis. Photoplethysmography uses the transmission of infrared light to estimate the amount of hemoglobin (directly related to the volume of blood) in a finger placed under a servo-controlled inflatable cuff. A feedback loop controlled by a microprocessor continually adjusts the pressure in the cuff to maintain the blood volume of the finger constant. Under these conditions, the pressure in the cuff reflects the pressure in the digital artery. The measurements obtained using photoplethysmography generally agree closely with those obtained by invasive monitoring of blood pressure.² However, these readings may be less accurate in patients with hypotension or hypothermia.

Invasive Monitoring of Arterial Blood Pressure

Direct and continuous monitoring of arterial pressure in critically ill patients may be performed by using fluid-filled tubing to connect an intra-arterial catheter to an external strain-gauge transducer. The signal generated by the transducer is electronically amplified and displayed as a continuous waveform by an oscilloscope or computerized display. Digital values for systolic and diastolic pressure also are displayed. Mean pressure, calculated by electronically averaging the amplitude of the pressure waveform, can also be displayed. The fidelity of the catheter-tubing-transducer system is determined by numerous factors, including the compliance of the tubing, the surface area of the transducer diaphragm, and the compliance of the diaphragm. If the system is underdamped, then the inertia of the system, which is a function of the mass of the fluid in the tubing and the mass of the diaphragm, causes overshoot of the points of maximum positive and negative displacement of the diaphragm during systole and diastole, respectively. Thus, in an underdamped system, systolic pressure will be overestimated and diastolic pressure will be underestimated. In an overdamped system, displacement

of the diaphragm fails to track the rapidly changing pressure waveform, and systolic pressure will be underestimated and diastolic pressure will be overestimated. It is important to note that even in an underdamped or overdamped system, mean pressure will be accurately recorded, provided the system has been properly calibrated. For these reasons, when using direct measurement of intra-arterial pressure to monitor patients, clinicians should make clinical decisions based primarily on the measured mean arterial blood pressure.

The radial artery at the wrist is the site most commonly used for intra-arterial pressure monitoring. Other sites include the femoral and axillary artery. It is important to recognize, however, that measured arterial pressure is determined in part by the site where the pressure is monitored. Central (i.e., aortic) and peripheral (e.g., radial artery) pressures typically are different as a result of the impedance and inductance of the arterial tree. Systolic pressures typically are higher and diastolic pressures are lower in the periphery, whereas mean pressure is approximately the same in the aorta and more distal sites.

Distal ischemia is an uncommon complication of intra-arterial catheterization. The incidence of thrombosis is increased when larger-caliber catheters are employed and when catheters are left in place for an extended period of time. The incidence of thrombosis can be minimized by using a 20-gauge (or smaller) catheter in the radial artery and removing the catheter as soon as feasible. The risk of distal ischemic injury can be reduced by ensuring that adequate collateral flow is present prior to catheter insertion. At the wrist, adequate collateral flow can be documented by performing a modified version of the Allen test, wherein the artery to be cannulated is digitally compressed while using a Doppler stethoscope to listen for perfusion in the palmar arch vessels.

Another potential complication of intra-arterial monitoring is retrograde embolization of air bubbles or thrombi into the intracranial circulation. In order to minimize this risk care should be taken to avoid flushing arterial lines when air is present in the system, and only small volumes of fluid (less than 5 mL) should be employed for this purpose. Catheter-related infections can occur with any intravascular monitoring device. However, catheter-related bloodstream infection is a relatively uncommon complication of intra-arterial lines used for monitoring, occurring in 0.4% to 0.7% of catheterizations.³ The incidence increases with longer duration of arterial catheterization.

ELECTROCARDIOGRAPHIC MONITORING

The electrocardiogram (ECG) records the electrical activity associated with cardiac contraction by detecting voltages on the body surface. A standard 3-lead ECG is obtained by placing electrodes that correspond to the left arm (LA), right arm (RA), and left leg (LL). The limb leads are defined as lead I (LA-RA), lead II (LL-RA), and lead III (LL-LA). The ECG waveforms can be continuously displayed on a monitor, and the devices can be set to sound an alarm if an abnormality of rate or rhythm is detected. Continuous ECG monitoring is widely available and applied to critically ill and perioperative patients. Monitoring of the ECG waveform is essential in patients with acute coronary syndromes or blunt myocardial injury because dysrhythmias are the most common lethal complication. In patients with shock or sepsis, dysrhythmias can occur as a consequence of inadequate myocardial oxygen delivery or as a complication of vasoactive or inotropic drugs used to support blood pressure and cardiac

output. Dysrhythmias can be detected by continuously monitoring the ECG tracing, and timely intervention may prevent serious complications. With appropriate computing hardware and software, continuous ST-segment analysis also can be performed to detect ischemia or infarction.

Additional information can be obtained from a 12-lead ECG, which is essential for patients with potential myocardial ischemia or to rule out cardiac complications in other acutely ill patients. Continuous monitoring of the 12-lead ECG may be beneficial in certain patient populations. In a study of 185 vascular surgical patients, continuous 12-lead ECG monitoring was able to detect transient myocardial ischemic episodes in 20.5% of the patients.⁴ This study demonstrated that the precordial lead V₄, which is not routinely monitored on a standard 3-lead ECG, is the most sensitive for detecting perioperative ischemia and infarction. To detect 95% of the ischemic episodes, two or more precordial leads were necessary. Furthermore, in a prospective observational study, 51 peripheral artery vascular surgery patients underwent ambulatory continuous 12-lead ECG monitoring in the postoperative setting. Ischemic load, defined as the area under the curve defined by ischemic ST-segment deviation and ischemic time, was shown to predict perioperative myocardial infarction with an area under the receiver operating characteristics curve of 0.87. Notably, ischemia was asymptomatic in 14 of the 17 identified patients, demonstrating value of this modality as a warning tool.⁵ Thus, continuous 12-lead ECG monitoring may provide greater sensitivity than 3-lead ECG for the detection of perioperative myocardial ischemia, and may become standard for monitoring high-risk surgical patients.

Currently, there is considerable interest in using computerized approaches to analyze ECG waveforms and patterns to uncover hidden information that can be used to predict sudden cardiac death or the development of serious dysrhythmias. ECG patterns of interest include repetitive changes in the morphology of the T-wave (T-wave alternans; TWA)⁶ and heart rate variability.⁷

ALGORITHMIC INTEGRATIVE MONITORING

Integrated monitoring systems employ software that integrates vital signs to produce a single-parameter index that allows early detection of physiologic perturbations. The input variables include noninvasive measurements of heart rate, respiratory rate, blood pressure, SpO₂, and temperature. The software uses neural networking to develop a probabilistic model of normality, previously developed from a representative sample patient training set. Variance from this data set is used to evaluate the probability that the patient-derived vital signs are within the normal range. An abnormal index can occur while no single vital sign parameter is outside the range of normal if their combined patterns are consistent with known instability patterns. Employing such an integrated monitoring system in step-down unit patients has been shown to be a sensitive method to detect early physiologic abnormalities that may precede hemodynamic instability.⁸ This subsequently was demonstrated to reduce the amount of overall patient instability by facilitating earlier identification and appropriate intervention by the medical team.⁹

The large expansion of the electronic medical record (EMR) is also driving the development of new algorithmic assessment tools for inpatient monitoring. The Rothman Index (RI) is a proprietary data analysis toolkit encompassing a total of 26 variables including vital signs, nursing assessments,

laboratory test values, and cardiac rhythms and was developed to make use of the vast amount of data input into the EMR on a real-time basis to help provide a global assessment of patient status. In the initial derivation, Rothman and colleagues demonstrated concordance of the RI with the Modified Early Warning Score (MEWS) system, which is designed to alert medical teams to clinical deterioration that precedes cardiac or pulmonary arrest events.¹⁰ Subsequent publications evaluated performance of the RI in predicting both readmission to surgical ICUs in the postoperative setting as well as for rapid response team activations.¹¹⁻¹³ Although more work is required to evaluate the broad applicability of the RI and similar measures, the evidence to date is compelling. Furthermore, as EMR interfaces become more sophisticated, other real-time data analysis software packages will likely be developed that provide further insight into the care of postsurgical patients.

CARDIAC OUTPUT AND RELATED PARAMETERS

Bedside catheterization of the pulmonary artery was introduced into clinical practice in the 1970s. Although the pulmonary artery catheter initially was used primarily to manage patients with cardiogenic shock and other acute cardiac diseases, indications for this form of invasive hemodynamic monitoring gradually expanded to encompass a wide variety of clinical conditions. Clearly, many clinicians believe that information valuable for the management of critically ill patients is afforded by having a pulmonary artery catheter (PAC) in place. However, unambiguous data in support of this view are scarce, and several studies suggest that bedside pulmonary artery catheterization may not benefit most critically ill patients and in fact may lead to some serious complications (see “Effect of Pulmonary Artery Catheterization on Outcome”).

Determinants of Cardiac Performance

Cardiac performance requires the integration of multiple mechanical and physiologic parameters of both the heart itself and of the circulatory system through which blood flows. The following sections discuss some of these factors, including preload, contractility, and afterload. A brief review of some of the graphical tools for evaluating cardiac physiology is demonstrated in Fig. 13-2.

Preload. Starling’s law of the heart states that the force of muscle contraction depends on the initial length of the cardiac fibers. Using terminology that derives from early experiments using isolated cardiac muscle preparations, *preload* is the stretch of ventricular myocardial tissue just prior to the next contraction. Strictly speaking, preload is determined by end-diastolic volume (EDV). In practice, EDV is challenging to measure precisely during the cardiac cycle, and so clinicians utilize the end-diastolic pressure (EDP) as a reasonable surrogate. For the right ventricle, central venous pressure (CVP) approximates right ventricular EDP. For the left ventricle, pulmonary artery occlusion pressure (PAOP), which is measured by transiently inflating a balloon at the end of a pressure monitoring catheter positioned in a small branch of the pulmonary artery, approximates left ventricular EDP. The presence of atrioventricular valvular stenosis may alter this relationship.

There are limits to the utilization of EDP as a surrogate for EDV when evaluating preload. For example, EDP is determined not only by volume but also by the diastolic compliance of the ventricular chamber. Ventricular compliance is altered by

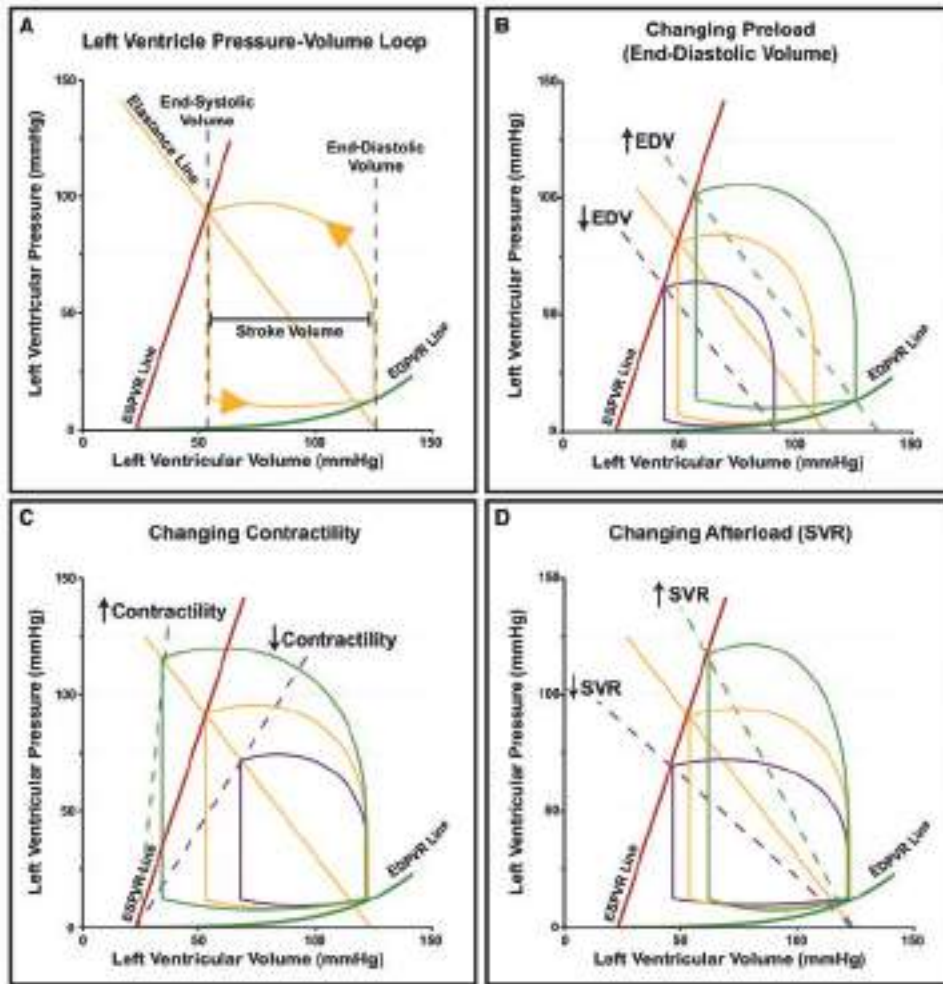

Figure 13-2 A-D. Left ventricular pressure-volume loops constructed for various clinically relevant scenarios. For further information refer to the text. **A.** Standard left ventricular pressure-volume loop, with stroke volume, end systolic volume, and end diastolic volume highlighted for reference. Note the directionality of the pressure-volume loop, which is not annotated in the other figures for clarity. **B-D.** Demonstration of the effect of changing preload (**B**), contractility (**C**), or afterload (**D**) on the pressure-volume relationships in the left ventricle. Note the differences in stroke volume for various conditions, as well as the end-systolic volume and pressures, as these represent clinically significant parameters that govern patient care.

various pathologic conditions and pharmacologic agents. Furthermore, the relationship between EDP and true preload is not linear, but rather is exponential (Fig. 13-2A,B). This fact limits the utility of EDP as a surrogate marker at extremes of EDV.

Contractility. Contractility is defined as the inotropic state of the myocardium. Contractility is said to increase when the force of ventricular contraction increases at constant preload and afterload. Clinically, contractility is difficult to quantify because virtually all of the available measures are dependent to a certain degree on preload and afterload. If pressure-volume loops are constructed for each cardiac cycle, small changes in preload and/or afterload will result in shifts of the point defining the end of systole. These end-systolic points on the pressure-versus-volume diagram describe a straight line, known as the end-systolic pressure-volume line. A steeper slope of this line indicates greater contractility, as illustrated in Fig. 13-2C.

Afterload. *Afterload* is another term derived from in vitro experiments using isolated strips of cardiac muscle and is defined as the force resisting fiber shortening once systole begins. Defined specifically for the in vivo system, afterload is the resistance to the expulsion of blood from the heart chamber

of interest, usually the left ventricle. Several factors comprise the in vivo correlate of ventricular afterload, including ventricular chamber geometry, intracavitary pressure generation, and the arterial impedance in the systemic circulation. Since these factors are difficult to assess clinically, afterload is commonly approximated by calculating systemic vascular resistance (SVR), defined as mean arterial pressure (MAP) divided by cardiac output (Fig. 13-2D).

PLACEMENT OF THE PULMONARY ARTERY CATHETER

In its simplest form, the PAC has four channels. One channel terminates in a balloon at the tip of the catheter. The proximal end of this channel is connected to a syringe to permit inflation of the balloon with air. Prior to insertion of the PAC, the integrity of the balloon should be verified by inflating it. In order to minimize the risk of vascular or ventricular perforation by the relatively inflexible catheter, it also is important to verify that the inflated balloon extends just beyond the tip of the device. A second channel in the catheter contains wires that are connected

Figure 13-3. Representative pressure traces at different stages of insertion of the PAC. In the central venous circulation, the pressure remains low, with characteristic waves from atrial filling and tricuspid valve closing. Upon entry into the right ventricle, the pressure increases sharply, with the broadest range between systole and diastole. When in the main pulmonary artery, the systolic pressure remains elevated to the same degree, but the diastolic pressure is now significantly elevated due to the closure of the pulmonic valve during the cardiac cycle. Upon further advancement with the balloon inflated, the pressure differences become smaller and the magnitude of the mean pressure drops, reflecting an estimate of the left atrial pressure.

to a thermistor located near the tip of the catheter. At the proximal end of the PAC, the wires terminate in a fitting that permits connection to appropriate hardware for the calculation of cardiac output using the thermodilution technique. The final two channels are used for pressure monitoring and the injection of the thermal indicator for determinations of cardiac output. One of these channels terminates at the tip of the catheter; the other terminates 20 cm proximal to the tip.

Placement of a PAC requires access to the central venous circulation. Such access can be obtained at a variety of sites, including the antecubital, femoral, jugular, and subclavian veins. Percutaneous placement through either the jugular or subclavian vein generally is preferred. Right internal jugular vein cannulation carries the lowest risk of complications, and the path of the catheter from this site into the right atrium is straight. In the event of inadvertent arterial puncture, local pressure is significantly more effective in controlling bleeding from the carotid artery as compared to the subclavian artery. Nevertheless, it is more difficult to keep occlusive dressings in place on the neck than in the subclavian fossa. Furthermore, the anatomic landmarks in the subclavian position are quite constant, even in patients with anasarca or massive obesity; the subclavian vein is always attached to the deep (concave) surface of the clavicle. In contrast, the appropriate landmarks to guide jugular venous cannulation are sometimes difficult to discern in obese or very edematous patients. However, ultrasonic guidance, which should be used routinely, has been shown to facilitate bedside jugular venipuncture.¹⁴

Cannulation of the vein is normally performed percutaneously, using the Seldinger technique. A small-bore needle is inserted through the skin and subcutaneous tissue into the vein. After documenting return of venous blood, a guidewire with a flexible tip is inserted through the needle into the vein, and the needle is withdrawn. A dilator/introducer sheath is passed over

the wire, and the wire and the dilator are removed. The proximal terminus of the distal port of the PAC is connected through low-compliance tubing to a strain-gauge transducer, and the tubing-catheter system is flushed with fluid. While constantly observing the pressure tracing on a monitor screen, the PAC is advanced with the balloon deflated until respiratory excursions are observed. The balloon is then inflated, and the catheter advanced further, while monitoring pressures sequentially in the right atrium and right ventricle en route to the pulmonary artery. The pressure waveforms for the right atrium, right ventricle, and pulmonary artery are each characteristic (Fig. 13-3). The catheter is advanced out the pulmonary artery until a damped tracing indicative of the “wedged” position is obtained. The balloon is then deflated, taking care to ensure that a normal pulmonary arterial tracing is again observed on the monitor; leaving the balloon inflated can increase the risk of pulmonary infarction or perforation of the pulmonary artery. Unnecessary measurements of the pulmonary artery occlusion pressure are discouraged as rupture of the pulmonary artery may occur.

HEMODYNAMIC MEASUREMENTS

Even in its simplest embodiment, the PAC is capable of providing clinicians with a remarkable amount of information about the hemodynamic status of patients. Additional information may be obtained if various modifications of the standard PAC are employed. By combining data obtained through use of the PAC with results obtained by other means (i.e., blood hemoglobin concentration and oxyhemoglobin saturation), derived estimates of systemic oxygen transport and utilization can be calculated. Direct and derived parameters obtainable by bedside pulmonary arterial catheterization, along with several associated approximate normal ranges, are summarized in Table 13-1.

Table 13-1

Directly measured and derived hemodynamic data obtainable by bedside pulmonary artery catheterization, with normal associated ranges

PARAMETER	NORMAL RANGE
CVP	0–6 mmHg
PAP	Varies
PAOP	6–12 mmHg
S $\bar{v}O_2$ (intermittent or continuous)	65%–70%
Q $_T$ (intermittent or continuous)	4–6 L/min
Q $_T^*$ (intermittent or continuous)	2.5–3.5 L·min ⁻¹ ·m ⁻²
RVEF	>55%
SV	40–80 mL
SVR	800–1400 dyne·sec·cm ⁻⁵
SVRI	1500–2400 dyne·sec·cm ⁻⁵ ·m ⁻²
PVR	100–150 dyne·sec·cm ⁻⁵
PVRI	200–400 dyne·sec·cm ⁻⁵ ·m ⁻²
RVEDV	Variable
$\dot{D}O_2$	400–660 mL·min ⁻¹ ·m ⁻²
$\bar{V}O_2$	115–165 mL·min ⁻¹ ·m ⁻²
ER	Variable
Q $_S/Q_T$	Variable

CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; ER = systemic oxygen extraction ratio; PAOP = pulmonary artery occlusion (wedge) pressure; PAP = pulmonary artery pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q $_S/Q_T$ = fractional pulmonary venous admixture (shunt fraction); Q $_T$ = cardiac output; Q $_T^*$ = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; S $\bar{v}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\bar{V}O_2$ = systemic oxygen utilization.

Measurement of Cardiac Output by Thermodilution

Before the development of the PAC, determining cardiac output (Q $_T$) at the bedside required careful measurements of oxygen consumption (Fick method) or spectrophotometric determination of indocyanine green dye dilution curves. Measurements of Q $_T$ using the thermodilution technique are simple and reasonably accurate. The measurements can be performed repetitively, and the principle is straightforward. If a bolus of an indicator is rapidly and thoroughly mixed with a moving fluid upstream from a detector, then the concentration of the indicator at the detector will increase sharply and then exponentially diminish back to zero. The area under the resulting time-concentration curve is a function of the volume of indicator injected and the flow rate of the moving stream of fluid. Larger volumes of indicator result in greater areas under the curve, and faster flow rates of the mixing fluid result in smaller areas under the curve. When Q $_T$ is measured by thermodilution, the indicator is heat and the

detector is a temperature-sensing thermistor at the distal end of the PAC. The relationship used for calculating Q $_T$ is called the Stewart-Hamilton equation:

$$Q_T = \frac{VK_1K_2(T_B - T_1)}{\int T_B(t) dt}$$

where V is the volume of the indicator injected, T $_B$ is the temperature of blood (i.e., core body temperature), T $_1$ is the temperature of the indicator, K $_1$ is a constant that is the function of the specific heats of blood and the indicator, K $_2$ is an empirically derived constant that accounts for several factors (the dead space volume of the catheter, heat lost from the indicator as it traverses the catheter, and the injection rate of the indicator), and $\int T_B(t) dt$ is the area under the time-temperature curve. In clinical practice, the Stewart-Hamilton equation is solved by a microprocessor.

Determination of cardiac output by the thermodilution method is generally quite accurate, although it tends to systematically overestimate Q $_T$ at low values. Changes in blood temperature and Q $_T$ during the respiratory cycle can influence the measurement. Therefore, results generally should be recorded as the mean of two or three determinations obtained at random points in the respiratory cycle. Using cold injectate widens the difference between T $_B$ and T $_1$ and thereby increases signal-to-noise ratio. Nevertheless, most authorities recommend using room temperature injectate (normal saline or 5% dextrose in water) to minimize errors resulting from warming of the fluid as it transferred from its reservoir to a syringe for injection.

Technologic innovations have been introduced that permit continuous measurement of Q $_T$ by thermodilution. In this approach, thermal transients are not generated by injecting a bolus of a cold indicator, but rather by heating the blood with a tiny filament located on the PAC upstream from the thermistor. By correlating the amount of current supplied to the heating element with the downstream temperature of the blood, it is possible to estimate the average blood flow across the filament and thereby calculate Q $_T$. Based upon the results of several studies, continuous determinations of Q $_T$ using this approach agree well with data generated by conventional measurements using bolus injections of a cold indicator.¹⁵ Information is lacking regarding the clinical value of being able to monitor Q $_T$ continuously.

Mixed Venous Oximetry

The Fick equation can be written as

$$Q_T = \frac{VO_2}{(C_aO_2 - C_vO_2)}$$

where C $_aO_2$ is the content of oxygen in arterial blood and C $_vO_2$ is the content of oxygen in mixed venous blood. The oxygen content in both arterial and venous blood is a function of the hemoglobin concentration in the blood, the hemoglobin saturation, and the partial pressure of oxygen:

$$C_{a/v}O_2 = \left(1.36 \times \text{Hgb} \times \frac{S_{a/v}O_2}{100} \right) + 0.0031 \times P_{a/v}O_2$$

$$C_{a/v}O_2 = \left(1.36 \times \text{Hgb} \times \frac{S_{a/v}O_2}{100} \right)$$

where S $_{a/v}O_2$ is the fractional saturation of hemoglobin in either arterial or venous blood, Hgb is the concentration of hemoglobin

in blood, and $P_{a/v}O_2$ is the partial pressure of oxygen in the arterial or venous blood. Under most circumstances the contribution of dissolved oxygen to both C_aO_2 and C_vO_2 is negligible, allowing the second portion of equation to be functionally eliminated (see previous equation). Given that, if the Fick equation is rearranged to the following:

$$C_vO_2 = C_aO_2 - \frac{VO_2}{Q_T}$$

Oxygen saturation can replace oxygen content, yielding the final clinically valuable equation:

$$S_vO_2 = S_aO_2 - \frac{VO_2}{(Q_T \times Hgb \times 1.36)}$$

where S_vO_2 is the fractional saturation of hemoglobin in mixed venous blood, S_aO_2 is the fractional saturation of hemoglobin in arterial blood, and Hgb is the concentration of hemoglobin in blood. Thus, it can be seen that S_vO_2 is a function of VO_2 (i.e., metabolic rate), Q_T , S_aO_2 , and Hgb. Accordingly, subnormal values of S_vO_2 can be caused by a decrease in Q_T (due, for example, to heart failure or hypovolemia), a decrease in S_aO_2 (due, for example, to intrinsic pulmonary disease), a decrease in Hgb (i.e., anemia), or an increase in metabolic rate (due, for example, to seizures or fever). With a conventional PAC, measurements of S_vO_2 require aspirating a sample of blood from the distal (i.e., pulmonary arterial) port of the catheter and injecting the sample into a blood gas analyzer. Therefore, for practical purposes, measurements of S_vO_2 can be performed only intermittently.

By adding a fifth channel to the PAC, it is possible to monitor S_vO_2 continuously. The fifth channel contains two fiberoptic bundles, which are used to transmit and receive light of the appropriate wavelengths to permit measurements of hemoglobin saturation by reflectance spectrophotometry. Continuous S_vO_2 devices provide measurements of S_vO_2 that agree quite closely with those obtained by conventional analyses of blood aspirated from the pulmonary artery. Despite the theoretical value of being able to monitor S_vO_2 continuously, data are lacking to show that this capability favorably improves outcomes. In a prospective, observational study of 3265 patients undergoing cardiac surgery with either a standard PAC or a PAC with continuous S_vO_2 monitoring, the oximetric catheter was associated with fewer arterial blood gases and thermodilution cardiac output determinations but no difference in patient outcome.¹⁶ Since pulmonary artery catheters that permit continuous monitoring of S_vO_2 are more expensive than conventional PACs, the routine use of these devices cannot be recommended.

The saturation of oxygen in the right atrium or superior vena cava ($S_{cv}O_2$) correlates closely with S_vO_2 over a wide range of conditions,¹⁷ although the correlation between $S_{cv}O_2$ and S_vO_2 has been questioned.¹⁸ Since measurement of $S_{cv}O_2$ requires placement of a central venous catheter rather than a PAC, it is somewhat less invasive and easier to carry out. By using a central venous catheter equipped to permit fiber-optic monitoring of $S_{cv}O_2$, it may be possible to titrate the resuscitation of patients with shock using a less invasive device than the PAC.^{17,19} The Surviving Sepsis Campaign international guidelines for the management of severe sepsis and septic shock recommends that during the first 6 hours of resuscitation, the goals of initial resuscitation of sepsis-induced hypoperfusion should include all of the following: CVP 8 to 12 mm Hg, MAP \geq 65 mm Hg, urine output \geq 0.5 mL/kg per hour, and $S_{cv}O_2$ of 70% or S_vO_2 65%.²⁰

EFFECT OF PULMONARY ARTERY CATHETERIZATION ON OUTCOME

Despite initial enthusiasm for using the PAC in the management of critically ill patients, several studies have failed to show improved outcomes with their use. Connors and colleagues reported results of a major observational study evaluating the value of pulmonary artery catheterization in critically ill patients.²¹ These researchers compared two groups of patients: those who did undergo placement of a PAC during their first 24 hours of ICU care and those who did not. The investigators recognized that the value of their intended analysis was completely dependent on the robustness of their methodology for case-matching because sicker patients (i.e., those at greater risk of mortality based upon the severity of their illness) were presumably more likely to undergo pulmonary artery catheterization. Accordingly, the authors used sophisticated statistical methods for generating a cohort of study (i.e., PAC) patients, each one having a paired control matched carefully for severity of illness. Connors and associates concluded that placement of a pulmonary artery catheter during the first 24 hours of stay in an ICU is associated with a significant increase in the risk of mortality, even when statistical methods are used to account for severity of illness.

A number of prospective, randomized controlled trials of pulmonary artery catheterization are summarized in Table 13-2. The study by Pearson and associates was underpowered with only 226 patients enrolled.²² In addition, the attending anesthesiologists were permitted to exclude patients from the CVP group at their discretion; thus randomization was compromised. The study by Tuman and coworkers was large (1094 patients were enrolled), but different anesthesiologists were assigned to the different groups.²³ Furthermore, 39 patients in the CVP group underwent placement of a PAC because of hemodynamic complications. All of the individual single-institution studies of vascular surgery patients were relatively underpowered, and all excluded at least certain categories of patients (e.g., those with a history of recent myocardial infarction).^{24,25}

In the largest randomized controlled trial of the PAC, Sandham and associates randomized nearly 2000 American Society of Anesthesiologists (ASA) classes III and IV patients undergoing major thoracic, abdominal, or orthopedic surgery to placement of a PAC or CVP catheter.²⁶ In the patients assigned to receive a PAC, physiologic goal-directed therapy was implemented by protocol. There were no differences in mortality at 30 days, 6 months, or 12 months between the two groups, and ICU length of stay was similar. There was a significantly higher rate of pulmonary emboli in the PAC group (0.9% vs. 0%). This study has been criticized because most of the patients enrolled were not in the highest risk category.

In the "PAC-Man" trial, a multicenter, randomized trial in 65 UK hospitals, over 1000 ICU patients were managed with or without a PAC.²⁷ The specifics of the clinical management were then left up to the treating clinicians. There was no difference in hospital mortality between the 2 groups (with PAC 68% vs. without PAC 66%, $P = 0.39$). However, a 9.5% complication rate was associated with the insertion or use of the PAC, although none of these complications were fatal. Clearly, these were critically ill patients, as noted by the high hospital mortality rates. Supporters of the PAC may cite methodology problems with this study, such as loose inclusion criteria and the lack of a defined treatment protocol.

Table 13-2

Summary of randomized, prospective clinical trials comparing pulmonary artery catheter (PAC) with central venous pressure (CVP) monitoring

AUTHOR	STUDY POPULATION	GROUPS	OUTCOMES	STRENGTHS/WEAKNESSES
Pearson et al ²²	“Low risk” patients undergoing cardiac or vascular surgery	CVP catheter (group 1); PAC (group 2); PAC with continuous $\text{S}\bar{\text{v}}\text{O}_2$ readout (group 3)	No differences among groups for mortality or length of ICU stay; significant differences in costs (group 1 < group 2 < group 3)	Underpowered (266 total patients enrolled); compromised randomization protocols
Tuman et al ²³	Cardiac surgical patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or significant noncardiac complications	Large trial (1094 patients); different anesthesiologists for different groups
Bender et al ²⁴	Vascular surgery patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or length of hospital stay	Relatively underpowered
Valentine et al ²⁵	Aortic surgery patients	PAC + hemodynamic optimization in ICU night before surgery; CVP	No difference between groups for mortality or length of ICU stay; significantly higher incidence of postoperative complications in PAC group	Relatively underpowered
Sandham et al ²⁶	“High risk” major surgery	PAC; CVP	No differences between groups for mortality, length of ICU stay; increased incidence of pulmonary embolism in PAC group	Largest RCT of PAC utilization; commonly criticized for smaller number of highest risk category patients
Harvey S et al ²⁷ PAC-Man Trial	Medical and surgical ICU patients	PAC vs no PAC, with option for alternative CO measuring device in non-PAC group	No difference in hospital mortality between the 2 groups, increased incidence of complications in the PAC group	Loose inclusion criteria with lack of a defined treatment protocol for use of PAC data
Binanay et al ²⁹ ESCAPE Trial	Patients with CHF	PAC vs no PAC	No difference in hospital mortality between the groups, increased incidence of adverse events in the PAC group	No formal treatment protocol for PAC-driven therapy
Wheeler et al ³⁰ FACTT Trial	Patients with ALI	PAC vs CVC with a fluid and inotropic management protocol	No difference in ICU or hospital mortality, or incidence of organ failure between the groups; increased incidence of adverse events in the PAC group	

ALI = acute lung injury; CHF = congestive heart failure; CO = cardiac output; CVC = central venous catheter; ICU = intensive care unit; PAC = pulmonary artery catheter; $\text{S}\bar{\text{v}}\text{O}_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation.

A meta-analysis of 13 randomized studies of the PAC that included over 5000 patients was published in 2005.²⁸ A broad spectrum of critically ill patients was included in these heterogeneous trials, and the hemodynamic goals and treatment strategies varied. While the use of the PAC was associated with an increased use of inotropes and vasodilators, there were no differences in mortality or hospital length of stay between the patients managed with a PAC and those managed without a PAC.

The ESCAPE trial (which was one of the studies included in the previous meta-analysis)²⁹ evaluated 433 patients with severe or recurrent congestive heart failure (CHF) admitted to

the ICU. Patients were randomized to management by clinical assessment and a PAC or clinical assessment without a PAC. The goal in both groups was resolution of CHF, with additional PAC targets of a pulmonary capillary occlusion pressure of 15 mmHg and a right atrial pressure of 8 mmHg. There was no formal treatment protocol, but inotropic support was discouraged. Substantial reduction in symptoms, jugular venous pressure, and edema was noted in both groups. There was no significant difference in the primary end point of days alive and out of the hospital during the first 6 months, or hospital mortality (PAC 10% vs without PAC 9%). Adverse events

were more common among patients in the PAC group (21.9% vs 11.5%; $P = 0.04$).

Finally, the Fluids and Catheters Treatment Trial (FACTT) conducted by the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network was published in 2006.³⁰ The risks and benefits of PAC compared with central venous catheters (CVC) were evaluated in 1000 patients with acute lung injury. Patients were randomly assigned to receive either a PAC or a CVC to guide management for 7 days via an explicit protocol. Patients also were randomly assigned to a conservative or liberal fluid strategy in a 2 × 2 factorial design (outcomes based on the fluid management strategy were published separately). Mortality during the first 60 days was similar in the PAC and CVC groups (27% and 26%, respectively; $P = .69$). The duration of mechanical ventilation and ICU length of stay also were not influenced by the type of catheter used. The type of catheter employed did not affect the incidence of shock, respiratory or renal failure, ventilator settings, or requirement for hemodialysis or vasopressors. There was a 1% rate of crossover from CVC-guided therapy to PAC-guided therapy. The catheter used did not affect the administration of fluids or diuretics, and the fluid balance was similar in the two groups. The PAC group had approximately twice as many catheter-related adverse events (mainly arrhythmias).

Few subjects in critical care medicine have historically generated more emotional responses among experts in the field than the use of the PAC. As these studies demonstrate, it is not possible to show that therapy directed by use of the PAC saves lives when it is evaluated in a large population of patients. Certainly, given the available evidence, routine use of the PAC cannot be justified.

▶ Whether selective use of the device in a few relatively uncommon clinical situations is warranted or valuable remains a controversial issue. Consequently, a marked decline in the use of the PAC from 5.66 per 1000 medical admissions in 1993 to 1.99 per 1000 medical admissions in 2004 has been seen.³¹ Based upon the results and exclusion criteria in these prospective randomized trials, reasonable criteria for perioperative monitoring without use of a PAC are presented in Table 13-3.

One of the reasons for using a PAC to monitor critically ill patients is to optimize cardiac output and systemic oxygen delivery. Defining what constitutes the optimum cardiac output, however, has proven to be difficult. A number of randomized trials evaluating the effect on outcome of goal-directed as compared to conventional hemodynamic resuscitation have

been published. Some studies provide support for the notion that interventions designed to achieve supraphysiologic goals for DO_2 , VO_2 , and Q_T improve outcome.^{32,33} However, other published studies do not support this view, and a meta-analysis concluded that interventions designed to achieve supraphysiologic goals for oxygen transport do not significantly reduce mortality rates in critically ill patients.^{34,35} At this time, supraphysiologic resuscitation of patients in shock cannot be endorsed.

There is no simple explanation for the apparent lack of effectiveness of pulmonary artery catheterization, although several concurrent possibilities exist. First, even though bedside pulmonary artery catheterization is quite safe, the procedure is associated with a finite incidence of serious complications, including ventricular arrhythmias, catheter-related sepsis, central venous thrombosis, pulmonary arterial perforation, and pulmonary embolism.²⁶ The adverse effects of these complications on outcome may equal or even outweigh any benefits associated with using a PAC to guide therapy. Second, the data generated by the PAC may be inaccurate, leading to inappropriate therapeutic interventions. Third, the measurements, even if accurate, are often misinterpreted.³⁶ Furthermore, the current state of understanding is primitive when it comes to deciding what is the best management for certain hemodynamic disturbances, particularly those associated with sepsis or septic shock. Taking all of this into consideration, it may be that interventions prompted by measurements obtained with a PAC are actually harmful to patients. As a result, the marginal benefit now available by placing a PAC may be quite small. Less invasive modalities are available that may provide clinically useful hemodynamic information.

It may be true that aggressive hemodynamic resuscitation of patients, guided by various forms of monitoring, is valuable only during certain critical periods, such as the first few hours after presentation with septic shock or during surgery. For example, Rivers and colleagues reported that survival of patients with septic shock is significantly improved when resuscitation in the emergency department is guided by a protocol that seeks to keep $S_{cv}O_2$ greater than 70%.¹⁹ Similarly, a study using an ultrasound-based device (see “Doppler Ultrasonography”) to assess cardiac filling and SV showed that maximizing SV intraoperatively results in fewer postoperative complications and shorter hospital length of stay.³⁷

MINIMALLY INVASIVE ALTERNATIVES TO THE PULMONARY ARTERY CATHETER

Because of the cost, risks, and questionable benefit associated with bedside pulmonary artery catheterization, there has been interest in the development of practical means for less invasive monitoring of hemodynamic parameters. Several approaches have been developed that have achieved variable degrees of success. None of these methods render the standard thermodilution technique of the pulmonary artery catheter obsolete. However, these strategies may contribute to improvements in the hemodynamic monitoring of critically ill patients.

Transpulmonary Thermodilution

In the standard PAC thermodilution technique, measurements rely on the detection of temperature changes in a relatively small area from the injection port to the thermistor on the same catheter. In contrast, the transpulmonary thermodilution (TPTD) technique measures temperature changes from cold

Table 13-3

Suggested criteria for perioperative monitoring without use of a pulmonary artery catheter in patients undergoing cardiac or major vascular surgical procedures

- No anticipated need for suprarenal or supraceliac aortic cross-clamping
- No history of myocardial infarction during 3 months prior to operation
- No history of poorly compensated congestive heart failure
- No history of coronary artery bypass graft surgery during 6 weeks prior to operation
- No history of ongoing symptomatic mitral or aortic valvular heart disease
- No history of ongoing unstable angina pectoris

bolus solution injected centrally, then measured using an arterial thermistor on a special arterial line, generally placed in the femoral artery. Both standard PAC thermodilution and TPTD make use of the Stewart-Hamilton equation to subsequently calculate cardiac output. Studies have demonstrated that this technique provides comparable estimates of cardiac output when compared to routine PAC thermodilution and can accurately detect changes in cardiac output as small as 12%.³⁸ However, due to the large blood circuit between the central injection point and the thermistor, data can be challenging to interpret in certain pathophysiologic conditions (e.g., in pulmonary edema, as excess lung water serves as a temperature sink). On the other hand, thoughtful application of TPTD data allows clinicians access to several additional variables that the traditional PAC does not provide, such as estimation of the global end-diastolic volume (GEDV) and the extravascular lung water volume (EVLW).³⁸ While these variables are of scientific interest, they are not yet in wide clinical use, and further studies are required to determine their utility. However, TPTD does currently play a prominent role in the real-time calibration of pulse contour analysis, described in greater detail later in this chapter.

Doppler Ultrasonography

When ultrasonic sound waves are reflected by moving erythrocytes in the bloodstream, the frequency of the reflected signal is increased or decreased, depending on whether the cells are moving toward or away from the ultrasonic source. This change in frequency is called the Doppler shift, and its magnitude is determined by the velocity of the moving red blood cells. Therefore, measurements of the Doppler shift can be used to calculate red blood cell velocity. With knowledge of both the cross-sectional area of a vessel and the mean red blood cell velocity of the blood flowing through it, one can calculate blood flow rate. If the vessel in question is the aorta, then Q_T can be calculated as:

$$Q_T = HR \times A \times \int V(t)dt$$

where A is the cross-sectional area of the aorta and $\int V(t)dt$ is the red blood cell velocity integrated over the cardiac cycle.

Two approaches have been developed for using Doppler ultrasonography to estimate Q_T . The first approach uses an ultrasonic transducer, which is manually positioned in the suprasternal notch and focused on the root of the aorta. Aortic cross-sectional area can be estimated using a nomogram, which factors in age, height, and weight, back-calculated if an independent measure of Q_T is available, or by using two-dimensional transthoracic or transesophageal ultrasonography. While this approach is completely noninvasive, it requires a highly-skilled operator in order to obtain meaningful results and is labor-intensive. Moreover, unless Q_T measured using thermodilution is used to back-calculate aortic diameter, accuracy using the suprasternal notch approach is not acceptable. Accordingly, the method is useful only for obtaining very intermittent estimates of Q_T , and it has not been widely adopted by clinicians.

A more promising, albeit more invasive, approach has been introduced. In this method blood flow velocity is continuously monitored in the descending thoracic aorta using a continuous-wave Doppler transducer introduced into the esophagus. The probe is connected to a monitor which continuously displays the blood flow velocity profile in the descending aorta as well as the calculated Q_T . In order to maximize the accuracy of the device, the probe position must be adjusted to obtain the peak velocity in the aorta. In order to transform blood flow in

the descending aorta into Q_T , a correction factor is applied that is based on the assumption that only 70% of the flow at the root of the aorta is still present in the descending thoracic aorta. Aortic cross-sectional area is estimated using a nomogram based on the patient's age, weight, and height. Results using these methods appear to be reasonably accurate across a broad spectrum of patients. A meta-analysis of the available data shows a good correlation between cardiac output estimates obtained by transesophageal Doppler and PAC in critically ill patients.³⁹ The ultrasonic device also calculates a derived parameter termed *flow time corrected* (FTc), which is the systolic flow time in the descending aorta corrected for heart rate. FTc is a function of preload, contractility, and vascular input impedance. Although it is not a pure measure of preload, Doppler-based estimates of SV and FTc have been used successfully to guide volume resuscitation in high-risk surgical patients undergoing major operations.³⁷

Impedance Cardiography

The impedance to flow of alternating electrical current in regions of the body is commonly called *bioimpedance*. In the thorax, changes in the volume and velocity of blood in the thoracic aorta lead to detectable changes in bioimpedance. The first derivative of the oscillating component of thoracic bioimpedance (dZ/dt) is linearly related to aortic blood flow. On the basis of this relationship, empirically derived formulas have been developed to estimate SV, and subsequently Q_T , noninvasively. This methodology is called *impedance cardiography*. The approach is attractive because it is noninvasive, provides a continuous readout of Q_T , and does not require extensive training. Despite these advantages, measurements of Q_T obtained by impedance cardiography are not sufficiently reliable to be used for clinical decision making and have poor correlation with thermodilution.⁴⁰

Because of the limitations of bioimpedance devices, a newer approach for processing the impedance signal was developed and commercialized. This approach is based on the recognition that the impedance signal has two components: amplitude and phase. Whereas the amplitude of the thoracic impedance signal is determined by all of the components of the thoracic cavity (bone, blood, muscle, and other soft tissues), phase shifts are determined entirely by pulsatile flow. The vast majority of pulsatile flow is related to blood moving within the aorta. Therefore, the "bioreactance" signal correlates closely with aortic flow, and cardiac output determined using this approach agrees closely with cardiac output measured using conventional indicator dilution techniques.⁴¹

Pulse Contour Analysis

Another method for determining cardiac output is an approach called *pulse contour analysis* for estimating SV on a beat-to-beat basis. The mechanical properties of the arterial tree and SV determine the shape of the arterial pulse waveform. The pulse contour method of estimating Q_T uses the arterial pressure waveform as an input for a model of the systemic circulation in order to determine beat-to-beat flow through the circulatory system. The parameters of resistance, compliance, and impedance are initially estimated based on the patient's age and sex and can be subsequently refined by using a reference standard measurement of Q_T . The reference standard estimation of Q_T is obtained periodically using the indicator dilution approach by injecting the indicator into a central venous catheter and

detecting the transient increase in indicator concentration in the blood using an arterial catheter. In one commercially available embodiment of this approach, the lithium ion (Li⁺) is the indicator used for the periodic calibrations of the device. The lithium carbonate indicator can be injected into a peripheral vein, and the doses do not exert pharmacologically relevant effects in adult patients. The Li⁺ indicator dilution method has shown to be at least as reliable as other thermodilution methods over a broad range of CO in a variety of patients.⁴¹ In another commercially available system, a conventional bolus of cold fluid is used as the indicator for calibration, via TPTD approaches as described previously. When the pulse contour analysis is combined with intermittent TPTD in this fashion, the continuous data provided by contour analysis is more precise than TPTD alone.³⁸

Measurements of Q_T based on pulse contour monitoring using these two approaches are comparable in accuracy to standard pulmonary artery catheter (PAC)-thermodilution methods, but they are less invasive because transcatheter catheterization is not needed.⁴² Using online pressure waveform analysis, the computerized algorithms can calculate SV, Q_T , SVR, and an estimate of myocardial contractility, the rate of rise of the arterial systolic pressure (dp/dT). The use of pulse contour analysis has been applied using noninvasive photoplethysmographic measurements of arterial pressure. However, the accuracy of this technique has been questioned, and its clinical utility remains to be determined.⁴³

One commercially available device that can be used for estimating cardiac output does not require external calibration. Instead, the relationship between pulse pressure and stroke volume is determined using a proprietary algorithm that uses biometric data, such as age, gender and height, as inputs. Although this methodology is gaining fairly wide acceptance in critical care medicine, reported accuracy (in comparison to “gold standard” approaches) is not very good.⁴¹

Partial Carbon Dioxide Rebreathing

Partial carbon dioxide (CO₂) rebreathing uses the Fick principle to estimate Q_T noninvasively. By intermittently altering the dead space within the ventilator circuit via a rebreathing valve, changes in CO₂ production (V_{CO_2}) and end-tidal CO₂ (ET_{CO₂}) are used to determine cardiac output using a modified Fick equation:

$$Q_T = \frac{\Delta V_{CO_2}}{\Delta ET_{CO_2}}$$

Commercially available devices use this Fick principle to calculate Q_T using intermittent partial CO₂ rebreathing through a disposable rebreathing loop. These devices consist of a CO₂ sensor based on infrared light absorption, an airflow sensor, and a pulse oximeter. Changes in intrapulmonary shunt and hemodynamic instability impair the accuracy of Q_T estimated by partial CO₂ rebreathing. Continuous inline pulse oximetry and inspired fraction of inspired O₂ (FiO₂) are used to estimate shunt fraction to correct Q_T .

Some studies of the partial CO₂ rebreathing approach suggest that this technique is not as accurate as thermodilution, the gold standard for measuring Q_T .^{42,44} However, other studies suggest that the partial CO₂ rebreathing method for determination of Q_T compares favorably to measurements made using a PAC in critically ill patients.⁴⁵

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) has made the transition from operating room to intensive care unit. TEE requires that the patient be sedated and usually intubated for airway protection. Using this powerful technology, global assessments of LV and RV function can be made, including determinations of ventricular volume, EF, and Q_T . Segmental wall motion abnormalities, pericardial effusions, and tamponade can be readily identified with TEE. Doppler techniques allow estimation of atrial filling pressures. The technique is somewhat cumbersome and requires considerable training and skill in order to obtain reliable results. Recently, a TEE probe has been introduced into practice that is small enough in diameter that it can be left in place for as long as 72 hours. While only limited data are currently available with this probe, it seems like it will be a useful cardiac monitoring tool for use in selected, complex patients.

Assessing Preload Responsiveness

Although pulse contour analysis or partial CO₂ rebreathing may be able to provide estimates of SV and Q_T , these approaches alone can offer little or no information about the adequacy of preload. Thus, if Q_T is low, some other means must be employed to estimate preload. Many clinicians assess the adequacy of cardiac preload by determining CVP or PAOP. However, neither CVP nor PAOP correlate well with the true parameter of interest, left ventricular end-diastolic volume (LVEDV).⁴⁶ Extremely high or low CVP or PAOP results are informative, but readings in a large middle zone (i.e., 5 to 20 mmHg) are less useful. Furthermore, changes in CVP or PAOP fail to correlate well with changes in stroke volume.^{47,48} Echocardiography can be used to estimate LVEDV, but this approach is dependent on the skill and training of the individual using it, and isolated measurements of LVEDV fail to predict the hemodynamic response to alterations in preload.⁴⁹

When intrathoracic pressure increases during the application of positive airway pressure in mechanically ventilated patients, venous return decreases, and as a consequence, left ventricular stroke volume (LVS_V) also decreases. Therefore, pulse pressure variation (PPV) during a positive pressure episode can be used to predict the responsiveness of cardiac output to changes in preload.^{50,51} PPV is defined as the difference between the maximal pulse pressure and the minimum pulse pressure divided by the average of these two pressures (Fig. 13-4). This approach has validated this by comparing PPV, CVP, PAOP, and systolic pressure variation as predictors of preload responsiveness in a cohort of critically ill patients. Patients were classified as being “preload responsive” if their cardiac index increased by at least 15% after rapid infusion of a standard volume of intravenous fluid.⁵² Receiver-operating characteristic (ROC) curves demonstrated that PPV was the best predictor of preload responsiveness. Although atrial arrhythmias can interfere with the usefulness of this technique, PPV remains a useful approach for assessing preload responsiveness in most patients because of its simplicity and reliability.⁴⁹

Near-Infrared Spectroscopic Measurement of Tissue Hemoglobin Oxygen Saturation

Near-infrared spectroscopy (NIRS) allows continuous, noninvasive measurement of tissue hemoglobin oxygen saturation (StO₂) using near-infrared wave lengths of light (700–1000 nm). This technology is based on Beer’s law, which states that the transmission of light through a solution with a dissolved

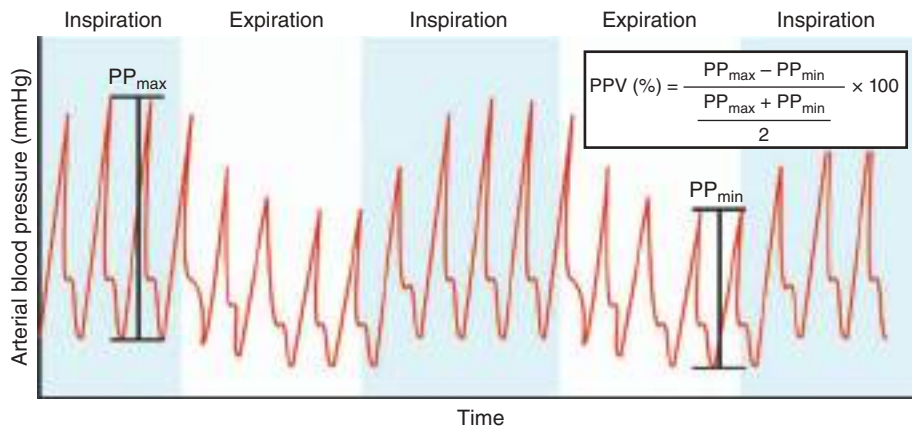

Figure 13-4. Calculation of pulse pressure variation as it would appear on bedside monitor. This provides a helpful and rapid assessment of fluid responsiveness in the critically ill mechanically ventilated patient.

solute decreases exponentially as the concentration of the solute increases. In mammalian tissue, three compounds change their absorption pattern when oxygenated: cytochrome aa3, myoglobin, and hemoglobin. Because of the distinct absorption spectra of oxyhemoglobin and deoxyhemoglobin, Beer's law can be used to detect their relative concentrations within tissue. Thus, the relative concentrations of the types of hemoglobin can be determined by measuring the change in light intensity as it passes through the tissue. Since about 20% of blood volume is intra-arterial and the StO_2 measurements are taken without regard to systole or diastole, spectroscopic measurements are primarily indicative of the venous oxyhemoglobin concentration.

NIRS has been evaluated to assess the severity of traumatic shock in animal models and in trauma patients. Studies have shown that peripheral muscle StO_2 , as determined by NIRS, is as accurate as other endpoints of resuscitation (i.e., base deficit, mixed venous oxygen saturation) in a porcine model of hemorrhagic shock.⁵³ Continuously measured StO_2 has been evaluated in blunt trauma patients as a predictor of the development of multiple organ dysfunction syndrome (MODS) and mortality.⁵⁴ 383 patients were prospectively studied at seven level I trauma centers. StO_2 was monitored for 24 hours after admission along with vital signs and other endpoints of resuscitation such as base deficit (BD). Minimum StO_2 (using a minimum $StO_2 \leq 75\%$ as a cutoff) had a similar sensitivity and specificity in predicting the development of MODS as $BD \geq 6$ mEq/L. StO_2 and BD were also comparable in predicting mortality. Thus, NIRS-derived muscle StO_2 measurements perform similarly to BD in identifying poor perfusion and predicting the development of MODS or death after severe torso trauma, yet have the additional advantages of being continuous and noninvasive. Ongoing prospective studies will help determine the clinical utility of continuous monitoring of StO_2 in clinical scenarios such as trauma, hemorrhagic shock, sepsis, etc.

RESPIRATORY MONITORING

The ability to monitor various parameters of respiratory function is of utmost importance in critically ill patients. Many of these patients require mechanical ventilation. Monitoring of their respiratory physiology is necessary to assess the adequacy of oxygenation and ventilation, guide weaning and liberation from mechanical ventilation, and detect adverse events associated with respiratory failure and mechanical ventilation. These

parameters include gas exchange, neuromuscular activity, respiratory mechanics, and patient effort.

Arterial Blood Gases

Blood gas analysis may provide useful information when caring for patients with respiratory failure. However, even in the absence of respiratory failure or the need for mechanical ventilation, blood gas determinations also can be valuable to detect alterations in acid-base balance due to low Q_T , sepsis, renal failure, severe trauma, medication or drug overdose, or altered mental status. Arterial blood can be analyzed for pH, PO_2 , PCO_2 , HCO_3^- concentration and calculated base deficit. When indicated, carboxyhemoglobin and methemoglobin levels also can be measured. In recent years, efforts have been made to decrease the unnecessary use of arterial blood gas analysis. Serial arterial blood gas determinations are not necessary for routine weaning from mechanical ventilation in the majority of postoperative patients.

Most bedside blood gas analyses still involve removal of an aliquot of blood from the patient, although continuous bedside arterial blood gas determinations are now possible without sampling via an indwelling arterial catheter that contains a biosensor. In studies comparing the accuracy of continuous arterial blood gas and pH monitoring with a conventional laboratory blood gas analyzer, excellent agreement between the two methods has been demonstrated.⁵⁵ Continuous monitoring can reduce the volume of blood loss due to phlebotomy and dramatically decrease the time necessary to obtain blood gas results. Continuous monitoring, however, is expensive and is not widely employed.

Determinants of Oxygen Delivery

The primary goal of the cardiovascular and respiratory systems is to deliver oxygenated blood to the tissues. DO_2 is dependent to a greater degree on the oxygen saturation of hemoglobin (Hgb) in arterial blood (SaO_2) than on the partial pressure of oxygen in arterial blood (PaO_2). DO_2 also is dependent on Q_T and Hgb. As discussed earlier and illustrated mathematically by previous equations, the dissolved oxygen in blood makes only a negligible contribution to DO_2 . SaO_2 in mechanically ventilated patients depends on the mean airway pressure, the fraction of inspired oxygen (FiO_2), and S_vO_2 . Thus, when SaO_2 is low, the clinician has only a limited number of ways to improve this parameter. The clinician can increase mean airway pressure by increasing positive-end expiratory pressure (PEEP) or inspiratory time. FiO_2 can be increased to a maximum of 1.0 by decreasing the amount of room air mixed with the oxygen supplied to the ventilator. S_vO_2 can be increased by increasing Hgb

or Q_T or decreasing oxygen utilization (e.g., by administering a muscle relaxant and sedation).

Peak and Plateau Airway Pressure

Airway pressures are routinely monitored in mechanically ventilated patients. The peak airway pressure measured at the end of inspiration (P_{peak}) is a function of the tidal volume, the resistance of the airways, lung/chest wall compliance, and peak inspiratory flow. The airway pressure measured at the end of inspiration when the inhaled volume is held in the lungs by briefly closing the expiratory valve is termed *the plateau airway pressure* (P_{plateau}). As a static parameter, plateau airway pressure is independent of the airway resistance and peak airway flow and is related to the lung/chest wall compliance and delivered tidal volume. Mechanical ventilators monitor P_{peak} with each breath and can be set to trigger an alarm if the P_{peak} exceeds a predetermined threshold. P_{plateau} is not measured routinely with each delivered tidal volume but rather is measured intermittently by setting the ventilator to close the exhalation circuit briefly at the end of inspiration and record the airway pressure when airflow is zero.

If both P_{peak} and P_{plateau} are increased (and tidal volume is not excessive), then the problem is a decrease in the compliance in the lung/chest wall unit. Common causes of this problem include pneumothorax, hemothorax, lobar atelectasis, pulmonary edema, pneumonia, acute respiratory distress syndrome (ARDS), active contraction of the chest wall or diaphragmatic muscles, abdominal distention, and intrinsic PEEP, such as occurs in patients with bronchospasm and insufficient expiratory times. When P_{peak} is increased but P_{plateau} is relatively normal, the primary problem is an increase in airway resistance, such as occurs with bronchospasm, use of a small-caliber endotracheal tube, or kinking or obstruction of the endotracheal tube. A low P_{peak} also should trigger an alarm, as it suggests a discontinuity in the airway circuit involving the patient and the ventilator. These scenarios are outlined in Table 13-4.

Ventilator-induced lung injury (VILI) is now an established clinical entity of great relevance to the care of critically ill patients. Excessive airway pressure and tidal volume adversely affect pulmonary and possibly systemic responses to critical illness. Subjecting the lung parenchyma to excessive pressure, known as barotrauma, can result in parenchymal lung injury, diffuse alveolar damage similar to ARDS, and pneumothorax, and can impair venous return and therefore limit cardiac output. Lung-protective ventilation strategies have been developed to prevent the development of VILI and improve patient outcomes.

Table 13-4

Scenarios associated with different combinations of P_{peak} and P_{plateau} in ventilated patients

CONDITION	P_{peak}	P_{plateau}
Decreased compliance of the system (ARDS, abdominal distention, intrinsic PEEP)	↑↑	↑↑
Increase in airway resistance (bronchospasm, endotracheal tube obstruction/kinking, or small-caliber endotracheal tube)	↑↑	normal
Disconnected circuit	↓↓	↓↓

In a large, multicenter, randomized trial of patients with ARDS from a variety of etiologies, limiting plateau airway pressure to less than 30 cm H₂O and tidal volume to less than 6 mL/kg of ideal body weight reduced 28-day mortality by 22% relative to a ventilator strategy that used a tidal volume of 12 mL/kg.⁵⁶ For this reason, monitoring of plateau pressure and using a low tidal volume strategy in patients with ARDS is now the standard of care. Recent data also suggest that a lung-protective ventilation strategy is associated with improved clinical outcomes in ventilated patients without ARDS.⁵⁷ Importantly, this strategy also has been shown to have benefit for high-risk patients undergoing general anesthesia for surgical procedures, leading to a reduced overall rate of pulmonary complications in the perioperative period as well as a reduced length of stay following surgery.⁵⁸

Pulse Oximetry

The pulse oximeter is a microprocessor-based device that integrates oximetry and plethysmography to provide continuous noninvasive monitoring of the oxygen saturation of arterial blood (Sa_{O_2}). It is considered one of the most important and useful technologic advances in patient monitoring. Continuous, noninvasive monitoring of arterial oxygen saturation is possible using light-emitting diodes and sensors placed on the skin. Pulse oximetry employs two wavelengths of light (i.e., 660 nm and 940 nm) to analyze the pulsatile component of blood flow between the light source and sensor. Because oxyhemoglobin and deoxyhemoglobin have different absorption spectra, differential absorption of light at these two wavelengths can be used to calculate the fraction of oxygen saturation of hemoglobin. Under normal circumstances, the contributions of carboxyhemoglobin and methemoglobin are minimal. However, if carboxyhemoglobin levels are elevated, the pulse oximeter will incorrectly interpret carboxyhemoglobin as oxyhemoglobin and the arterial saturation displayed will be falsely elevated. When the concentration of methemoglobin is markedly increased, the Sa_{O_2} will be displayed as 85%, regardless of the true arterial saturation.⁵⁹ The accuracy of pulse oximetry begins to decline at Sa_{O_2} values less than 92% and tends to be unreliable for values less than 85%.⁶⁰

Several studies have assessed the frequency of arterial oxygen desaturation in hospitalized patients and its effect on outcome. Monitoring pulse oximetry in surgical patients is associated with a reduction in unrecognized deterioration, rescue events, and transfers to the ICU.⁶¹ Because of its clinical relevance, ease of use, noninvasive nature, and cost-effectiveness, pulse oximetry has become a routine monitoring strategy in patients with respiratory disease, intubated patients, and those undergoing surgical intervention under sedation or general anesthesia. Pulse oximetry is especially useful in the titration of F_{iO_2} and PEEP for patients receiving mechanical ventilation, and during weaning from mechanical ventilation. The widespread use of pulse oximetry has decreased the need for arterial blood gas determinations in critically ill patients.

Pulse CO-Oximetry

While simple pulse oximeters such as those described previously are helpful for determination of the Sa_{O_2} , extensions of the technology may prove valuable for determination of total hemoglobin concentration as well. Through the use of multiple additional wavelengths of light, clinicians can leverage the different spectrophotometric properties of the multiple different

oxidative states of hemoglobin to get a complete readout of the total hemoglobin present in a given volume, leading to a noninvasive measurement of Hgb. These devices are referred to as pulse CO-Oximeters, as opposed to pulse oximeters, to differentiate that they are capable of measuring other hemoglobin moieties. Currently, there are two such devices that are commercially available for clinical use.

Theoretically, the capacity to noninvasively measure Hgb concentration in real time would offer significant clinical benefit. These include obviating the need for serial blood draws, the early detection of potential postsurgical hemorrhage, and more judicious usage of blood transfusions. In practice, there are multiple factors that currently affect the accuracy of the technique. Multiple studies have demonstrated that biases with noninvasive Hgb monitoring are inversely correlated with hemoglobin concentration in a variety of monitoring scenarios; with decreasing hemoglobin values the noninvasive approaches tend to overestimate the true Hgb.⁶²⁻⁶⁴ This poses a significant challenge for monitoring the critically ill patient, as frequently anemia is a common comorbid condition. On the other hand, if the continuous monitoring capacity afforded by these monitors can provide usable trend data, that may still provide clinical utility despite less accuracy at low hemoglobin levels. To date, there have been relatively few studies validating the trending capacity of noninvasive Hgb monitoring compared to serial blood draws, with limited agreement due to differences in analysis and study design.⁶⁵ Further studies are required to evaluate the clinical utility of this potentially useful technology.

Capnometry

Capnometry is the measurement of carbon dioxide in the airway throughout the respiratory cycle. Capnometry is most commonly measured by infrared light absorption. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 μm. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PETCO₂) is used as a surrogate for the partial pressure of CO₂ in arterial blood (PaCO₂) during mechanical ventilation. In healthy subjects, PETCO₂ is about 1 to 5 mmHg less than PaCO₂.⁶⁶ Thus, PETCO₂ can be used to estimate PaCO₂ without the need for blood gas determination. However, changes in PETCO₂ may not correlate with changes in PaCO₂ during a number of pathologic conditions.

Capnography allows the confirmation of endotracheal intubation and continuous assessment of ventilation, integrity of the airway, operation of the ventilator, and cardiopulmonary function. Capnometers are configured with either an inline sensor or a sidestream sensor. The sidestream systems are lighter and easy to use, but the thin tubing that samples the gas from the ventilator circuit can become clogged with secretions or condensed water, preventing accurate measurements. The inline devices are bulky and heavier but are less likely to become clogged. Continuous monitoring with capnography has become routine during surgery under general anesthesia and for some intensive care patients. A number of situations can be promptly detected with continuous capnography. A sudden reduction in PETCO₂ suggests either obstruction of the sampling tubing with water or secretions, or a catastrophic event such as loss of the airway, airway disconnection or obstruction,

ventilator malfunction, or a marked decrease in Q_T. If the airway is connected and patent and the ventilator is functioning properly, then a sudden decrease in PETCO₂ should prompt efforts to rule out cardiac arrest, massive pulmonary embolism, or cardiogenic shock. PETCO₂ can be persistently low during hyperventilation or with an increase in dead space such as occurs with pulmonary embolization (even in the absence of a change in Q_T). Causes of an increase in PETCO₂ include reduced minute ventilation or increased metabolic rate.

RENAL MONITORING

Urine Output

Bladder catheterization with an indwelling catheter allows the monitoring of urine output, usually recorded hourly by the nursing staff. With a patent Foley catheter, urine output is a gross indicator of renal perfusion. The generally accepted normal urine output is 0.5 mL/kg per hour for adults and 1 to 2 mL/kg per hour for neonates and infants. Oliguria may reflect inadequate renal artery perfusion due to hypotension, hypovolemia, or low Q_T. Low urine flow also can be a sign of intrinsic renal dysfunction. It is important to recognize that normal urine output does not exclude the possibility of impending renal failure.

Bladder Pressure

The triad of oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure is known as abdominal compartment syndrome (ACS). This syndrome, first described in patients after repair of ruptured abdominal aortic aneurysm, is associated with interstitial edema of the abdominal organs, resulting in elevated intra-abdominal pressure (IAP). When IAP exceeds venous or capillary pressures, perfusion of the kidneys and other intra-abdominal viscera is impaired. Oliguria is a cardinal sign. While the diagnosis of ACS is a clinical one, measuring IAP is useful to confirm the diagnosis. Ideally, a catheter inserted into the peritoneal cavity could measure IAP to substantiate the diagnosis. In practice, transurethral bladder pressure measurement reflects IAP and is most often used to confirm the presence of ACS. After instilling 50 to 100 mL of sterile saline into the bladder via a Foley catheter, the tubing is connected to a transducing system to measure bladder pressure in the supine position at end-expiration.

Intra-abdominal hypertension is defined as an IAP ≥12 mmHg recorded on three standard measurements conducted 4 to 6 hours apart and is separated into several grades. The diagnosis of ACS is the presence of an IAP ≥20 mmHg recorded by three measurements 1 to 6 hours apart, along with new onset of organ dysfunction (Table 13-5).⁶⁷⁻⁶⁹ Less commonly, gastric or inferior vena cava pressures can be monitored with appropriate catheters to detect elevated intra-abdominal pressures.

NEUROLOGIC MONITORING

Intracranial Pressure

Because the brain is rigidly confined within the bony skull, cerebral edema or mass lesions increase intracranial pressure (ICP). Monitoring of ICP is currently recommended in patients with severe traumatic brain injury (TBI), defined as a Glasgow Coma Scale (GCS) score less than or equal to 8 with an abnormal computed tomography (CT) scan, and in patients with severe TBI and a normal CT scan if two or more of the following are present: age >40 years, unilateral or bilateral motor posturing,

Table 13-5

Bladder pressure measurements in the assessment of intra-abdominal hypertension or abdominal compartment syndrome

RECORDED PRESSURE (mmHg)	GRADE OF IAH OR ACS
5–7	Normal
In the absence of organ dysfunction:	
12–15	Grade I IAH
16–20	Grade II IAH
21–25	Grade III IAH
>25	Grade IV IAH
In the presence of new onset organ dysfunction:	
>20	ACS

Data from Kirkpatrick AW, Roberts DJ, De Waele J, et al. Intra-abdominal hypertension and the abdominal compartment syndrome: updated consensus definitions and clinical practice guidelines from the World Society of the Abdominal Compartment Syndrome, *Intensive Care Med.* 2013 Jul;39(7):1190-1206.

or systolic blood pressure <90 mmHg.⁷⁰ ICP monitoring also is indicated in patients with acute subarachnoid hemorrhage with coma or neurologic deterioration, intracranial hemorrhage with intraventricular blood, ischemic middle cerebral artery stroke, fulminant hepatic failure with coma and cerebral edema on CT scan, and global cerebral ischemia or anoxia with cerebral edema on CT scan. The goal of ICP monitoring is to ensure that cerebral perfusion pressure (CPP) is adequate to support perfusion of the brain. CPP is equal to the difference between MAP and ICP: $CPP = MAP - ICP$.

One type of ICP measuring device, the ventriculostomy catheter, consists of a fluid-filled catheter inserted into a cerebral ventricle and connected to an external pressure transducer. This device permits measurement of ICP but also allows drainage of cerebrospinal fluid (CSF) as a means to lower ICP and sample CSF for laboratory studies. Other devices locate the pressure transducer within the central nervous system and are used only to monitor ICP. These devices can be placed in the intraventricular, parenchymal, subdural, or epidural spaces. Ventriculostomy catheters are the accepted standard for monitoring ICP in patients with TBI due to their accuracy, ability to drain CSF, and low complication rate. The associated complications include infection (5%), hemorrhage (1.1%), catheter malfunction or obstruction (6.3–10.5%), and malposition with injury to cerebral tissue.⁷¹

The purpose of ICP monitoring is to detect and treat abnormal elevations of ICP that may be detrimental to cerebral perfusion and function. In TBI patients, ICP greater than 20 mmHg is associated with unfavorable outcomes.⁷² However, few studies have shown that treatment of elevated ICP improves clinical outcomes in human trauma patients. In a randomized, controlled, double-blind trial, Eisenberg and colleagues demonstrated that maintaining ICP less than 25 mmHg in patients without craniectomy and less than 15 mmHg in patients with craniectomy is associated with improved outcome.⁷³ In patients with low CPP, therapeutic strategies to correct CPP can be directed at increasing MAP or decreasing ICP. While it has been recommended that CPP be maintained between 50 and 70 mmHg, the evidence to support this recommendation are

not overly compelling.⁷⁴ Furthermore, a retrospective cohort study of patients with severe TBI found that ICP/ CPP-targeted neurointensive care was associated with prolonged mechanical ventilation and increased therapeutic interventions, without evidence for improved outcome in patients who survive beyond 24 hours.⁷⁵

Electroencephalogram and Evoked Potentials

Electroencephalography offers the capacity to monitor global neurologic electrical activity, while evoked potential monitoring can assess pathways not detected by the conventional EEG. Continuous EEG (CEEG) monitoring in the intensive care unit permits ongoing evaluation of cerebral cortical activity. It is especially useful in obtunded and comatose patients. CEEG also is useful for monitoring of therapy for status epilepticus and detecting early changes associated with cerebral ischemia. CEEG can be used to adjust the level of sedation, especially if high-dose barbiturate therapy is being used to manage elevated ICP. Somatosensory and brain stem evoked potentials are less affected by the administration of sedatives than is the EEG. Evoked potentials are useful for localizing brain stem lesions or proving the absence of such structural lesions in cases of metabolic or toxic coma. They also can provide prognostic data in posttraumatic coma.

An advance in EEG monitoring is the use of the bispectral index (BIS) to titrate the level of sedative medications. While sedative drugs are usually titrated to the clinical neurologic examination, the BIS device has been used in the operating room to continuously monitor the depth of anesthesia. The BIS is an empiric measurement statistically derived from a database of over 5000 EEGs.⁷⁶ The BIS is derived from bifrontal EEG recordings and analyzed for burst suppression ratio, relative alpha to beta ratio, and bicoherence. Using a multivariate regression model, a linear numeric index (BIS) is calculated, ranging from 0 (isoelectric EEG) to 100 (fully awake). Its use has been associated with lower consumption of anesthetics during surgery and earlier awakening and faster recovery from anesthesia.⁷⁷ The BIS also has been validated as a useful approach for monitoring the level of sedation for ICU patients, using the revised Sedation-Agitation Scale as a gold standard.⁷⁸

Transcranial Doppler Ultrasonography

This modality provides a noninvasive method for evaluating cerebral hemodynamics. Transcranial Doppler (TCD) measurements of middle and anterior cerebral artery blood flow velocity are useful for the diagnosis of cerebral vasospasm after subarachnoid hemorrhage. Qureshi and associates demonstrated that an increase in the middle cerebral artery mean flow velocity as assessed by TCD is an independent predictor of symptomatic vasospasm in a prospective study of patients with aneurysmal subarachnoid hemorrhage.⁷⁹ In addition, while some have proposed using TCD to estimate ICP, studies have shown that TCD is not a reliable method for estimating ICP and CPP and currently cannot be endorsed for this purpose.⁸⁰ TCD also is useful to confirm the clinical examination for determining brain death in patients with confounding factors such as the presence of CNS depressants or metabolic encephalopathy.

Jugular Venous Oximetry

When the arterial oxygen content, hemoglobin concentration, and the oxyhemoglobin dissociation curve are constant, changes in jugular venous oxygen saturation (S_{jO_2}) reflect changes in the difference between cerebral oxygen delivery and demand.

Generally, a decrease in SjO_2 reflects cerebral hypoperfusion, whereas an increase in SjO_2 indicates the presence of hyperemia. SjO_2 monitoring cannot detect decreases in regional cerebral blood flow if overall perfusion is normal or above normal. This technique requires the placement of a catheter in the jugular bulb, usually via the internal jugular vein. Catheters that permit intermittent aspiration of jugular venous blood for analysis or continuous oximetry catheters are available.

Low SjO_2 is associated with poor outcomes after TBI.⁸¹ Nevertheless, the value of monitoring SjO_2 remains unproven. If it is employed, it should not be the sole monitoring technique, but rather should be used in conjunction with ICP and CPP monitoring. By monitoring ICP, CPP, and SjO_2 , early intervention with volume, vasopressors, and hyperventilation has been shown to prevent ischemic events in patients with TBI.⁸²

Transcranial Near-Infrared Spectroscopy

Transcranial near-infrared spectroscopy (NIRS) is a noninvasive continuous monitoring method to determine cerebral oxygenation. It employs technology similar to that of pulse oximetry to determine the concentrations of oxy- and deoxyhemoglobin with near-infrared light and sensors and takes advantage of the relative transparency of the skull to light in the near-infrared region of the spectrum. Continuous monitoring of cerebral perfusion via transcranial NIRS may provide a method to detect early cerebral ischemia in patients with traumatic brain injury.⁸³ Nevertheless, this form of monitoring remains largely a research tool at the present time.

Recently, some authors have reported its use as a potential triage tool for prehospital care in the management of TBI, as NIRS allows for rapid screening for intracranial hematoma. Two small EMS studies demonstrated that handheld NIRS devices may be feasible adjunct tools in this setting, particularly when CT scanners may not be readily available.^{84,85}

Brain Tissue Oxygen Tension

While the standard of care for patients with severe TBI includes ICP and CPP monitoring, this strategy does not always prevent secondary brain injury. Growing evidence suggests that monitoring local brain tissue oxygen tension ($PbtO_2$) may be a useful adjunct to ICP monitoring in these patients. Normal values for $PbtO_2$ are 20 to 40 mmHg, and critical levels are 8 to 10 mmHg. A recent clinical study sought to determine whether the addition of a $PbtO_2$ monitor to guide therapy in severe traumatic brain injury was associated with improved patient outcomes.⁸⁶ Twenty-eight patients with severe traumatic brain injury (GCS score ≤ 8) were enrolled in an observational study at a level I trauma center. These patients received invasive ICP and $PbtO_2$ monitoring and were compared with 25 historical controls matched for age, injuries, and admission GCS score that had undergone ICP monitoring alone. Goals of therapy in both groups included maintaining an ICP < 20 mmHg and a CPP > 60 mmHg. Among patients with $PbtO_2$ monitoring, therapy also was directed at maintaining $PbtO_2 > 25$ mmHg. The groups had similar mean daily ICP and CPP levels. The mortality rate in the historical controls treated with standard ICP and CPP management was 44%. Mortality was significantly lower in the patients who had therapy guided by $PbtO_2$ monitoring in addition to ICP and CPP (25%; $P < .05$). The benefits of $PbtO_2$ monitoring may include the early detection of brain tissue ischemia despite normal ICP and CPP. In addition, $PbtO_2$ -guided management may reduce potential adverse effects associated with therapies to maintain ICP and CPP.

CONCLUSIONS

Modern intensive care is predicated by the need and ability to continuously monitor a wide range of physiologic parameters. This capability has dramatically improved the care of critically ill patients and advanced the development of the specialty of critical care medicine. In some cases, the technological ability to measure such variables has surpassed our understanding of the significance or the knowledge of the appropriate intervention to ameliorate such pathophysiologic changes. In addition, the development of less invasive monitoring methods has been promoted by the recognition of complications associated with invasive monitoring devices. The future portends the continued development of noninvasive monitoring devices along with their application in an evidenced-based strategy to guide rational therapy.

INTRODUCTION

Minimally invasive surgery describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure. Some believe that the term *minimal access surgery* more accurately describes the small incisions generally necessary to gain access to surgical sites in high-tech surgery, but John Wickham's term *minimally invasive surgery* (MIS) is widely used because it describes the paradox of postmodern high-tech surgery—small holes, big operations.

Robotic surgery today is practiced using a single platform (Intuitive, Inc, Sunnyvale, CA) and should better be termed *computer-enhanced surgery* because the term *robotics* assumes autonomous action that is not a feature of the da Vinci robotic system. Instead, the da Vinci robot couples an ergonomic workstation that features stereoptic video imaging and intuitive micromanipulators (surgeon side) with a set of arms delivering specialized laparoscopic instruments enhanced with more degrees of freedom than are allowed by laparoscopic surgery alone (patient side). A computer between the surgeon side and patient side removes surgical tremor and scales motion to allow

precise microsurgery, which is helpful for microdissection and difficult anastomoses.

Single-incision laparoscopic surgery (SILS), also called *laparoendoscopic single-site surgery* (LESS), is a recent addition to the armamentarium of the minimally invasive surgeon. As public awareness has grown, so too has its spread outside of larger institutions. SILS challenges the well-established paradigm of standard laparoscopic surgery by placing multiple trocars within the fascia at the umbilicus or through a single multichannel trocar at the umbilicus. The manipulation of tightly spaced instruments across the fulcrum of the abdominal wall requires that the surgeon either operate in a crossed hands fashion or use specialized curved instruments to avoid clashing outside the body while working intra-abdominally. The primary advantage of SILS is the reduction to one surgical scar. Greater efficacy, safety, and cost savings have yet to be fully elucidated in the increasing number of procedures that are being attempted in this manner. The advent of a robotic SILS platform now enables the computer reassignment of the surgeon's hands, thus eliminating the difficult ergonomic challenges making the technique far more accessible.

Natural orifice transluminal endoscopic surgery (NOTES) is an extension of interventional endoscopy. Using the mouth, anus, vagina, and urethra (natural orifices), flexible endoscopes are passed through the wall of the esophagus, stomach, colon,

Key Points

- 1▶ Minimally invasive surgery describes a philosophical approach to surgery in which access trauma is minimized without compromising the quality of the surgical procedure.
- 2▶ The carbon dioxide pneumoperitoneum used for laparoscopy induces some unique pathophysiologic consequences.
- 3▶ Robotic surgery has been most valuable in the performance of minimally invasive urologic, gynecologic, colorectal, and complex abdominal wall reconstruction procedures.
- 4▶ Natural orifice transluminal endoscopic surgery represents an opportunity to perform truly scar-free surgery.
- 5▶ Single-incision laparoscopic surgery reduces the amount of abdominal wall trauma but presents unique challenges to the traditional tenets of laparoscopic ergonomics.
- 6▶ Laparoscopy during pregnancy is best performed in the second trimester and is safe if appropriate monitoring is performed.
- 7▶ Laparoscopic surgery for cancer is also appropriate if good tissue handling techniques are maintained.
- 8▶ Training for laparoscopy requires practice outside of the operating room in a simulation laboratory.

bladder, or vagina entering the mediastinum, the pleural space, or the peritoneal cavity. The advantage of this method of minimal access is principally the elimination of the scar associated with laparoscopy or thoracoscopy. Other advantages have yet to be elucidated, including pain reduction, need for hospitalization, and cost savings.

HISTORICAL BACKGROUND

Although the term *minimally invasive surgery* is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety of MIS, laparoscopy, is in fact the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901.¹ Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s, Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss.¹ Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiber optics and allowing the rapid development of flexible endoscopes.^{2,3} In the 1970s, the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics.⁴ By the mid-1970s, rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 20 years was a result of the development of compact, high-resolution, charge-coupled devices (CCDs) that could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiber-optic cables, and high-definition video monitors, the videoendoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

Flexible endoscopic imaging started in the 1960s with the first bundling of many quartz fibers into bundles, one for illumination and one for imaging. The earliest upper endoscopes revolutionized the diagnosis and treatment of gastroesophageal reflux and peptic ulcer disease and made possible early detection of upper and lower gastrointestinal (GI) cancer at a stage that could be cured. The first endoscopic surgical procedure was the colonoscopic polypectomy, developed by Shinya and Wolfe, two surgeons from New York City. The percutaneous endoscopic gastrostomy (PEG) invented by Gauderer and Ponsky may have been the first NOTES procedure, reported

in 1981.⁵ Endoscopic pancreatic pseudocyst drainage is thought to be the next NOTES procedure developed; however, there was little energy and money put into the development of NOTES until a number of gastroenterologists claimed the ability to remove the gallbladder with a flexible endoscope, using a transgastric technique. With this pronouncement, the surgical community took notice and seized the momentum for NOTES research and development. Today most intra-abdominal NOTES procedures remain within the realm of research or incorporate a hybrid laparoscopic technique outside of highly specialized centers. Clinically the transvaginal approach has been studied the most extensively. Evaluation of 551 female patients from the German NOTES registry has shown conversion and complication rates similar to conventional laparoscopic surgery for cholecystectomy and appendectomy procedures.⁶ Endoscopic mucosal resection (EMR) of early-stage esophageal and gastric lesions has revolutionized the management of these malignancies. The peroral endoscopic myotomy (POEM) procedure for achalasia is showing clinical efficacy and gaining popularity.

As the race to minimize the size and increase the functionality of laparoscopic instruments progressed, the notion of using fewer access points to accomplish the same operations resulted in the development of *single-incision laparoscopic surgery* (SILS), synonymously termed *laparoendoscopic single-site surgery* (LESS). Viewed as a progression of laparoscopic surgery, SILS has recently garnered greater enthusiasm over its transvisceral NOTES counterpart.⁷ Currently the single-incision technique is used regularly across a wide variety of surgical areas including general, urologic, gynecologic, colorectal, and bariatric surgery.⁸ Although optical imaging produced the majority of MIS procedures, other (traditionally radiologic) imaging technologies allowed the development of innovative procedures in the 1970s. Fluoroscopic imaging allowed the adoption of percutaneous vascular procedures, the most revolutionary of which was balloon angioplasty. Balloon-based procedures spread into all fields of medicine used to open up clogged lumens with minimal access. Stents were then developed that were used in many disciplines to keep the newly ballooned segment open. The culmination of fluoroscopic balloon and stent proficiency is exemplified by the transvenous intrahepatic portosystemic shunt and by the aortic stent graft, which has nearly replaced open elective abdominal aortic aneurysm repair.

MIS procedures using ultrasound imaging have been limited to fairly crude exercises, such as fragmenting kidney stones and freezing liver tumors, because of the relatively low

resolution of ultrasound devices. Newer, high-resolution ultrasound methods with high-frequency crystals may act as a guide while performing minimally invasive resections of individual layers of the intestinal wall.

Axial imaging, such as computed tomography (CT), has allowed the development of an area of MIS that often is not recognized because it requires only a CT scanner and a long needle. CT-guided drainage of abdominal fluid collections and percutaneous biopsy of abnormal tissues are minimally invasive means of performing procedures that previously required a celiotomy. CT-guided percutaneous radiofrequency (RF) ablation has emerged as a useful treatment for primary and metastatic liver tumors. This procedure also is performed laparoscopically under ultrasound guidance.⁹

A powerful, noninvasive method of imaging that will allow the development of the least invasive—and potentially noninvasive—surgery is magnetic resonance imaging (MRI). MRI is an extremely valuable diagnostic tool, but it is only slowly coming to be of therapeutic value. One obstacle to the use of MRI for MIS is that image production and refreshment of the image as a procedure progresses are slow. Another is that all instrumentation must be nonmetallic when working with the powerful magnets of an MRI scanner. Moreover, MRI magnets are bulky and limit the surgeon's access to the patient. Open magnets have been developed that allow the surgeon to stand between two large MRI coils, obtaining access to the portion of the patient being scanned. The advantage of MRI, in addition to the superb images produced, is that there is no radiation exposure to patient or surgeon. Some neurosurgeons are accumulating experience using MRI to perform frameless stereotactic surgery.

Robotic surgery has been dreamed about for some time, and many science fiction–like devices have been developed over the years to provide mechanical assistance for the surgeon. The first computer-assisted robot was designed to accurately drill femoral shaft bone for wobble-free placement of hip prostheses. Although the concept was appealing, the robot proved no better than a skilled orthopedic surgeon and was a good deal slower. Following this, the first and only two commercially successful robots for laparoscopic surgery were developed in California. Computer Motion, founded by Yulun Wang in Santa Barbara, used National Science Foundation funds to create a mechanical arm, the Aesop robot, which held and moved the laparoscope with voice, foot, or hand control. In Northern California, a master-slave system first developed for surgery on the multinational space station by Philip Green was purchased by Fred Moll and Lonnie Smith, and then reengineered with the surgeon in mind to create a remarkably intuitive computer-enhanced surgical platform. The company, Intuitive Surgical, was aptly named, and their primary product, the da Vinci robot, is currently the only major robotic platform on the market, although competitors are rapidly emerging in the horizon. Although eschewed by many experienced laparoscopists, the da Vinci achieved a toehold among many skilled surgeons who found that the robot could facilitate MIS procedures that were difficult with standard laparoscopic procedures. The latest iteration of the da Vinci Xi platform released in 2014 features high-definition, three-dimensional vision and a dual-console capability allowing greater visualization, assistance, and instruction capabilities. Additionally, the new overhead boom design facilitates anatomical access from virtually any position enabling complex multi-quadrant surgeries.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF MINIMALLY INVASIVE SURGERY

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally invasive procedures require minimal or no sedation, and there are few adverse consequences to the cardiovascular, endocrinologic, or immunologic systems. The least invasive of such procedures include stereotactic biopsy of breast lesions and flexible GI endoscopy. Minimally invasive procedures that require general anesthesia have a greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

Laparoscopy

The unique feature of laparoscopic surgery is the need to lift the abdominal wall from the abdominal organs. Two methods have been devised for achieving this.¹⁰ The first, used by most surgeons, is a pneumoperitoneum. Throughout the early 20th century, intraperitoneal visualization was achieved by inflating the abdominal cavity with air, using a sphygmomanometer bulb.¹¹ The problem with using air insufflation is that nitrogen is poorly soluble in blood and is slowly absorbed across the peritoneal surfaces. Air pneumoperitoneum was believed to be more painful than nitrous oxide (N₂O) pneumoperitoneum, but less painful than carbon dioxide (CO₂) pneumoperitoneum. Subsequently,

2► CO₂ and N₂O were used for inflating the abdomen. N₂O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO₂ or air.¹² Despite initial concerns that N₂O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity.¹³ In addition, N₂O has been shown to reduce the intraoperative end-tidal CO₂ and minute ventilation required to maintain homeostasis when compared to CO₂ pneumoperitoneum.¹³ The effect of N₂O on tumor biology and the development of port site metastasis are unknown. As such, caution should be exercised when performing laparoscopic cancer surgery with this agent. Finally, the safety of N₂O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO₂ pneumoperitoneum can be divided into two areas: (a) gas-specific effects and (b) pressure-specific effects (Fig. 14-1). CO₂ is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation,

Figure 14-1. Carbon dioxide gas insufflated into the peritoneal cavity has both local and systemic effects that cause a complex set of hemodynamic and metabolic alterations. (*Reproduced with permission from Hunter JG: Bailliere's Clinical Gastroenterology Laparoscopic Surgery. London/Philadelphia: Bailliere Tindall; 1993.*)

CO₂ creates a respiratory acidosis by the generation of carbonic acid.¹⁴ Body buffers, the largest reserve of which lies in bone, absorb CO₂ (up to 120 L) and minimize the development of hypercarbia or respiratory acidosis during brief endoscopic procedures.¹⁴ Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO₂ and its release from these buffers.

In patients with normal respiratory function, this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per minute, there may be less efficient gas exchange and increasing hypercarbia.¹⁵ Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion-induced disruption of the upper abdominal operative field. In some situations, it is advisable to evacuate the pneumoperitoneum or reduce the intra-abdominal pressure to allow time for the anesthesiologist to adjust for hypercarbia.¹⁶ Although mild respiratory acidosis probably is an insignificant problem, more severe respiratory acidosis leading to cardiac arrhythmias has been reported.¹⁷ Hypercarbia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand.^{14,17}

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and decreased cardiac output.^{14,18} This is not seen in the normovolemic patient. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and, occasionally, hypotension.¹⁹ The appropriate management of this event is desufflation of the abdomen, administration of vagolytic agents (e.g., atropine), and adequate volume replacement.²⁰

With the increased intra-abdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis.^{21,22} Many series of advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrate the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low molecular weight heparin.^{20,23} In short-duration laparoscopic procedures, such as appendectomy, hernia repair, or cholecystectomy, the risk of DVT may not be sufficient to warrant extensive DVT prophylaxis.

The increased pressure of the pneumoperitoneum is transmitted directly across the paralyzed diaphragm to the thoracic cavity, creating increased central venous pressure and increased filling pressures of the right and left sides of the heart. If the intra-abdominal pressures are kept under 20 mmHg, the cardiac output usually is well maintained.²²⁻²⁴ The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall, and also, the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery.²⁴ Pneumothoraces occurring with laparoscopic esophageal surgery may

be very significant. The pathophysiology and management are discussed at the end of this section. Increased intra-abdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein.^{25,26} The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules.²⁷ Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes such as elevated antidiuretic hormone levels decrease urine output for up to 1 hour after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status; intravenous (IV) fluid administration during an uncomplicated laparoscopic procedure should not be linked to urine output. Because insensible fluid losses through the open abdomen are eliminated with laparoscopy, the need for supplemental fluid during a laparoscopic surgical procedure should only keep up with venous pooling in the lower limbs, third-space losses into the bowel, and blood loss, which is generally less than occurs with an equivalent open operation.

The hemodynamic and metabolic consequences of pneumoperitoneum are well tolerated by healthy individuals for a prolonged period and by most individuals for at least a short period. Difficulties can occur when a patient with compromised cardiovascular function is subjected to a long laparoscopic procedure. It is during these procedures that alternative approaches should be considered or insufflation pressure reduced. Alternative gases that have been suggested for laparoscopy include the inert gases helium, neon, and argon. These gases are appealing because they cause no metabolic effects, but are poorly soluble in blood (unlike CO₂ and N₂O) and are prone to create gas emboli if the gas has direct access to the venous system.²² Gas emboli are rare but serious complications of laparoscopic surgery.^{23,28} They should be suspected if hypotension develops during insufflation. Diagnosis may be made by listening (with an esophageal stethoscope) for the characteristic “mill wheel” murmur. The treatment of gas embolism is to place the patient in a left lateral decubitus position with the head down to trap the gas in the apex of the right ventricle.²³ A rapidly placed central venous catheter then can be used to aspirate the gas out of the right ventricle.

In some situations, minimally invasive abdominal surgery can be performed without insufflation. This is possible with the assistance of an abdominal lift device that can be placed through a 10- to 12-mm trocar at the umbilicus.²⁹ These devices have the advantage of creating little physiologic derangement, but they are bulky and intrusive. The exposure and working room offered by lift devices also are inferior to those accomplished by pneumoperitoneum. Lifting the anterior abdominal wall reduces space available laterally and thereby displaces the bowel medially and anteriorly into the operative field. A pneumoperitoneum, with its well-distributed intra-abdominal pressure, provides better exposure. Abdominal lift devices also cause more postoperative pain, but they do allow the performance of MIS with standard (nonlaparoscopic) surgical instruments.

Endocrine responses to laparoscopic surgery are not always intuitive. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision.³⁰ The greatest difference

between the endocrine response of open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy.³¹

Transhiatal mobilization of the distal esophagus is commonly performed as a component of many laparoscopic upper abdominal procedures. If there is compromise of the mediastinal pleura with resultant CO₂ pneumothorax, the defect should be enlarged so as to prevent a tension pneumothorax. Even with such a strategy, tension pneumothorax may develop, as mediastinal structures may seal the hole during inspiration, allowing the chest to fill during expiration. In addition to enlargement of the hole, a thoracostomy tube (chest tube) should be placed across the breach into the abdomen with intra-abdominal pressures reduced below 8 mmHg, or a standard chest tube may be placed. When a pneumothorax occurs with laparoscopic Nissen fundoplication or Heller myotomy, it is preferable to place an 18-French red rubber catheter with multiple side holes cut out of the distal end across the defect. At the end of the procedure, the distal end of the tube is pulled out a 10-mm port site (as the port is removed), and the pneumothorax is evacuated to a primitive water seal using a bowl of sterile water or saline. During laparoscopic esophagectomy, it is preferable to leave a standard chest tube, as residual intra-abdominal fluid will tend to be siphoned through the defect postoperatively if the tube is removed at the end of the case.

Thoracoscopy

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax, it is unnecessary to use positive pressure when working in the thorax.³² The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to use standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally Invasive Surgery

Many MIS procedures create working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior extraperitoneal Retzius space.^{33,34} Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Endoscopic retroperitoneal approaches to pancreatic necrosectomy have seen some limited use.³⁵ Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions.³⁶ Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space (Fig. 14-2). These techniques produce fewer and less severe adverse physiologic consequences than does the

Figure 14-2. Balloons are used to create extra-anatomic working spaces. In this example (A through C), a balloon is introduced into the space between the posterior rectus sheath and the rectus abdominal muscle. The balloon is inflated in the preperitoneal space to create working room for extraperitoneal endoscopic hernia repair.

pneumoperitoneum, but the insufflation of carbon dioxide into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Anesthesia

Proper anesthesia management during laparoscopic surgery requires a thorough knowledge of the pathophysiology of the CO₂ pneumoperitoneum.²⁰ The laparoscopic surgeon can influence cardiovascular performance by reducing or removing the CO₂ pneumoperitoneum. Insensible fluid losses are negligible, and therefore, IV fluid administration should not exceed that necessary to maintain circulating volume. MIS procedures are often outpatient procedures, so short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) when hemostasis allows it and the liberal use of antiemetic agents, including ondansetron and steroids.

The Minimally Invasive Team

From the beginning, the tremendous success of MIS was founded on the understanding that a team approach was

Table 14-1

Laparoscopic surgical procedures

BASIC	ADVANCED	
Appendectomy	Nissen fundoplication	Lymph node dissection
Cholecystectomy	Heller myotomy	Robotics
Inguinal hernia repair	Paraesophageal hernia	Bariatric
Enteral access	Gastroectomy	Complex abdominal wall reconstruction
	Lysis of adhesions	Esophagectomy
	Bile duct exploration	Hepatectomy
	Colectomy	Pancreatectomy
	Splenectomy	Prostatectomy
	Adrenalectomy	Hysterectomy
	Nephrectomy	

necessary. The many laparoscopic procedures performed daily range from basic to advanced complexity, and require that the surgical team have an intimate understanding of the operative conduct (Table 14-1). Minimally invasive procedures require complicated and fragile equipment that demands constant maintenance. In addition, multiple intraoperative adjustments to the equipment, camera, insufflator, monitors, and patient/surgeon position are made during these procedures. As such, a coordinated team approach is mandated to ensure patient safety and excellent outcomes. More and more, flexible endoscopes are used to guide or provide quality control for laparoscopic procedures. As NOTES, SILS, and robotic surgery become more common, hybrid procedures (laparoscopy and endoscopy) and complicated robotics cases will require a nursing staff capable of maintaining flexible endoscopes and understanding the operation of sophisticated technology.

A typical MIS team may consist of a laparoscopic surgeon and an operating room (OR) nurse with an interest in laparoscopic and endoscopic surgery. Adding dedicated assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance team competency. Studies have demonstrated that having a designated laparoscopic team increases the efficiency and safety of laparoscopic surgery, which is translated into a benefit for the patient and the hospital.³⁷

Room Setup and the Minimally Invasive Suite

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally, two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography, laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also

Figure 14-3. An example of a typical minimally invasive surgery suite. All core equipment is located on easily movable consoles.

lies between the surgeon and the monitor. In pelviscopic surgery, it is best to place the video monitor at the patient's feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o'clock position (relative to the patient) while the surgeon stands on the patient's left at the 4 o'clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon so that the insufflating pressure and the patient's vital signs and end-tidal CO₂ tension can be monitored.

The development of the minimally invasive surgical suite has been a tremendous contribution to the field of laparoscopy in that it has facilitated the performance of advanced procedures and techniques (Fig. 14-3). By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such as laparoscopic ultrasound.³⁸ Although having a minimally invasive surgical suite available is very useful, it is not essential to successfully carry out advanced laparoscopic procedures.

Patient Positioning

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45° tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion to open the intercostal spaces and the distance between the iliac crest and costal margin (Fig. 14-4). Additional consideration must be made in robotic operations to position the

Figure 14-4. Proper padding and protection of pressure points is an essential consideration in laparoscopic and thoracoscopic approaches. In preparation for thoracoscopy, this patient is placed in left lateral decubitus position with the table flexed, which serves to open the intercostal spaces and increase the distance between the iliac crest and the inferior costal margin.

patient appropriately before starting. Clashing of the robotic arms with surrounding equipment or each other can occur if not positioned correctly. This is more common in predecessors of the da Vinci Xi platform. Unless an operative table with integrated table motion is available, once the robot is docked to the patient the bed cannot be moved without undocking.

When the patient's knees are to be bent for extended periods or the patient is going to be placed in a reverse Trendelenburg position for more than a few minutes, DVT prophylaxis should be used. Sequential compression devices should be placed on the lower extremities during laparoscopic procedures to increase venous return and provides inhibition of thromboplastin activation.

General Principles of Access

The most natural ports of access for MIS and NOTES are the anatomic portals of entry and exit. The nares, mouth, anus, vagina, and urethra are used to access the respiratory, GI, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest. For NOTES procedures, the vagina may serve as point of access, entering the abdomen via the posterior cul-de-sac of the pelvis. Similarly, the peritoneal cavity may be reached through the side wall of the stomach or colon.

Access to the vascular system may be accomplished under local anesthesia by cutting down and exposing the desired vessel, usually in the groin. Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different-sized access devices. This approach, known as the Seldinger technique, is most frequently used by general surgeons for placement of Hickman catheters, but it also is used to gain access to the arterial and venous system for performance of minimally invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as PEG, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures, general anesthesia and single lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access

The requirements for laparoscopy are more involved because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures.^{39,40} The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity (Fig. 14-5).

A

B

Figure 14-5. A. Tip of spring loaded (Veress) needle. B. Veress needle held at its serrated collar with a thumb and forefinger. At the umbilicus, the abdominal wall is grasped with fingers or penetrating towel clip to elevate the abdominal wall away from the underlying structures.

Figure 14-6. It is essential to be able to interpret the insufflator pressure readings and flow rates. These readings indicate proper intraperitoneal placement of the Veress needle.

With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred point of access because, in this location, the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO₂ gas usually is used, with maximal pressures in the range of 14 to 15 mmHg. During the process of insufflation, it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip (Fig. 14-6). Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N₂O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mmHg is reached.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. This can be performed through a radially dilating sheath placed over the Veress needle or an optical viewing trocar. In the latter technique, a camera is placed inside of a clear pyramidal trocar. Direct puncture entry is observed as the trocar is passed through the abdominal wall. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. An optical viewing trocar can be used without prior insufflation; however, proper recognition of the abdominal wall layers is critical to avoid entry into the mesentery or underlying structures. In all direct puncture entry the trocar must be pointed away from the sacral promontory and the great vessels.⁴¹ Patient position should be surveyed before trocar placement to ensure a proper trajectory.

Occasionally, the direct peritoneal access (Hasson) technique is advisable.⁴² With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with curved Mayo scissors, a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity (Fig. 14-7). Rapid insufflation can make up for some of the time lost with

Figure 14-7. The open laparoscopy technique involves identification and incision of the peritoneum, followed by the placement of a specialized trocar with a conical sleeve to maintain a gas seal. Specialized wings on the trocar are attached to sutures placed through the fascia to prevent loss of the gas seal.

the initial dissection. This technique is preferable for the abdomen of patients who have undergone previous operations in which small bowel may be adherent to the undersurface of the abdominal wound. The close adherence of bowel to the peritoneum in the previously operated abdomen does not eliminate the possibility of intestinal injury but should make great vessel injury extremely unlikely. Because of the difficulties in visualizing the abdominal region immediately adjacent to the primary trocar, it is recommended that the telescope be passed through a secondary trocar to inspect the site of initial abdominal access.⁴⁰ Secondary punctures are made with 5- and 10-mm trocars. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry.^{41,42} At the completion of the operation, all trocars are removed under direct vision, and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3 to 5 minutes. When this is not successful, a full-thickness abdominal wall suture has been used successfully to tamponade trocar site bleeding.

It is generally agreed that 5-mm trocars need no site suturing. Ten-millimeter trocars placed off the midline, through a radially dilating sheath or above the transverse mesocolon do not typically require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder or other organ, it should be repaired at the fascial level with interrupted sutures. The port site may be closed with suture delivery systems similar to crochet needles enabling mass closure of the abdominal wall. This is especially helpful in obese patients where direct fascial closure may be challenging, through a small skin incision. Failure to close lower abdominal trocar sites that are 10 mm in diameter or larger can lead to an incarcerated hernia.

Access for Subcutaneous and Extraperitoneal Surgery

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection.^{43,44} The

Figure 14-8. With two small incisions, virtually the entire saphenous vein can be harvested for bypass grafting.

initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated, and a Hasson trocar is placed. An insufflation pressure of 10 mmHg usually is adequate to keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema. Higher gas pressures force CO₂ into the soft tissues and may contribute to hypercarbia. Extraperitoneal endosurgery provides less working space than laparoscopy but eliminates the possibility of intestinal injury, intestinal adhesion, herniation at the trocar sites, and ileus. These issues are important for laparoscopic hernia repair because extraperitoneal approaches prevent the small bowel from sticking to the prosthetic mesh.³⁴

Subcutaneous surgery has been most widely used in cardiac, vascular, and plastic surgery.³⁶ In cardiac surgery, subcutaneous access has been used for saphenous vein harvesting, and in vascular surgery for ligation of subfascial perforating veins (Linton procedure). With minimally invasive techniques, the entire saphenous vein above the knee may be harvested through a single incision (Fig. 14-8).^{45,46} Once the saphenous vein is located, a long retractor that holds a 5-mm laparoscope allows the coaxial dissection of the vein and coagulation or clipping of

each side branch. A small incision above the knee also can be used to ligate perforating veins in the lower leg.

Subcutaneous access also is used for plastic surgery procedures.⁴⁶ Minimally invasive approaches are especially well suited to cosmetic surgery, in which attempts are made to hide the incision. It is easier to hide several 5-mm incisions than one long incision. The technique of blunt dissection along fascial planes combined with lighted retractors and endoscope-holding retractors is most successful for extensive subcutaneous surgery. Some prefer gas insufflation of these soft tissue planes. The primary disadvantage of soft tissue insufflation is that subcutaneous emphysema can be created.

Hand-Assisted Laparoscopic Access

Hand-assisted laparoscopic surgery is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach commonly is used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, hand-assisted laparoscopic surgery is used to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures.⁴⁷ This technology uses an entryway for the hand that preserves the pneumoperitoneum and enables laparoscopic visualization in combination with the use of minimally invasive instruments (Fig. 14-9). Formal investigation of this modality has been limited primarily to case reports and small series and has focused primarily on solid organ and colon surgery.

Intraperitoneal, intrathoracic, and retroperitoneal access for robotic surgery adheres to the principles of laparoscopic and thoracoscopic access; however, the port size for the primary puncture is 12 mm to allow placement of the stereo laparoscope. Remaining trocars are 8 mm.

Natural Orifice Transluminal Endoscopic Surgery Access

Multiple studies have shown safety in the performance of NOTES procedures. Transvaginal, transvesicle, transanal, transcolonic, transgastric, and transoral approaches have all been attempted with varying success. The ease of decontamination, entry, and closure of these structures create variable challenges. The transvaginal approach for resection of the uterus has been employed for many years by gynecologists and has been modified by laparoscopists with great success. Extraction of the gallbladder, kidney, bladder, large bowel, and stomach can be

Figure 14-9. This is an example of hand-assisted laparoscopic surgery during left colectomy. The surgeon uses a hand to provide retraction and counter tension during mobilization of the colon from its retroperitoneal attachments, as well as during division of the mesocolon. This technique is particularly useful in the region of the transverse colon.

Figure 14-10. Submucosal tunnel technique for transesophageal mediastinoscopy. (Reproduced with permission from Khashab MA, Kalloo AN. NOTES: current status and new horizons, *Gastroenterology*. 2012 Apr;142(4):704-710.e1.)

performed via the vagina. The esophagus can be traversed to enter the mediastinum. Leaving the orifice or organ of entry with an endoscope requires the use of an endoscopic needle knife followed by submucosal tunneling or direct puncture and balloon dilation (Fig. 14-10). Closure has been performed using endoscopic clips or sutures with advanced endoscopic platforms.

Single-Incision Laparoscopic Surgery Access

There is no standardized approach for SILS, and access techniques vary by surgeon preference. Traditionally, a single skin incision is made directly through the umbilical scar ranging from 1 to 3 cm. Through this single incision, multiple low-profile trocars can be placed separately into the fascia to allow insufflation, camera, and working instruments. The advantage of this technique is that conventional laparoscopic tools can be employed. The disadvantage becomes apparent when an extraction site is needed. A variety of specialized multilumen trocars are on the market that can be placed through the umbilical ring⁴⁸ (Fig. 14-11A,B). The advantages of these devices include faster access, improved safety, minimization of air leaks, and platform-derived instrument triangulation. The major disadvantage is cost.

Port Placement

Trocars for the surgeon's left and right hand should be placed at least 10 cm apart. For most operations, it is possible to orient

the telescope between these two trocars and slightly back from them. The ideal trocar orientation creates an equilateral triangle between the surgeon's right hand, left hand, and the telescope, with 10 to 15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond (Fig. 14-12). The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or mechanical camera holder) reach between the surgeon's hands to guide the telescope. SILS is challenging for even the experienced laparoscopist because it violates most of the aforementioned ergonomic principles. Having only a single point of entry into the abdominal cavity creates an inherently crowded port and hand position. The inability to space trocars severely limits the ability to triangulate the left- and right-hand instruments. As a result, the surgeon must often work in a crossed hands fashion (Fig. 14-13). Additionally, the axis of the camera view is often in line with the working instruments, making visualization difficult without a deflectable tip laparoscope.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90° at the elbow.⁴⁹ It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field.^{50,51}

Figure 14-11. A. Specialized multilumen trocars can facilitate instrument placement. B. For single-incision laparoscopic surgery, multiple fascial punctures can be performed via a single skin incision. Imaging Systems

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a charge-coupled device (CCD), which is an array of photosensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a color image.⁵²

With videoendoscopy, the CCD chip is placed on the internal end of a long, flexible endoscope. With older flexible endoscopes, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard GI endoscopes have the CCD chip at the distal end, but small, delicate choledochoscopes and nephroscopes are equipped with fiber-optic bundles.⁵³ Distally mounted CCD chips have been developed for laparoscopy but remain very expensive and therefore have not become as widely used.

Video cameras come in two basic designs. Nearly all laparoscopic cameras contain a red, green, and blue input, and are identical to the color cameras used for television production.⁵²

An additional feature of many video cameras is digital enhancement. Digital enhancement detects edges, areas where there are drastic color or light changes between two adjacent pixels.⁵⁴ By enhancing this difference, the image appears sharper and surgical resolution is improved. New laparoscopic cameras contain a high-definition (HD) chip, which increases the lines of resolution from 480 to 1080 lines. To enjoy the benefit of the clarity of HD video imaging, HD monitors also are necessary.

Priorities in a video imaging system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Illumination and resolution are as dependent on the telescope, light source, and light cable as on the video camera used. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. Longer telescopes are available for obese patients and for reaching the mediastinum and deep in the pelvis from a periumbilical entry site. The standard

Figure 14-12. The diamond configuration created by placing the telescope between the left and the right hand, recessed from the target by about 15 cm. The distance between the left and the right hand is also ideally 10 to 15 cm. In this “baseball diamond” configuration, the surgical target occupies the second base position.

Figure 14-13. The single point of abdominal entry for trocars often requires that the surgeon work in a crossed hands fashion. (Reproduced with permission from The Johns Hopkins University School of Medicine, Baltimore, MD; 2014. Illustration by Corinne Sandone.)

Figure 14-14. The laparoscope tips come in a variety of angled configurations. All laparoscopes have a 70° field of view. A 30°-angled scope enables the surgeon to view this field at a 30° angle to the long axis of the scope.

telescope contains a series of quartz optical rods and focusing lenses.⁵⁵ Telescopes vary in size from 2 to 12 mm in diameter. Because light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled. Little illumination is needed in highly reflective, small spaces such as the knee, and a very small telescope will suffice. When working in the abdominal cavity, especially if blood is present, the full illumination of a 10-mm telescope usually is necessary.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view (0°), and the angled end provides an oblique view (30° or 45°).⁵² Angled telescopes allow greater flexibility in viewing a wider operative field through a single trocar site (Fig. 14-14A); rotating an angled telescope changes

the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication. Flexible tip laparoscopes offer even greater optical freedom.

Light is delivered to the endoscope through a fiber-optic light cable. These light cables are highly inefficient, losing >90% of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for laparoscopic surgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain (Fig. 14-15). Therefore, it is important to use a video monitor that has a resolution equal to or greater than the camera being used.⁵⁵ Resolution is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. HD television can deliver up to eight times more resolution than standard monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved.^{52,55} A heads-up display is a high-resolution liquid crystal monitor that is built into eyewear worn by the surgeon.⁵⁶ This technology allows the surgeon to view the endoscopic image and operative field simultaneously. The proposed advantages of heads-up display include a high-resolution monocular image, which affords the surgeon mobility and reduces vertigo and eyestrain. However, this technology has not yet been widely adopted.

Interest in three-dimensional (3-D) laparoscopy has waxed and waned. 3-D laparoscopy provides the additional depth of field that is lost with two-dimensional endosurgery and improves performance of novice laparoscopists performing complex tasks of dexterity, including suturing and knot tying.⁵⁷ The advantages of 3-D systems are less obvious to experienced

Figure 14-15. The Hopkins rod lens telescope includes a series of optical rods that effectively transmit light to the eyepiece. The video camera is placed on the eyepiece to provide the working image. The image is only as clear as the weakest link in the image chain. CCD = charge-coupled device. (Reproduced with permission from Toouli JG, Gossot D, Hunter JG: *Endosurgery*. New York/London: Churchill-Livingstone/Elsevier; 1996.)

laparoscopists. Additionally, because 3-D systems require the flickering of two similar images, which are resolved with special glasses, the images' edges become fuzzy and resolution is lost. The optical accommodation necessary to rectify these slightly differing images is tiring and may induce headaches when one uses these systems for a long period of time. The da Vinci robot uses a specialized laparoscope with two optical bundles on opposite sides of the telescope. A specialized binocular eyepiece receives input from two CCD chips, each capturing the image from one of the two quartz rod lens systems, thereby creating true 3-D imaging without needing to employ active or passive technologies that have made 3-D laparoscopy so disappointing.

Single-incision laparoscopy presents new challenges to visualization of the operative field. In the traditional laparoscope, the light source enters the scope at a 90° angle. That position coupled with a bulky scope handle creates crowding in an already limited space. Additionally, because the scope and instruments enter the abdomen at the same point, an adequate perspective is often unobtainable even with a 30° scope. The advent of increased length laparoscopes with lighting coming from the end and a deflectable tip now allows the surgeon to recreate a sense of internal triangulation with little compromise externally. The ability to move the shaft of the scope off line while maintaining the same image provides a greater degree of freedom for the working ports.

Energy Sources for Endoscopic and Endoluminal Surgery

Many MIS procedures use conventional energy sources, but the benefits of bloodless surgery to maintain optimal visualization have spawned new ways of applying energy. The most common energy source is RF electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation (60°C [140°F]), vaporization and desiccation (100°C [212°F]), and carbonization (>200°C [392°F]).⁵⁸

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery, a remote ground plate on the patient's leg or back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects.⁵⁹ A short-duration, high-voltage discharge of current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery, the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used alone, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues.⁶⁰ Advanced laparoscopic device manufacturers have leveraged the ability to selectively use bipolar energy and combined it with compressive force and a controllable blade to create a number of highly functional dissection and vessel-sealing tools (Fig. 14-16).

Figure 14-16. Examples of advanced bipolar devices. The flow of electrons passes from one electrode to the other heating and desiccating tissue. A controllable blade travels the length of the jaw to divide intervening tissue.

To avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. In addition, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn, the current is bled off of a metal sleeve or laparoscope into the viscera⁵⁴ (Fig. 14-17A). This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel⁵⁸ (Fig. 14-17B).

Another method of delivering RF electrosurgery is argon beam coagulation. This is a type of monopolar electrosurgery in which a uniform field of electrons is distributed across a tissue surface by the use of a jet of argon gas. The argon gas jet distributes electrons more evenly across the surface than does spray electrofulguration. This technology has its greatest application for coagulation of diffusely bleeding surfaces such as the cut edge of liver or spleen. It is of less value in laparoscopic procedures because the increased intra-abdominal pressures created by the argon gas jet can increase the chances of a gas embolus. It is paramount to vent the ports and closely monitor insufflation pressure when using this source of energy within the context of laparoscopy.

With endoscopic endoluminal surgery, RF alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and biopsy.^{61,62} A grounding (return) electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Gas, liquid, and solid-state lasers have been available for medical application since the mid-1960s.⁶³ The CO₂ laser (wavelength 10.6 μm) is most appropriately used for cutting

Figure 14-17. A. Capacitive coupling occurs as a result of high current density bleeding from a port sleeve or laparoscope into adjacent bowel. B. Direct coupling occurs when current is transmitted directly from the electrode to a metal instrument or laparoscope, and then into adjacent tissue. (Reproduced with permission from Hunter JG, Sackier JM: *Minimally Invasive Surgery*. New York, NY: McGraw-Hill Education; 1993.)

and superficial ablation of tissues. It is most helpful in locations unreachable with a scalpel such as excision of vocal cord granulomas. The CO₂ laser beam must be delivered with a series of mirrors and is therefore somewhat cumbersome to use. The next most popular laser is the neodymium yttrium-aluminum garnet (Nd:YAG) laser. Nd:YAG laser light is 1.064 μm (1064 nm) in wavelength. It is in the near-infrared portion of the spectrum and, like CO₂ laser light, is invisible to the naked eye. A unique feature of the Nd:YAG laser is that 1064-nm light is poorly absorbed by most tissue pigments and therefore travels deep into tissue.⁶⁴ Deep tissue penetration provides deep tissue heating (Fig. 14-18). For this reason, the Nd:YAG laser is capable of the greatest amount of tissue destruction with a single application.⁶³

Figure 14-18. This graph shows the absorption of light by various tissue compounds (water, melanin, and oxyhemoglobin) as a function of the wavelength of the light. The nadir of the oxyhemoglobin and melanin curves is close to 1064 nm, the wavelength of the neodymium yttrium-aluminum garnet laser. (Reproduced with permission from Hunter JG, Sackier JM: *Minimally Invasive Surgery*. New York, NY: McGraw-Hill Education; 1993.)

Such capabilities make it the ideal laser for destruction of large fungating tumors of the rectosigmoid, tracheobronchial tree, or esophagus. A disadvantage is that the deep tissue heating may cause perforation of a hollow viscus.

When it is desirable to coagulate flat lesions in the cecum, a different laser should be chosen. The frequency-doubled Nd:YAG laser, also known as the KTP laser (potassium thionyl phosphate crystal is used to double the Nd:YAG frequency), provides 532-nm light. This is in the green portion of the spectrum, and at this wavelength, selective absorption by red pigments in tissue (such as hemangiomas and arteriovenous malformations) is optimal. The depth of tissue heating is intermediate, between those of the CO₂ and the Nd:YAG lasers. Coagulation (without vaporization) of superficial vascular lesions can be obtained without intestinal perforation.⁶⁴

In flexible GI endoscopy, the CO₂ and Nd:YAG lasers have largely been replaced by heater probes and endoluminal stents. The heater probe is a metal ball that is heated to a temperature (60–100°C [140°–212°F]) that allows coagulation of bleeding lesions without perforation.

Photodynamic therapy is a palliative treatment for obstructing cancers of the GI tract.⁶⁵ Patients are given an IV dose of porfimer sodium, which is a photosensitizing agent that is taken up by malignant cells. Two days after administration, the drug is endoscopically activated using a laser. The activated porfimer sodium generates oxygen free radicals, which kill the tumor cells. The tumor is later endoscopically debried. The use of this modality for definitive treatment of early cancers is limited.

A unique application of laser technology provides extremely rapid discharge (<10⁻⁶ s) of large amounts of energy (>10³ volts). These high-energy lasers, of which the pulsed dye laser has seen the most clinical use, allow the conversion of light energy to mechanical disruptive energy in the form of a shock wave. Such energy can be delivered through a quartz fiber, and with rapid repetitive discharges, can provide sufficient shock-wave energy to fragment kidney stones and gallstones.⁶⁶ Shock waves also may be created with miniature electric spark-plug discharge systems known as electrohydraulic lithotriptors. These devices

also are inserted through thin probes for endoscopic application. Lasers have the advantage of pigment selectivity, but electrohydraulic lithotrippers are more popular because they are substantially less expensive and are more compact.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones. Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology.⁶⁷ An example of its application is the laparoscopic coagulation shears device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel (Fig. 14-19). This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures.⁶⁸ It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery. The ability to clamp tissue between an active blade and passive blade allows annealing of tissues followed by cutting.

Instrumentation

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury.⁶⁹

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3 to 5 mm and a length of 20 to 45 cm, but other instruments such as forceps and clamps cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures.⁶⁹ A unique laparoscopic hand instrument is the monopolar electrical hook. This device usually is configured with a suction and irrigation apparatus to eliminate smoke and blood from the operative

Figure 14-19. Ultrasonic shear. When closed vibration of black (active blade) against white (passive blade) cuts and cauterizes intervening tissue.

field. The monopolar hook allows tenting of tissue over a bare metal wire with subsequent coagulation and division of the tissue.

Instrumentation for NOTES is still evolving, but many long micrograspers, microscissors, electrocautery adapters, suturing devices, clip applicators, and visceral closure devices are in design and application. These instruments often require an entirely different endoscopic platform requiring manipulation by a surgeon and assistant to accomplish complex maneuvers. Techniques such as mucosotomy, hydrodissection, and clip application require specialized training. The sheer size of the instrumentation often requires an overtube to allow easy exchange throughout the procedure. Instrumentation for SILS seeks to restore the surgeon's ability to triangulate the left and right hands through variation in length, mechanical articulation, or curved design. Additionally, a lower profile camera head helps reduce the instrument crowding that occurs at the single point of abdominal entry.

Robotic Surgery

The term robot defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The devices that have earned the title "surgical robots" would be more aptly termed computer-enhanced surgical devices, as they are controlled entirely by the surgeon for the purpose of improving performance. The first computer-assisted surgical device was the laparoscopic camera holder (Aesop, Computer Motion, Goleta, CA), which enabled the surgeon to maneuver the laparoscope either with a hand control, foot control, or voice activation. Randomized studies with such camera holders demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings.⁷⁰ This device had the advantage of eliminating the need for a human camera holder, which served to free valuable OR personnel for other duties. This technology has now been eclipsed by simpler systems using passive positioning of the camera with a mechanical arm, but the benefits of a steadier image and fewer members of the OR team remain.

The major revolution in robotic surgery was the development of a master-slave surgical platform that returned the wrist to laparoscopic surgery and improved manual dexterity by developing an ergonomically comfortable work station, with 3-D imaging, tremor elimination, and scaling of movement (e.g., large, gross hand movements can be scaled down to allow suturing with microsurgical precision) (Fig. 14-20). The most recent iteration of the robotic platform features a second surgical console enabling greater assisting and teaching opportunities. The surgeon is physically separated from the operating table, and the working arms of the device are placed over the patient (Fig. 14-21). An assistant remains at the bedside and changes the instruments as needed, providing retraction as needed to facilitate the procedure. The robotic platform (da Vinci, Intuitive Surgical, Sunnyvale, CA) was initially greeted with some skepticism by expert laparoscopists, as it was difficult to prove additional value for operations performed with the da Vinci robot. Not only were the operations longer and the equipment more expensive, but additional quality could not be demonstrated. Two randomized controlled trials compared robotic and conventional laparoscopic approaches to Nissen fundoplication.^{71,72} In both of these trials, the operative time was longer for robotic surgery, and there was no difference in ultimate outcome. Similar results were achieved for laparoscopic cholecystectomy.⁷³ Nevertheless, the increased dexterity provided by the da

Figure 14-20. Robotic instruments and hand controls. The surgeon is in a sitting position, and the arms and wrists are in an ergonomic and relaxed position.

Vinci robot convinced many surgeons and health administrators that robotic platforms were worthy of investment, for marketing purposes if for no other reason. The success story for computer-enhanced surgery with the da Vinci started with cardiac surgery and migrated to the pelvis. Mitral valve surgery, performed with right thoroscopic access, became one of the more popular procedures performed with the robot.⁷⁴

To date, a myriad of publications have demonstrated success performing procedures from thyroidectomies to colectomies with total mesorectal excision. Almost any procedure performed laparoscopically has been attempted robotically, although true advantage is demonstrated only very sparingly. In most cases, increased cost and operative time challenge the notion of “better.”

The tidal wave of enthusiasm for robotic surgery came when most minimally invasive urologists declared robotic prostatectomy to be preferable to laparoscopic and open prostatectomy.⁷⁵ The great advantage—it would appear—of robotic prostatectomy is the ability to visualize and spare the pelvic nerves responsible for erectile function. In addition, the creation of the neocystourethrotomy, following prostatectomy, was greatly facilitated by needle holders and graspers with a wrist in them. Female pelvic surgery with the da Vinci robot is also reaching wide appeal. The magnified imaging provided makes this approach ideal for microsurgical tasks such as reanastomosis of the Fallopian tubes. In general surgery, there is emerging

Figure 14-21. Room setup and position of surgeon and assistant for robotic surgery. (© 2013 Intuitive Surgical, Inc. Reprinted with permission.)

popularity for the use of the robotic platform for revisional bariatric surgery and complex abdominal wall reconstruction. The ability to close the defect before placement of mesh in ventral hernia repairs or to perform complex transversus abdominus release herniorrhaphy is revolutionizing MIS hernia repair.

The final frontier for computer-enhanced surgery is the promise of telesurgery, in which the surgeon is a great distance from the patient (e.g., combat or space). This application has rarely been used, as the safety provided by having the surgeon at bedside cannot be sacrificed to prove the concept. However, remote laparoscopic cholecystectomy has been performed when a team of surgeons located in New York performed a cholecystectomy on a patient located in France.⁷⁶

Endoluminal and Endovascular Surgery

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency. Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of access devices, catheters, guidewires, balloon dilators, stents, and other devices (e.g., lasers, atherectomy catheters) that are capable of opening up the occluded biologic cylinder⁷⁷ (Table 14-2). Endoluminal balloon dilators may be inserted through an endoscope, or they may be fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).⁷⁸

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent.⁷⁹ Stenting is particularly valuable in treating malignant lesions and atherosclerotic

Figure 14-22. The deployment of a metal stent across an isolated vessel stenosis is illustrated. (Reproduced with permission from Hunter JG, Sackier JM, eds. *Minimally Invasive Surgery*. New York: McGraw-Hill; 1993:235.)

occlusions or aneurysmal disease (Fig. 14-22). Stenting is also of value to seal leaky cylinders, including aortic dissections, traumatic vascular injuries, leaking GI anastomoses, and fistulas. Stenting usually is not applicable for long-term management of benign GI strictures except in patients with limited life expectancy (Fig. 14-23).⁷⁹⁻⁸¹

A variety of stents are available that are divided into six basic categories: plastic stents, metal stents, drug-eluting stents (to decrease fibrovascular hyperplasia), covered metal stents, anchored stent grafts, and removable covered plastic stents⁸⁰ (Fig. 14-24). Plastic stents came first and are used widely as endoprotheses for temporary bypass of obstructions in the biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol and are still used in coronary stenting. A chemotherapeutic agent was added to coronary stents several years ago to decrease endothelial proliferation. These drug-eluting stents provide greater long-term patency but require long-term anticoagulation with antiplatelet agents to prevent thrombosis.⁸² Coated metal stents are used to prevent tissue ingrowth. Ingrowth may

Figure 14-23. This is an esophagram in a patient with severe dysphagia secondary to advanced esophageal cancer (A) before and (B) after placement of a covered self-expanding metal stent.

be an advantage in preventing stent migration, but such tissue ingrowth may occlude the lumen and cause obstruction anew. This is a particular problem when stents are used for palliation of GI malignant growth and may be a problem for the long-term use of stents in vascular disease. Filling the interstices with

Figure 14-24. Covered self-expanding metal stents. These devices can be placed fluoroscopically or endoscopically.

Silastic or other materials may prevent tumor ingrowth but also makes stent migration more likely. In an effort to minimize stent migration, stents have been incorporated with hooks and barbs at the proximal end of the stent to anchor it to the wall of the vessel. Endovascular stenting of aortic aneurysms has nearly replaced open surgery for this condition. Lastly, self-expanding plastic stents have been developed as temporary devices to be used in the GI tract to close internal fistulas and bridge leaking anastomoses.

Natural Orifice Transluminal Endoscopic Surgery

The use of the flexible endoscope to enter the GI, urinary, or reproductive tracts and then traverse the wall of the structure to enter the peritoneal cavity, the mediastinum, or the chest has

strong appeal to patients wishing to avoid scars and pain caused by abdominal wall trauma. In truth, transluminal surgery has been performed in the stomach for a long time, either from the inside out (e.g., percutaneous, PEG, and transgastric pseudocyst drainage) or from the outside in (e.g., laparoscopic-assisted intragastric tumor resection). The catalyzing events for NOTES were the demonstration that a porcine gallbladder could be removed with a flexible endoscope passed through the wall of the stomach and then removed through the mouth and the demonstration in a series of 10 human cases from India of the ability to perform transgastric appendectomy. Since that time, a great deal of money has been invested by endoscopic and MIS companies to help surgeons and gastroenterologists explore this new territory. Systemic inflammatory markers such as C-reactive protein, tumor necrosis factor- α , interleukin (IL)-1 β , and IL-6 have been shown to be similar in transgastric and transcolonic NOTES when compared to laparoscopy in porcine models.⁸³ Concerns about the safety of transluminal access and limitations in equipment remain the greatest barriers to expansion. To date, the most headline-grabbing procedures have been the transvaginal and transgastric removal of the gallbladder⁸⁴⁻⁸⁶ (Fig. 14-25). To ensure safety, all human cases thus far have involved laparoscopic assistance to aid in retraction and ensure adequate closure of the stomach or vagina. To date, thousands of transvaginal and transgastric procedures have been performed internationally, with two large registries demonstrating noninferiority to conventional laparoscopy.⁸⁷ The fact that the vast majority of these procedures are being done transvaginally creates an obvious limitation in applicability.

The rapid growth of endoscopic technology catalyzed by NOTES has already spun off new technologies capable of performing a wide variety of endoscopic surgical procedures from EMR, to ablation of Barrett's esophagus, to creation of competent antireflux valves in patients with gastroesophageal reflux disease.

Peroral esophageal myotomy (POEM) has shown promise as a NOTES treatment for esophageal achalasia.⁸⁸ In this procedure, a 1.5- to 2-cm mucosotomy is created within the anterior esophagus 10 cm proximal to the gastroesophageal junction. A submucosal tunnel is then created using a combination of electrocautery, hydrodissection, and carbon dioxide insufflation. The scope is advanced beyond the gastroesophageal junction, and a circular myotomy is performed avoiding disruption of the longitudinal fibers. The mucosotomy is then closed using endoscopic clips (Fig. 14-26). Over 1000 clinical POEM cases have been performed worldwide. Data from expert NOTES surgeons suggest that this selective myotomy avoids abdominal trauma

Figure 14-25. Transgastric cholecystectomy using natural orifice transluminal endoscopic surgery technology and one to three laparoscopic ports has been performed occasionally in several locations around the world. and minimally disrupts the normal anatomic characteristics of the gastroesophageal junction while providing significant relief of symptoms.⁸⁹ Randomized clinical trials and long-term follow-up need to be performed to further evaluate efficacy.

Although this application is still considered experimental, there is little doubt that when equivalent operations can be performed with less pain, fewer scars, and less disability, patients will flock to it. NOTES procedures are associated with an increased mental workload and significant learning curve for even experienced surgical endoscopists. Surgeons should engage only when they can perform these procedures with the safety and efficacy demanded by our profession.

Single-Incision Laparoscopic Surgery

As a surgical technique, SILS seems to be a natural progression from conventional laparoscopic surgery. As surgeons sought to reduce the number and size of abdominal wall trocars and NOTES procedures necessitated laparoscopic surveillance, the idea of a hybridization took off. An incision in the umbilicus, a preexisting scar, is thought to be less painful, have fewer wound complications, lead to quicker return to activity, and have a better cosmetic appearance than conventional laparoscopy. Perhaps one of the earliest examples of SILS is the application of laparoscopic instrumentation to resect lesions in the rectum or

sigmoid colon. Using the anus as the portal of entry, transanal endoscopic microsurgery (TEMs) employs a specialized multichannel trocar to reach lesions located 8 to 18 cm away from the anal verge (Fig. 14-27).

More deformable versions of these complex trocars have been developed with features to allow insufflation and be amenable to maintaining a seal within the natural orifice of the umbilicus (see Fig. 14-11). Ports typically contain three or four channels. The latter often affords the ability to place a dedicated retractor.

There are many challenges faced by the operating surgeon in SILS procedures. These include crowded trocar placement, a lack of triangulation of left- and right-hand instruments, frequent crossing or clashing of instruments, limited visualization, and limited retraction ability. These challenges are mitigated by surgeon's experience and the development of specialized instruments. Articulating or curved instruments of varying lengths and an extended length can improve working space. Curved instruments are typically reusable and offer less clutter than their more sophisticated counterparts, providing some cost reduction (Fig. 14-28). A low-profile HD scope with or without a deflectable tip can improve visualization greatly. Even with such instrumentation, the learning curve is very steep, particularly when the surgeon is forced to work in a cross-handed technique. The accomplished SILS surgeon will possess a tool bag of innovative

strategies to retract structures like the gallbladder away from the operative field. These tricks may range from the use of percutaneous needlescopic instruments to the application of transfascial sutures. Expert consensus recommendations for efficient SILS are

Figure 14-27. Transanal endoscopic microsurgery scope. (Reproduced with permission from The Johns Hopkins University School of Medicine, Baltimore, MD; 2014. Illustration by Corinne Sandone.)

Figure 14-28. Example of curved instruments used in single-incision laparoscopic surgery. (© 2013 Intuitive Surgical, Inc. Reprinted with permission.)

shown in Tables 14-3 and 14-4.⁸ When performing SILS procedures, it is imperative to follow proven tenets of operative conduct such as visualizing the “critical view” of safety in a laparoscopic cholecystectomy. As safety should always be the paramount concern, the addition of extra trocars or conversion to traditional laparoscopy should not be considered a failure.

Contraindications include those true of traditional laparoscopy. Relative contraindications include previous surgery and high body mass index (BMI). Patients with a high BMI or central obesity can pose a challenge because the umbilicus may be located far from operative target. Size and morphology of the target organ should always be considered when doing SILS.

Many studies have demonstrated equivalency to standard laparoscopic procedures regarding intraoperative and postoperative complications. However, it is questionable what the full benefit of the dramatic reduction in ergonomics and the increase in complexity provide beyond an improved cosmetic appearance. This is in large part due to the already improved benefits of laparoscopic surgery.

A meta-analysis performed by Ahmed and colleagues in 2010 found the conversion rate from SILS to conventional laparoscopy to be 0% to 24% for cholecystectomies, 0% to 41%

Table 14-3

Expert panel recommendations for accomplishing single-incision laparoscopic surgery efficiently

Multichannel port preferably to be placed intraumbilically, but an extraumbilical approach can be used in certain cases

Extra ports should be used where there is a clinical need

When applicable, sutures can be useful for added retraction

Closure should be accomplished using sutures of absorbable material placed either continuously or interrupted

Skin should be closed with absorbable sutures or glue

Reproduced with permission from Ahmed I, Cianco F, Ferrar V, et al. Current status of single-incision laparoscopic surgery: European experts' views, *Surg Laparosc Endosc Percutan Tech*. 2012 Jun;22(3):194-199.

Table 14-4

Expert panel recommendations for single-incision laparoscopic surgery equipment and instrumentation

RECOMMENDED EQUIPMENT/ INSTRUMENTATION	BENEFIT TO SURGEON
Slimline instruments with low-profile design	Reduces internal and external clashing
Varied-length instruments	Reduces extracorporeal clashing
Longer instruments	Advantageous for reaching the surgical field
Articulating (or prebent) instruments	Restore triangulation
Small-diameter, low-profile angle scope	Reduces clashing by providing additional space
High-definition camera	Achieves high-quality images for intraoperative visualization

Reproduced with permission from Ahmed I, Cianco F, Ferrar V, et al. Current status of single-incision laparoscopic surgery: European experts' views, *Surg Laparosc Endosc Percutan Tech*. 2012 Jun;22(3):194-199.

for appendectomies, and 0% to 33% for nephrectomies.⁹⁰ The most common complications were intra-abdominal abscesses and wound infections. Existing and emerging robotics platforms may provide the bridge necessary to bypass the significant technical skills learning curve required to operate through a single site (Fig. 14-29).

SPECIAL CONSIDERATIONS

Pediatric Laparoscopy

The advantages of MIS in children may be more significant than in the adult population. MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions usually can be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15–20 cm), and many are 3 mm in diameter rather than 5 mm. Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy.⁹¹ Because the abdominal wall is much thinner in infants, a pneumoperitoneum pressure of 8 mmHg can provide adequate exposure. DVT is rare in children, so prophylaxis against thrombosis probably is unnecessary. A wide variety of pediatric surgical procedures are frequently performed with MIS access, from pull-through procedures for colonic aganglionosis (Hirschsprung's disease) to repair of congenital diaphragmatic hernias.⁹²

Laparoscopy During Pregnancy

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been thoroughly investigated and are readily managed. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at 20 weeks. In

▶ order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach should be

A

B

Figure 14-29. A and B. Robotic single-incision surgery platform. (©2013 Intuitive Surgical, Inc. Reprinted with permission.)

used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures. Fetal acidosis induced by maternal hypercarbia also has been raised as a concern. The arterial pH of the fetus follows the pH of the mother linearly; and therefore, fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother.⁹³ The pneumoperitoneum pressure induced by laparoscopy is not a safety issue either as it has been proved that mid-pregnancy uterine contractions provide a much greater pressure in utero than a pneumoperitoneum of 15 mmHg. More than 100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results.⁹⁴ The operation should be performed during the second trimester of pregnancy if possible. Protection of the fetus against intraoperative X-rays

is imperative. Some believe it advisable to track fetal pulse rates with a transvaginal ultrasound probe; however, the significance of fetal tachycardia or bradycardia is a bit unclear in the second trimester of pregnancy. To be prudent, however, heart rate decelerations reversibly associated with pneumoperitoneum creation might signal the need to convert to open cholecystectomy or appendectomy.

Minimally Invasive Surgery and Cancer Treatment

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to reestablish the continuity of an obstructed esophagus, bile duct, ureter, or airway. MIS techniques also have been used in the staging of cancer. Mediastinoscopy is still used occasionally before thoracotomy to assess the status of the mediastinal lymph nodes. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection. New technology and greater surgical skills allow for accurate minimally invasive staging of cancer.⁹⁵ Occasionally, it is appropriate to perform palliative measures (e.g., laparoscopic gastrojejunostomy to bypass a pancreatic cancer) at the time of diagnostic laparoscopy if diagnostic findings preclude attempts at curative resection.

Initially controversial, the role of MIS to provide a safe curative treatment of cancer has proven to be no different from the principles of open surgery. All gross and microscopic tumor should be removed (an R0 resection), and an adequate lymphadenectomy should be performed to allow accurate staging. Generally, this number has been 10 to 15 lymph nodes, although there is still debate as to the value of more extensive lymphadenectomy. All of the major abdominal cancer operations have been performed with laparoscopy. Of the three major cancer resections of GI cancer (liver lobe, pancreatic head, and esophagus), only esophagectomy is routinely performed by a fair number of centers.^{96,97} Laparoscopic hepatectomy has attracted a loyal following, and distal pancreatectomy frequently is performed with laparoscopic access. In Japan, laparoscopic-assisted gastrectomy has become quite popular for early gastric cancer, an epidemic in Japan far exceeding that of colon cancer in North America and Northern Europe. The most common cancer operation performed laparoscopically is segmental colectomy, which has proven itself safe and efficacious in a multicenter, controlled, randomized trial.⁹⁸

Considerations in the Elderly and Infirm

Laparoscopic cholecystectomy has made possible the removal of a symptomatic gallbladder in many patients previously thought to be too elderly or too ill to undergo a laparotomy. Older patients are more likely to require conversion to laparotomy because of disease chronicity.⁹⁸

Operations on these patients require close monitoring of anesthesia. The intraoperative management of these patients may be more difficult with laparoscopic access than with open access. The advantage of MIS lies in what happens after the operation. Much of the morbidity of surgery in the elderly is a result of impaired mobility. In addition, pulmonary complications, urinary tract sepsis, DVT, pulmonary embolism, congestive heart failure, and myocardial infarction often are the result of improper fluid management and decreased mobility. By allowing rapid and early mobilization, laparoscopic surgery

has made possible the safe performance of procedures in the elderly and infirm.

Cirrhosis and Portal Hypertension

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention.⁹⁹ The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction.¹⁰⁰ Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore, a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the severity of hepatic cirrhosis as judged by a Model of End-Stage Liver Disease (MELD) score or Child's classification. Additionally, the presence of portal hypertension is a relative contraindication to laparoscopic surgery until the portal pressures are reduced with portal decompression. For example, if a patient has an incarcerated umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced to prevent a decrease in cardiac output, and minimal amounts of Na⁺-sparing IV fluids should be given.

Economics of Minimally Invasive Surgery

Minimally invasive surgical procedures reduce the costs of surgery most when length of hospital stay can be shortened and return to work is quickened. For example, shorter hospital stays can be demonstrated in laparoscopic cholecystectomy, Nissen fundoplication, splenectomy, and adrenalectomy. Procedures such as inguinal herniorrhaphy that are already performed as outpatient procedures are less likely to provide cost savings. Procedures that still require a 4- to 7-day hospitalization, such as laparoscopy-assisted colectomy, are less likely to deliver a lower bottom line than their open surgery counterparts. Nonetheless, with responsible use of disposable instrumentation and a commitment to the most effective use of the inpatient setting, most laparoscopic procedures can be made less expensive than their conventional equivalents.

Education and Skill Acquisition

Historically, surgeons in training (residents, registrars, and fellows) acquired their skills in minimally invasive techniques through a series of operative experiences of graded complexity. This training occurred on patients. Although such a paradigm did not compromise patient safety, learning in the OR is costly. In addition, the recent worldwide constraint placed on resident work hours makes it attractive to teach laparoscopic skills outside of the OR.

Skills labs started at nearly every surgical training center in the 1990s with low fidelity box-type trainers. These were rudimentary simulated abdominal cavities with a video camera, monitor, trocars, laparoscopic instruments, and target models. These targets were often as simple as a pegboard and rubber rings, or a latex drain to practice suturing and knot tying. Virtual reality training devices present a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy

for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to determine progress in skill acquisition and, ultimately, technical competency.¹⁰¹ Several of these devices have been validated as a means of measuring proficiency in skill performance. More importantly, training on virtual reality platforms has proven to translate to improved operative performance in randomized trials.^{102,103} Currently, surgical skills labs are mandatory for Residency Review Committee credentialing. Successful completion of the Fundamentals of Laparoscopic Surgery (FLS) technical and cognitive examination became a mandatory prerequisite for the American Board of Surgery (ABS) qualification examination in general surgery in 2010. The Fundamentals of Endoscopic Surgery (FES) became a prerequisite to ABS qualification in 2015. In the future, institutions may require simulator training to document specific entrustable professional activities (EPA) related to laparoscopic procedures before privileging in the OR. A Fundamentals of Robotic Surgery (FRS) high stakes exam is on the horizon for future surgical trainees. The American College of Surgeons has taken a leadership position in accrediting skills labs across the world as American College of Surgeons–accredited educational institutes.

Telementoring

In response to the Institute of Medicine's call for the development of unique technologic solutions to deliver health care to rural and underserved areas, surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting or directly in the OR when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently is being used, especially in states and provinces with large geographically remote populations.¹⁰³

Innovation and Introduction of New Procedures

The revolution in minimally invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was this: If competence is gained from experience, how was the surgeon to climb the competence curve (otherwise known as the learning curve) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate

this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development (i.e., there is great individual variation in the performance of procedures, but no difference between one tablet and the next), adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset, the surgeon must identify the problem that is not solved with current surgical procedures. For example, although the removal of a gallbladder through a Kocher incision is certainly effective, it creates a great deal of disability, pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly, there was a need for developing a less invasive approach (Fig. 14-30).

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, where secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. These types of studies are controversial because of the resistance to animal experimentation, and yet without such studies, many humans would be injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps often are called the preclinical phase of procedure development.

The decision as to when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with patients, it is important to achieve full institutional support. Involvement of the medical board, the chief of the medical staff, and the institutional review board is essential before commencing on a new procedure. These bodies are responsible for the use of safe, high-quality medical practices within their institution, and they will demand that great caution and all possible safeguards are in place before proceeding.

The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology

Figure 14-30. The progress of general surgery can be reflected by a series of performance curves. General anesthesia and sterile technique allowed the development of maximally invasive open surgery over the last 125 years. Video optics allowed the development of minimally invasive surgery over the last 25 years. Noninvasive (seamless) surgery will result when a yet undiscovered transformational event allows surgery to occur without an incision, and perhaps without anesthesia.

that allows a patient to decide to be first is quite interesting, and may, under certain circumstances, require psychiatric evaluation. Certainly, if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it generally is wise to assemble the best possible operative team, including a surgeon experienced with the old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good as or better than the procedure that is being replaced. This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the **8▶** introduction of new technology into the OR. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or healthcare system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. Although this may be difficult for them, the best interest of the patient must be put before the education of the resident.

The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. Although it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners as to whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. Although this approach may sound obvious, it is fraught with difficulties. In many situations, ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

If innovative procedures and technologies are to be developed and applied without the mistakes of the past, surgeons must be honest when they answer these questions: Is this procedure safe? Would I consider undergoing this procedure if I developed a surgical indication? Is the procedure as good as or better than the procedure it is replacing? Do I have the skills to apply this procedure safely and with equivalent results to the more experienced surgeon? Answering these questions in the affirmative should be a professional obligation. A negative response should motivate the surgeon to seek an alternative procedure or outside assistance before subjecting a patient to the new procedure.

OVERVIEW OF MOLECULAR CELL BIOLOGY

The beginning of modern medicine can be traced back to centuries ago when physicians and scientists began studying human anatomy from cadavers in morgues and animal physiology following hunting expeditions. Gradually, from the study of animals and plants in greater detail and the discovery of microbes, scientific principles governing life led to the emergence of the biologic sciences. As biologic science developed and expanded, scientists and physicians began to utilize its principles to solve challenges of human diseases while continuing to explore the fundamentals of life in greater detail. With ever-evolving state-of-the-art scientific tools, our understanding of how cells, tissues, organs, and entire organisms function, down to the level of molecular and subatomic structure, has resulted in modern biology with an enormous impact on modern healthcare and the discovery of amazing treatments for disease at an exponential pace. Significant progress has been made in molecular studies of organ development, cell signaling, and gene regulation. The advent of recombinant DNA technology, polymerase chain reaction (PCR) techniques, and next-generation genomic sequencing, which resulted in the sequencing of the human genome, holds the potential to have a transformational influence on healthcare and society this century by not only broadening our understanding of the pathophysiology of disease, but also by bringing about necessary changes in personalized medicine.

Today's practicing surgeons are becoming increasingly aware that many modern surgical procedures rely on the information gained through molecular research (i.e., precision surgery). Genomic information, such as deleterious *BRCA* and *RET* proto-oncogene mutations, is being used to help direct prophylactic procedures to remove potentially harmful tissues before they do damage to patients. Molecular engineering has led to cancer-specific gene therapy that could serve in the near future as a more effective adjunct to surgical debulking of tumors than radiation or chemotherapy, so surgeons will benefit from a clear

introduction to how basic biochemical and biologic principles relate to the developing area of molecular biology. This chapter reviews the current information on modern molecular biology for the surgical community.

Basic Concepts of Molecular Research

The modern era of molecular biology, which has been mainly concerned with how genes govern cell activity, began in 1953 when James D. Watson and Francis H. C. Crick made one of the greatest scientific discoveries by deducing the double-helical structure of deoxyribonucleic acid (DNA).^{1,2} The year 2003 marked the 50th anniversary of this great discovery. In the same year, the Human Genome Project completed with sequencing approximately 20,000 to 25,000 genes and 3 billion base pairs in human DNA.³ Before 1953, one of the most mysterious aspects of biology was how genetic material was precisely duplicated from one generation to the next. Although DNA had been implicated as genetic material, it was the base-paired structure of DNA that provided a logical interpretation of how a double helix could “unzip” to make copies of itself. This DNA synthesis, termed *replication*, immediately gave rise to the notion that a template was involved in the transfer of information between generations, and thus confirmed the suspicion that DNA carried an organism's hereditary information.

Within cells, DNA is packed tightly into chromosomes. One important feature of DNA as genetic material is its ability to encode important information for all of a cell's functions (Fig. 15-1). Based on the principles of base complementarity, scientists also discovered how information in DNA is accurately transferred into the protein structure. DNA serves as a template for RNA synthesis, termed *transcription*, including messenger RNA (mRNA, or the protein-encoding RNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA carries the information from DNA to make proteins, termed *translation*, with the assistance of rRNA and tRNA. Each of these steps is precisely

Key Points

- 1▶ The biologic sciences have developed drastically in the last 66 years after the uncovering of DNA structure by Watson and Crick.
- 2▶ The completion of the human genome sequence in 2003 represents a great milestone in modern science.
- 3▶ The technology emerging from molecular and cellular biology has revolutionized the understanding of disease and will radically transform the practice of surgery.
- 4▶ The use of genetically modified mouse models and cell lines using gene therapy and RNA interference therapy has greatly contributed to the understanding of the molecular basis for human diseases and targeted therapies.
- 5▶ The sequencing of each individual's genome has the potential to improve the predication, prevention, and targeted treatment of disease, resulting in precision medicine and surgery.
- 6▶ Fast-developing targeted genome editing tools like the CRISPR-Cas9 system greatly facilitate biomedical research in native conditions and have shown their potential in the treatment of genetic diseases, including cancers, with a high degree of personalization and precision.
- 7▶ The use of functional genomics and modern molecular analyses will facilitate the discovery of actionable genes to guide choice of care, including precision surgery.

controlled in such a way that genes are properly expressed in each cell at a specific time and location. In recent years, new classes of noncoding RNAs (ncRNA), for example, microRNA (or miRNA), piwi-interacting RNA (or piRNA), and long intergenic noncoding RNA (or lincRNA), have been identified. Although the number of ncRNAs encoded in the human genome is unknown and a lot of ncRNAs have not been validated for their functions, ncRNAs have been associated to regulate gene expression through posttranscriptional gene regulation such as mRNA degradation or epigenetic regulation such as chromatin structure modification and DNA methylation induction.⁴ Consequently, the differential gene activity in a cell determines its actions, properties, and functions.

Molecular Approaches to Surgical Research

Rapid advances in molecular and cellular biology over the past half century have revolutionized the understanding of disease and will radically transform the practice of surgery. In the future, molecular techniques will be increasingly applied to surgical disease and will lead to new strategies for the selection

Figure 15-1. The flow of genetic information from DNA to protein to cell functions. The process of transmission of genetic information from DNA to RNA is called *transcription*, and the process of transmission from RNA to protein is called *translation*. Proteins are the essential controlling components for cell structure, cell signaling, and metabolism. *Genomics* and *proteomics* are the study of the genetic composition of a living organism at the DNA and protein level, respectively. The study of the relationship between genes and their cellular functions is called *functional genomics*.

and implementation of operative therapy. Surgeons should be familiar with the fundamental principles of molecular and cellular biology so that emerging scientific breakthroughs can be translated into improved care of the surgical patient.

The greatest advances in the field of molecular biology have been in the areas of analysis and manipulation of DNA.¹ Since Watson and Crick's discovery of DNA structure, an intensive effort has been made to unlock the deepest biologic secrets of DNA. Among the avalanche of technical advances, one discovery in particular has drastically changed the world of molecular biology: the uncovering of the enzymatic and microbiologic techniques that produce recombinant DNA. Recombinant DNA technology involves the enzymatic manipulation of DNA and, subsequently, the cloning of DNA. DNA molecules are cloned for a variety of purposes including safeguarding DNA samples, facilitating sequencing, generating probes, and expressing recombinant proteins in one or more host organisms. DNA can be produced by a number of means, including restricted digestion of an existing vector, PCR, and cDNA synthesis. As DNA cloning techniques have developed over the last quarter century, researchers have moved from studying DNA to studying the functions of proteins, and from cell and animal models to molecular therapies in humans. Expression of recombinant proteins provides a method for analyzing gene regulation, structure, and function. In recent years, the uses for recombinant proteins have expanded to include a variety of new applications, including gene therapy and biopharmaceuticals. The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients.

FUNDAMENTALS OF MOLECULAR AND CELL BIOLOGY

DNA and Heredity

DNA forms a right-handed, double-helical structure that is composed of two antiparallel strands of unbranched polymeric deoxyribonucleotides linked by phosphodiester bonds between the 5' carbon of one deoxyribose moiety to the 3' carbon of the next (Fig. 15-2). DNA is composed of four types of deoxyribonucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). The nucleotides are joined together by phosphodiester bonds. In the double-helical structure deduced by Watson and Crick, the two strands of DNA are complementary to each other.

Figure 15-2. Schematic representation of a DNA molecule forming a double helix. DNA is made of four types of nucleotides, which are linked covalently into a DNA strand. A DNA molecule is composed of two DNA strands held together by hydrogen bonds between the pair bases. The arrowheads at the ends of the DNA strands indicate the polarities of the two strands, which run antiparallel to each other in the DNA molecule. The diagram at the bottom left of the figure shows the DNA molecule straightened out. In reality, the DNA molecule is twisted into a double helix, of which each turn of DNA is made up of 10.4 nucleotide pairs, as shown on the right.

Because of size, shape, and chemical composition, A always pairs with T, and C with G, through the formation of hydrogen bonds between complementary bases that stabilize the double helix.

Recognition of the hereditary transmission of genetic information is attributed to the Austrian monk, Gregor Mendel. His seminal work, ignored upon publication until its rediscovery in 1900, established the laws of segregation and of independent assortment. These two principles established the existence of paired elementary units of heredity and defined the statistical laws that govern them.⁵ DNA was isolated in 1869, and a number of important observations of the inherited basis of certain diseases were made in the early part of the 20th century. Although today it appears easy to understand how DNA replicates, before the 1950s the idea of DNA as the primary genetic material was

not appreciated. The modern era of molecular biology began in 1944 with the demonstration that DNA was the substance that carried genetic information. The first experimental evidence that DNA was genetic material came from simple transformation experiments conducted in the 1940s using *Streptococcus pneumoniae*. One strain of the bacteria could be converted into another by incubating it with DNA from the other, just as the treatment of the DNA with deoxyribonuclease would inactivate the transforming activity of the DNA. Similarly, in the early 1950s, before the discovery of the double-helical structure of DNA, the entry of viral DNA and not the protein into the host bacterium was believed to be necessary to initiate infection by the bacterial virus or bacteriophage. Key historical events concerning genetics are outlined in Table 15-1.

For cells to pass on the genetic material (DNA) to each progeny, the amount of DNA must be doubled. Watson and Crick recognized that the complementary base-pair structure of DNA implied the existence of a template-like mechanism for the copying of genetic material.¹ The transfer of DNA material from the mother cell to daughter cells takes place during somatic cell division (also called *mitosis*). Before a cell divides, DNA must be precisely duplicated. During replication, the two strands of DNA separate, and each strand creates a new complementary strand by precise base-pair matching (Fig. 15-3). The two, new, double-stranded DNAs carry the same genetic information, which can then be passed on to two daughter cells. Proofreading mechanisms ensure that the replication process occurs in a highly accurate manner. The fidelity of DNA replication is absolutely crucial to maintaining the integrity of the genome from generation to generation. However, mistakes can still occur during this process, resulting in *mutations*, which may lead to a change of the DNA's encoded protein and, consequently, a change of the cell's behavior. The reliable dependence of many features of modern organisms on subtle changes in genome is linked to Mendelian inheritance and also contributes to the processes of Darwinian evolution. In addition, massive changes, so-called *genetic instability*, can occur in the genome of somatic cells such as cancer cells.

Gene Regulation

Living cells have the necessary machinery to enzymatically transcribe DNA into RNA and translate the mRNA into protein. This machinery accomplishes the two major steps required for gene expression in all organisms: transcription and translation (Fig. 15-4). However, gene regulation is far more complex, particularly in eukaryotic organisms. For example, many gene transcripts must be spliced to remove the intervening sequences. The sequences that are spliced off are called *introns*, which appear to be useless, but in fact may carry some regulatory information. The sequences that are joined together, and are eventually translated into protein, are called *exons*. Additional regulation of gene expression includes modification of mRNA, control of mRNA stability, and its nuclear export into cytoplasm (where it is assembled into ribosomes for translation). After mRNA is translated into protein, the levels and functions of the proteins can be further regulated posttranslationally. However, the following sections will mainly focus on gene regulation at transcriptional and translational levels.

Transcription. Transcription is the enzymatic process of RNA synthesis from DNA.⁶ In bacteria, a single RNA polymerase carries out all RNA synthesis, including that of mRNA, rRNA,

Table 15-1

Historical events in genetics and molecular biology

YEAR	INVESTIGATOR	EVENT
1865	Mendel	Laws of genetics established
1869	Miescher	DNA isolated
1905	Garrod	Human inborn errors of metabolism
1913	Sturtevant	Linear map of genes
1927	Muller	X-rays cause inheritable genetic damage
1928	Griffith	Transformation discovered
1941	Beadle and Tatum	“One gene, one enzyme” concept
1944	Avery, MacLeod, McCarty	DNA as material of heredity
1950	McKlinton	Existence of transposons confirmed
1953	Watson and Crick	Double-helical structure of DNA
1957	Benzer and Kornberg	Recombination and DNA polymerase
1966	Nirenberg, Khorana, Holley	Genetic code determined
1970	Temin and Baltimore	Reverse transcriptase
1972	Cohen, Boyer, Berg	Recombinant DNA technology
1975	Southern	Transfer of DNA fragments from sizing gel to nitrocellulose (Southern blot)
1977	Sanger, Maxim, Gilbert	DNA sequencing methods
1982	—	GenBank database established
1985	Mullis	Polymerase chain reaction
1986	—	Automated DNA sequencing
1989	Collins	Cystic fibrosis gene identified by positional cloning and linkage analysis
1990	—	Human Genome Project initiated
1997	Roslin Institute	Mammalian cloning (Dolly)
2001	IHGSC and Celera Genomics	Draft versions of human genome sequence published
2003	—	Human Genome Project completed

IHGSC = International Human Genome Sequencing Consortium.

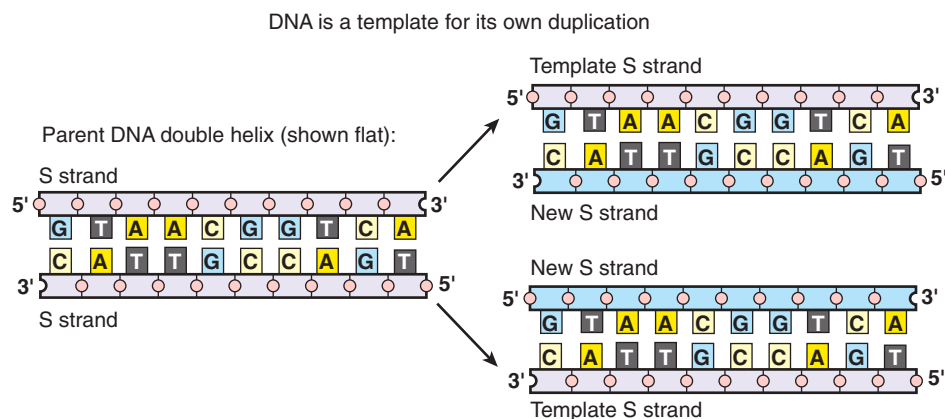

Figure 15-3. DNA replication. As the nucleotide A only pairs with T, and G with C, each strand of DNA can determine the nucleotide sequence in its complementary strand. In this way, double-helical DNA can be copied precisely.

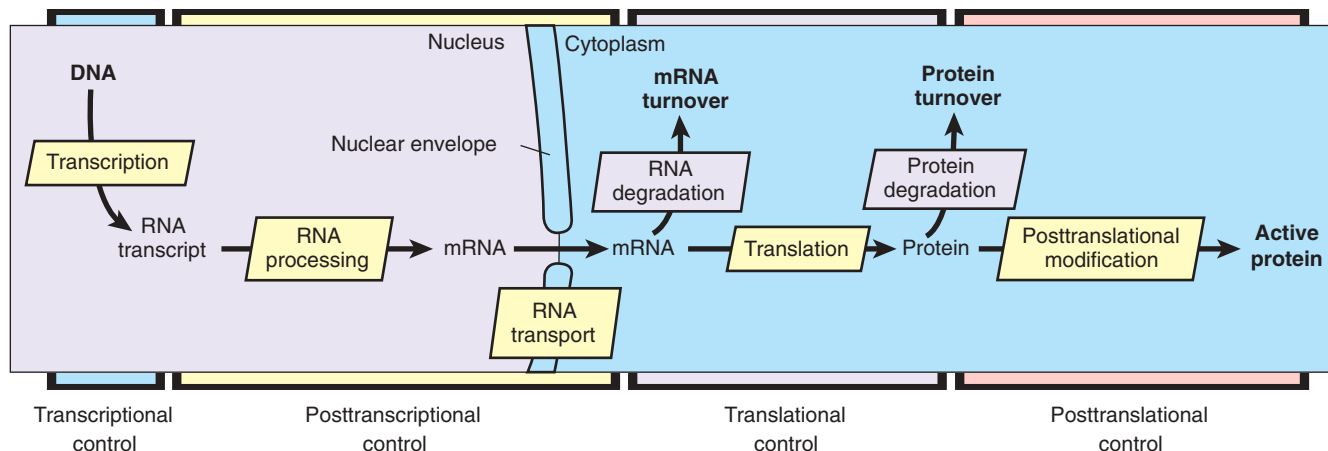

Figure 15-4. Four major steps in the control of eukaryotic gene expression. Transcriptional and posttranscriptional control determine the level of messenger RNA (mRNA) that is available to make a protein, while translational and posttranslational control determine the final outcome of functional proteins. Note that posttranscriptional and posttranslational controls consist of several steps.

and tRNA. Transcription often is coupled with translation in such a way that an mRNA molecule is completely accessible to ribosomes, and bacterial protein synthesis begins on an mRNA molecule even while it is still being synthesized. Therefore, a discussion of gene regulation with a look at the simpler prokaryotic system precedes that of the more complex transcription and posttranscriptional regulation of eukaryotic genes.

Transcription in Bacteria Initiation of transcription in prokaryotes begins with the recognition of DNA sequences by RNA polymerase. First, the bacterial RNA polymerase catalyzes RNA synthesis through loose binding to any region in the double-stranded DNA and then through specific binding to the *promoter* region with the assistance of accessory proteins called σ factors (sigma factors). A promoter region is the DNA region upstream of the transcription initiation site. RNA polymerase binds tightly at the promoter sites and causes the double-stranded DNA structure to unwind. Consequently, few nucleotides can be base-paired with the DNA template to begin transcription. Once transcription begins, the σ factor is released. The growing RNA chain may begin to peel off as the chain elongates. This occurs in such a way that there are always about 10 to 12 nucleotides of the growing RNA chains that are base-paired with the DNA template.

The bacterial promoter contains a region of about 40 bases that include two conserved elements called *-35 region* and *-10 region*. The numbering system begins at the initiation site, which is designated +1 position, and counts backward (in negative numbers) on the promoter and forward on the transcribed region. Although both regions on different promoters are not the same sequences, they are fairly conserved and very similar. This conservation provides the accurate and rapid initiation of transcription for most bacterial genes. It is also common in bacteria that one promoter serves to transcribe a series of clustered genes, called an *operon*. A single transcribed mRNA contains a series of coding regions, each of which is later independently translated. In this way, the protein products are synthesized in a coordinated manner. Most of the time, these proteins are involved in the same metabolic pathway, thus demonstrating that the control by one operon is an efficient system. After initiation of transcription, the polymerase moves along the DNA to elongate the chain of RNA, although at a certain point, it will stop. Each step of RNA synthesis, including initiation,

elongation, and termination, will require the integral functions of RNA polymerase as well as the interactions of the polymerase with regulatory proteins.

Transcription in Eukaryotes Transcription mechanisms in eukaryotes differ from those in prokaryotes. The unique features of eukaryotic transcription are as follows: (a) Three separate RNA polymerases are involved in eukaryotes: RNA polymerase I transcribes the precursor of 5.8S, 18S, and 28S rRNAs; RNA polymerase II synthesizes the precursors of mRNA as well as microRNA; and RNA polymerase III makes tRNAs and 5S rRNAs. (b) In eukaryotes, the initial transcript is often the precursor to final mRNAs, tRNAs, and rRNAs. The precursor is then modified and/or processed into its final functional form. RNA splicing is one type of processing to remove the noncoding introns (the region between coding exons) on an mRNA. (c) In contrast to bacterial DNA, eukaryotic DNA often is packaged with histone and nonhistone proteins into chromatin. Transcription will only occur when the chromatin structure changes in such a way that DNA is accessible to the polymerase. (d) RNA is made in the nucleus and transported into cytoplasm, where translation occurs. Therefore, unlike bacteria, eukaryotes undergo uncoupled transcription and translation.

Eukaryotic gene transcription also involves the recognition and binding of RNA polymerase to the promoter DNA. However, the interaction between the polymerase and DNA is far more complex in eukaryotes than in prokaryotes. Because the majority of studies have been focused on the regulation and functions of proteins, this chapter primarily focuses on how protein-encoding mRNA is made by RNA polymerase II.

Translation. DNA directs the synthesis of RNA; RNA in turn directs the synthesis of proteins. Proteins are variable-length polypeptide polymers composed of various combinations of 20 different amino acids and are the working molecules of the cell. The process of decoding information on mRNA to synthesize proteins is called *translation* (see Fig. 15-1). Translation takes place in ribosomes composed of rRNA and ribosomal proteins. The numerous discoveries made during the 1950s made it easy to understand how DNA replication and transcription involve base-pairing between DNA and DNA or DNA and RNA. However, at that time, it was still impossible to comprehend how mRNA transfers the information to the protein-synthesizing machinery. The genetic information on mRNA is composed of

arranged sequences of four bases that are transferred to the linear arrangement of 20 amino acids on a protein. Amino acids are characterized by a central carbon unit linked to four side chains: an amino group ($-\text{NH}_2$), a carboxy group ($-\text{COOH}$), a hydrogen, and a variable ($-\text{R}$) group. The amino acid chain is assembled via peptide bonds between the amino group of one amino acid and the carboxy group of the next. Because of this decoding, the information carried on mRNA relies on tRNA. Translation involves all three RNAs. The precise transfer of information from mRNA to protein is governed by *genetic code*, the set of rules by which codons are translated into an amino acid (Table 15-2). A *codon*, a triplet of three bases, codes for one amino acid. In this case, random combinations of the four bases form $4 \times 4 \times 4$, or 64 codes. Because 64 codes are more than enough for 20 amino acids, most amino acids are coded by more than one codon. The start codon is AUG, which also corresponds to methionine; therefore, almost all proteins begin with this amino acid. The sequence of nucleotide triplets that follows the start codon signal is termed the *reading frame*. The codons on mRNA are sequentially recognized by tRNA adaptor proteins. Specific enzymes termed *aminoacyl-tRNA synthetases* link a specific amino acid to a specific tRNA. The translation of mRNA to protein requires the ribosomal complex to move stepwise along the mRNA until the initiator methionine sequence is identified. In concert with various protein initiator factors, the methionyl-tRNA is positioned on the mRNA and protein synthesis begins. Each new amino acid is added sequentially by the appropriate tRNA in conjunction with proteins called

elongation factors. Protein synthesis proceeds in the amino-to-carboxy-terminus direction.

The biologic versatility of proteins is astounding. Among many other functions, proteins serve as enzymes that catalyze critical biochemical reactions, carry signals to and from the extracellular environment, and mediate diverse signaling and regulatory functions in the intracellular environment. They also transport ions and various small molecules across plasma membranes. Proteins make up the key structural components of cells and the extracellular matrix and are responsible for cell motility. The unique functional properties of proteins are largely determined by their structure (Fig. 15-5).

Regulation of Gene Expression. The human organism is made up of a myriad of different cell types that, despite their vastly different characteristics, contain the same genetic material. This cellular diversity is controlled by the *genome* and is accomplished by tight regulation of gene expression. This leads to the synthesis and accumulation of different complements of RNA and, ultimately, to the proteins found in different cell types. For example, muscle and bone express different genes or the same genes at different times. Moreover, the choice of which genes are expressed in a given cell at a given time depends on signals received from its environment. There are multiple levels at which gene expression can be controlled along the pathway from DNA to RNA to protein (see Fig. 15-4). *Transcriptional control* refers to the mechanism for regulating when and how often a gene is transcribed. Splicing of the primary RNA transcript (*RNA processing control*) and selection of completed

A = adenine; C = cytosine; G = guanine; U = uracil; Ala = alanine; Arg = arginine; Asn = asparagine; Asp = aspartic acid; Cys = cysteine; Glu = glutamic acid; Gln = glutamine; Gly = glycine; His = histidine; Ile = isoleucine; Leu = leucine; Lys = lysine; Met = methionine; Phe = phenylalanine; Pro = proline; Ser = serine; Thr = threonine; Trp = tryptophan; Tyr = tyrosine; Val = valine. Letter in [] indicates single letter code for amino acid.

Figure 15-5. Maturation of a functional protein. Although the linear amino acid sequence of a protein often is shown, the function of a protein also is controlled by its correctly folded three-dimensional structure. In addition, many proteins also have covalent posttranslational modifications such as phosphorylation or noncovalent binding to a small molecule or a protein.

mRNAs for nuclear export (*RNA transport control*) represent additional potential regulatory steps. The mRNAs in the cytoplasm can be selectively translated by ribosomes (*translational control*) or selectively stabilized or degraded (*mRNA degradation control*). Finally, the resulting proteins can undergo selective activation, inactivation, or compartmentalization (*protein activity control*).

Because a large number of genes are regulated at the transcriptional level, regulation of gene transcripts (i.e., mRNA) often is referred to as *gene regulation* in a narrow definition. Each of the steps during transcription is properly regulated in eukaryotic cells. Because genes are differentially regulated from one another, one gene can be differentially regulated in different cell types or at different developmental stages. Therefore, gene regulation at the level of transcription is largely context dependent. However, there is a common scheme that applies to transcription at the molecular level (Fig. 15-6). Each gene promoter possesses unique sequences called *TATA boxes* that can be recognized and bound by a large complex containing RNA polymerase II, forming the basal transcription machinery. Usually located upstream of the TATA box (but sometimes longer distances) are a number of regulatory sequences referred to as *enhancers* that are recognized by regulatory proteins called *transcription factors*. These transcription factors specifically bind to the enhancers, often in response to environmental or developmental cues, and cooperate with each other and with basal transcription factors to initiate transcription. Regulatory sequences that negatively regulate the initiation of transcription also are present on the promoter DNA. The transcription factors that bind to these sites are called *repressors*, in contrast to the *activators* that activate transcription. The molecular interactions

Figure 15-6. Transcriptional control by RNA polymerase. DNA is packaged into a chromatin structure. TATA = the common sequence on the promoter recognized by TBP and polymerase II holoenzyme; TBP = TATA-binding protein and associated factors; TF = hypothetical transcription factor; TFBS = transcription factor binding site; ball-shaped structures = nucleosomes. Coactivator or corepressor is a factor linking the TF with the Pol II complex.

between transcription factors and promoter DNA, as well as between the cooperative transcription factors, are highly regulated and context-dependent. Specifically, the recruitment of transcription factors to the promoter DNA occurs in response to physiologic signals. A number of structural motifs in these DNA-binding transcription factors facilitate this recognition and interaction. These include the helix-turn-helix, the homeodomain motif, the zinc finger, the leucine zipper, and the helix-loop-helix motifs.

Human Genome

Genome is a collective term for all genes present in one organism. The human genome contains DNA sequences of 3 billion base pairs, carried by 23 pairs of chromosomes. The human genome has an estimated 25,000 to 30,000 genes, and overall it is 99.9% identical in all people.^{7,8} Approximately 3 million locations where single-base DNA differences exist have been identified and termed *single nucleotide polymorphisms*. Single nucleotide polymorphisms may be critical determinants of human variation in disease susceptibility and responses to environmental factors.

The completion of the human genome sequence in 2003 represented another great milestone in modern science. The Human Genome Project created the field of *genomics*, which is the study of genetic material in detail (see Fig. 15-1). The medical field is building on the knowledge, resources, and technologies emanating from the human genome to further the understanding of the relationship of the genes and their mutations to human health and disease. This expansion of genomics into human health applications resulted in the field of genomic medicine.

The emergence of genomics as a science will transform the practice of medicine and surgery in this century. This breakthrough has allowed scientists the opportunity to gain remarkable insights into the lives of humans. Ultimately, the goal is to use this information to develop new ways to treat, cure, or even prevent the thousands of diseases that afflict humankind. In the 21st century, work will begin to incorporate the information embedded in the human genome sequence into surgical practices. By doing so, the genomic information can be used for diagnosing and predicting disease and disease susceptibility. Diagnostic tests can be designed to detect errant genes in patients suspected of having particular diseases or of being at risk for developing them. Furthermore, exploration into the function of each human gene is now possible, which will shed

light on how faulty genes play a role in disease causation. This knowledge also makes possible the development of a new generation of therapeutics based on genes. Drug design is being revolutionized as researchers create new classes of medicines based on a reasoned approach to the use of information on gene sequence and protein structure function rather than the traditional trial-and-error method. Drugs targeted to specific sites in the body promise to have fewer side effects than many of today's medicines. Finally, other applications of genomics will involve the transfer of genes to replace defective versions or the use of gene therapy to enhance normal functions such as immunity.

Proteomics refers to the study of the structure and expression of proteins as well as the interactions among proteins encoded by a human genome (see Fig. 15-1).⁹ A number of Internet-based repositories for protein sequences exist, including Swiss-Prot (www.expasy.ch). These databases allow comparisons of newly identified proteins with previously characterized sequences to allow prediction of similarities, identification of splice variants, and prediction of membrane topology and posttranslational modifications. Tools for proteomic profiling include two-dimensional gel electrophoresis, time-of-flight mass spectrometry, matrix-assisted laser desorption/ionization, and protein microarrays. *Structural proteomics* aims to describe the three-dimensional structure of proteins that is critical to understanding function. *Functional genomics* seeks to assign a biochemical, physiologic, cell biologic, and/or developmental function to each predicted gene. An ever-increasing arsenal of approaches, including transgenic animals, RNA interference (RNAi), and various systematic mutational strategies, will allow dissection of functions associated with newly discovered genes. Although the potential of this field of study is vast, it is in its early stages.

It is anticipated that a genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment.¹⁰ For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational identification of therapeutic targets, and thereby not only accelerate drug development, but also lead to new strategies to evaluate therapeutic efficacy and potential toxicity.⁹

Cell Cycle and Apoptosis

Every organism is composed of many different cell types at different developmental stages. Some cell types continue to grow, while some cells stop growing after a developmental stage or resume growth after a break. For example, embryonic stem cells grow continuously, while nerve cells and striated muscle cells stop dividing after maturation. Cell cycle is the process for every cell including DNA replication and protein synthesis, DNA segregation in half, and package DNA and protein in two newly formed cells to enable passage of identical genetic information from one parental cell to two daughter cells. Thus, the cell cycle is the fundamental mechanism to maintain tissue homeostasis. A cell cycle comprises four periods: G_1 (first gap phase before DNA synthesis), S (synthesis phase when DNA replication occurs), G_2 (the gap phase before mitosis), and M (mitosis, the phase when two daughter cells with identical DNA are generated) (Fig. 15-7). After a full cycle, the daughter

Figure 15-7. The cell cycle and its control system. M is the mitosis phase, when the nucleus and the cytoplasm divide; S is the phase when DNA is duplicated; G_1 is the gap between M and S; G_2 is the gap between S and M. A complex of cyclin and cyclin-dependent kinase (CDK) controls specific events of each phase. Without cyclin, CDK is inactive. Different cyclin/CDK complexes are shown around the cell cycle. A, B, D, and E stand for cyclin A, cyclin B, cyclin D, and cyclin E, respectively.

cells enter G_1 again, and when they receive appropriate signals, undergo another cycle, and so on. The machinery that drives cell cycle progression is made up of a group of enzymes called *cyclin-dependent kinases* (CDKs). Cyclin expression fluctuates during the cell cycle, and cyclins are essential for CDK activities and form complexes with CDK. The cyclin A/CDK1 and cyclin B/CDK1 drive the progression for the M phase, while cyclin A/CDK2 is the primary S phase complex. Early G_1 cyclin D/CDK4/6 or late G_1 cyclin E/CDK2 controls the G_1 -S transition. There also are negative regulators for CDK termed *CDK inhibitors*, which inhibit the assembly or activity of the cyclin-CDK complex. Expression of cyclins and CDK inhibitors often is regulated by developmental and environmental factors.

The cell cycle is connected with signal transduction pathways as well as gene expression. Although the S and M phases rarely are subjected to changes imposed by extracellular signals, the G_1 and G_2 phases are the primary periods when cells decide whether or not to move on to the next phase. During the G_1 phase, cells receive green- or red-light signals, S phase entry or G_1 arrest, respectively. Growing cells proliferate only when supplied with appropriate mitogenic growth factors. Cells become committed to entry of the cell cycle only toward the end of G_1 . Mitogenic signals stimulate the activity of early G_1 CDKs (e.g., cyclin D/CDK4) that inhibit the activity of pRb protein and activate the transcription factor called *E2F* to induce the expression of batteries of genes essential for G_1 -S progression. Meanwhile, cells also receive antiproliferative signals such as those from tumor suppressors. These antiproliferative signals also act in the G_1 phase to stop cells' progress into the S phase by inducing CKI production. For example, when DNA is damaged, cells will repair the damage before entering the S phase. Therefore, G_1 contains one of the most important checkpoints for cell cycle progression. If the analogy is made that CDK is to a cell as an engine is to a car, then cyclins and CKI are the gas pedal and brake, respectively. Accelerated proliferation or

Figure 15-8. A simplified view of the apoptosis pathways. Extracellular death receptor pathways include the activation of Fas and tumor necrosis factor (TNF) receptors and consequent activation of the caspase pathway. Intracellular death pathway indicates the release of cytochrome c from mitochondria, which also triggers the activation of the caspase cascade. During apoptosis, cells undergo DNA fragmentation and nuclear and cell membrane breakdown and are eventually digested by other cells.

improper cell cycle progression with damaged DNA would be disastrous. Genetic gain-of-function mutations in oncogenes (that often promote expression or activity of the cyclin/CDK complex) or loss-of-function mutations in tumor suppressor (that stimulate production of CKI) are causal factors for malignant transformation.

In addition to cell cycle control, cells use genetically programmed mechanisms to kill cells. This cellular process, called *apoptosis* or *programmed cell death*, is essential for the maintenance of tissue homeostasis (Fig. 15-8).

Normal tissues undergo proper apoptosis to remove unwanted cells, those that have completed their jobs or have been damaged or improperly proliferated. Apoptosis can be activated by many physiologic stimuli such as death receptor signals (e.g., Fas or cytokine tumor necrosis factor), growth factor deprivation, DNA damage, and stress signals. Two major pathways control the biochemical mechanisms governing apoptosis: the death receptor and mitochondrial. However, recent advances in apoptosis research suggest an interconnection of the two pathways. What is central to the apoptotic machinery is the activation of a cascade of proteinases called caspases. Similar to CDK in the cell cycle, activities and expression of caspases are well controlled by positive and negative regulators. The complex machinery of apoptosis must be tightly controlled. Perturbations of this process can cause neoplastic transformation or other diseases.

Signal Transduction Pathways

Gene expression in a genome is controlled in a temporal and spatial manner, at least in part by signaling pathways.¹¹ A signaling pathway generally begins at the cell surface and, after a signaling relay by a cascade of intracellular effectors, ends up in the nucleus (Fig. 15-9). All cells have the ability to sense changes in their external environment. The bioactive substances to which cells can respond are many and include proteins, short peptides, amino acids, nucleotides/nucleosides, steroids, retinoids, fatty acids, and dissolved gases. Some of these substances are lipophilic and thereby can cross the plasma membrane by

Figure 15-9. Cell-surface and intracellular receptor pathways. Extracellular signaling pathway: Most growth factors and other hydrophilic signaling molecules are unable to move across the plasma membrane and directly activate cell-surface receptors such as G-protein-coupled receptors and enzyme-linked receptors. The receptor serves as the receiver and in turn activates the downstream signals in the cell. Intracellular signaling pathway: Hormones or other diffusible molecules enter the cell and bind to the intracellular receptor in the cytoplasm or in the nucleus. Either extracellular or intracellular signals often reach the nucleus to control gene expression.

diffusion to bind to a specific target protein within the cytoplasm (intracellular receptor). Other substances bind directly with a transmembrane protein (cell-surface receptor). Binding of ligand to receptor initiates a series of biochemical reactions (*signal transduction*) typically involving protein-protein interactions and the transfer of high-energy phosphate groups, leading to various cellular end responses.

Control and specificity through simple protein-protein interactions—referred to as *adhesive interactions*—is a common feature of signal transduction pathways in cells.¹² Signaling also involves catalytic activities of signaling molecules, such as protein kinases/phosphatases, that modify the structures of key signaling proteins. Upon binding and/or modification by upstream signaling molecules, downstream effectors undergo a conformational (allosteric) change and, consequently, a change in function. The signal that originates at the cell surface and is relayed by the cytoplasmic proteins often ultimately reaches the transcriptional apparatus in the nucleus. It alters the DNA binding and activities of transcription factors that directly turn genes on or off in response to the stimuli. Abnormal alterations in signaling activities and capacities in otherwise normal cells can lead to diseases such as cancer.

Advances in biology in the last two decades have dramatically expanded the view on how cells are wired with signaling pathways. In a given cell, many signaling pathways operate simultaneously and crosstalk with one another. A cell generally may react to a hormonal signal in a variety of ways: (a) by changing its metabolite or protein, (b) by generating an electric current, or (c) by contracting. Cells continually are subject to multiple input signals that simultaneously and sequentially activate multiple receptor- and non-receptor-mediated signal transduction pathways, which form a signaling network. Although the regulators responsible for cell behavior are rapidly identified as a result of genomic and proteomic techniques, the specific functions of the individual proteins, how they assemble, and the networks that control cellular behavior remain to be defined. An increased understanding of cell regulatory pathways—and how they are disrupted in disease—will likely reveal common themes based on protein interaction domains that direct associations of proteins with other polypeptides, phospholipids, nucleic acids, and other regulatory molecules. Advances in the understanding of signaling networks will require methods of investigation that move beyond traditional “linear” approaches into medical informatics and computational biology. The bewildering biocomplexity of such networks mandates multidisciplinary and transdisciplinary research collaboration. The vast amount of information that is rapidly emerging from genomic and proteomic data mining will require the development of new modeling methodologies within the emerging disciplines of medical mathematics and physics.

Signaling pathways often are grouped according to the properties of signaling receptors. Many hydrophobic signaling molecules are able to diffuse across plasma membranes and directly reach specific cytoplasmic targets. Steroid hormones, thyroid hormones, retinoids, and vitamin D are examples that exert their activity upon binding to structurally related receptor proteins that are members of the *nuclear hormone receptor superfamily*. Ligand binding induces a conformational change that enhances transcriptional activity of these receptors. Most extracellular signaling molecules interact with transmembrane protein receptors that couple ligand binding to intracellular signals, leading to biologic actions.

There are three major classes of cell-surface receptors: *transmitter-gated ion channels*, *seven-transmembrane G-protein-coupled receptors (GPCRs)*, and *enzyme-linked receptors*. The superfamily of GPCRs is one of the largest families of proteins, representing over 800 genes of the human genome. Members of this superfamily share a characteristic seven-transmembrane configuration. The ligands for these receptors are diverse and include hormones, chemokines, neurotransmitters, proteinases, inflammatory mediators, and even sensory signals such as odorants and photons. Most GPCRs signal through *heterotrimeric G proteins*, which are guanine-nucleotide regulatory complexes. Thus, the receptor serves as the receiver, the G protein serves as the transducer, and the enzyme serves as the effector arm. *Enzyme-linked receptors* possess an extracellular ligand-recognition domain and a cytosolic domain that either has intrinsic enzymatic activity or directly links with an enzyme. Structurally, these receptors usually have only one transmembrane-spanning domain. Of at least five forms of enzyme-linked receptors classified by the nature of the enzyme activity to which they are coupled, the growth factor receptors such as tyrosine kinase receptor or serine/threonine kinase receptors mediate diverse cellular events including cell growth, differentiation, metabolism, and survival/apoptosis. Dysregulation (particularly mutations) of these receptors is thought to underlie conditions of abnormal cellular proliferation in the context of cancer. The following sections will further review two examples of growth factor signaling pathways and their connection with human diseases.

Insulin Pathway and Diabetes.¹³ The discovery of insulin in the early 1920s is one of the most dramatic events in the treatment of human disease. *Insulin* is a peptide hormone that is secreted by the β -cell of the pancreas. Insulin is required for the growth and metabolism of most mammalian cells, which contain cell-surface insulin receptors (InsR). Insulin binding to InsR activates the kinase activity of InsR. InsR then adds phosphoryl groups, a process referred to as *phosphorylation*, and subsequently activates its immediate intracellular effector, called *insulin receptor substrate (IRS)*. IRS plays a central role in coordinating the signaling of insulin by activating distinct signaling pathways, the PI3K-Akt pathway and MAPK pathway, both of which possess multiple protein kinases that can control transcription, protein synthesis, and glycolysis (Fig. 15-10).

The primary physiologic role of insulin is in glucose homeostasis, which is accomplished through the stimulation of glucose uptake into insulin-sensitive tissues such as fat and skeletal muscle. Defects in insulin synthesis/secretion and/or responsiveness are major causal factors in diabetes, one of the leading causes of death and disability in the United States, affecting an estimated 16 million Americans. Type 2 diabetes accounts for about 90% of all cases of diabetes. Clustering of type 2 diabetes in certain families and ethnic populations points to a strong genetic background for the disease. More than 90% of affected individuals have insulin resistance, which develops when the body is no longer able to respond correctly to insulin circulating in the blood. Although relatively little is known about the biochemical basis of this metabolic disorder, it is clear that the insulin-signaling pathways malfunction in this disease. It is also known that genetic mutations in the InsR or IRS cause type 2 diabetes, although which one is not certain. The majority of type 2 diabetes cases may result from defects in downstream-signaling components in the insulin-signaling pathway.

Figure 15-10. Insulin-signaling pathway. Insulin is a peptide growth factor that binds to and activates the heterotetrameric receptor complex (InsR). InsR possesses protein tyrosine kinase activity and is able to phosphorylate the downstream insulin receptor substrate (IRS). Phosphorylated IRS serves as a scaffold and controls the activation of multiple downstream pathways for gene expression, cell survival, and glucose metabolism. Inactivation of the insulin pathway can lead to type 2 diabetes.

Type 2 diabetes also is associated with declining β -cell function, resulting in reduced insulin secretion; these pathways are under intense study. A full understanding of the basis of insulin resistance is crucial for the development of new therapies for type 2 diabetes. Furthermore, apart from type 2 diabetes, insulin resistance is a central feature of several other common human disorders, including atherosclerosis and coronary artery disease, hypertension, and obesity.

Transforming Growth Factor- β (TGF- β) Pathway and Cancers.¹⁴ Growth factor signaling controls cell growth, differentiation, and apoptosis. Although insulin and many mitogenic growth factors promote cell proliferation, some growth factors and hormones inhibit cell proliferation. TGF- β is one of them. The balance between mitogens and TGF- β plays an important role in controlling the proper pace of cell cycle progression. The growth inhibition function of TGF- β signaling in epithelial cells plays a major role in maintaining tissue homeostasis.

The TGF- β superfamily comprises a large number of structurally related growth and differentiation factors that act through a receptor complex at the cell surface (Fig. 15-11). The complex consists of transmembrane serine/threonine kinases. The receptor signals through activation of heterotrimeric complexes of intracellular effectors called SMADs (which are contracted from homologous *Caenorhabditis elegans* Sma and *Drosophila* Mad, two evolutionarily conserved genes for TGF- β signaling). Upon phosphorylation by the receptors, SMAD complexes translocate into the nucleus, where they bind to gene promoters and cooperate with specific transcription factors to regulate the expression of genes that control cell proliferation and differentiation. For example, TGF- β strongly induces the transcription

Figure 15-11. TGF- β signaling pathway. The TGF- β family has at least 29 members encoded in the human genome. They are also peptide growth factors. Each member binds to a heterotetrameric complex consisting of a distinct set of type I and type II receptors. TGF- β receptors are protein serine/threonine kinases and can phosphorylate the downstream substrates called *SMAD proteins*. Phosphorylated SMADs are directly transported into the nucleus, where they bind to the DNA and regulate gene expression that is responsible for inhibition of cell proliferation. Inactivation of the TGF- β pathway through genetic mutations in the TGF- β receptors or SMADs is frequent in human cancer, leading to the uncontrolled proliferation of cancer cells.

of a gene called *p15^{INK4B}* (a type of CKI) and, at the same time, reduces the expression of many oncogenes such as *c-Myc*. The outcome of the altered gene expression leads to the inhibition of cell cycle progression. Meanwhile, the strength and duration of TGF- β signaling is fine-tuned by a variety of positive or negative modulators, including protein phosphatases. Therefore, controlled activation of TGF- β signaling is an intrinsic mechanism for cells to ensure controlled proliferation.

Resistance to TGF- β 's anticancer action is one hallmark of human cancer cells. TGF- β receptors and SMADs are identified as tumor suppressors. The TGF- β signaling circuit can be disrupted in a variety of ways and in different types of human tumors. Some lose TGF- β responsiveness through downregulation or mutations of their TGF- β receptors. The cytoplasmic SMAD4 protein, which transduces signals from ligand-activated TGF- β receptors to downstream targets, may be eliminated through mutation of its encoding gene. The locus encoding cell cycle inhibitor *p15^{INK4B}* may be deleted. Alternatively, the immediate downstream target of its actions, cyclin-dependent kinase 4 (CDK4), may become unresponsive to the inhibitory actions of *p15^{INK4B}* because of mutations that block *p15^{INK4B}* binding. The resulting cyclin D/CDK4 complexes constitutively inactivate tumor suppressor pRb by hyperphosphorylation. Finally, functional pRb, the end target of this pathway, may be lost through mutation of its gene. For example, in pancreatic and colorectal cancers, 100% of cells derived from these cancers carry genetic defects in the TGF- β signaling pathway. Therefore, the antiproliferative pathway converging onto pRb

and the cell division cycle is, in one way or another, disrupted in a majority of human cancer cells. Besides cancer, dysregulation of TGF- β signaling also has been associated with other human diseases such as Marfan's syndrome and thoracic aortic aneurysm.

Gene Therapy and Molecular Drugs in Cancer

Modern advances in the use of molecular biology to manipulate genomes have greatly contributed to the understanding of the molecular basis for how cells live, die, or differentiate. Given the fact that human diseases arise from improper changes in the genome, the continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. Although significant hurdles remain, the course toward therapeutic application of molecular biology already has been mapped out by many proof-of-principle studies in the literature. In this section, cancer is used as an example to elaborate some therapeutic applications of molecular biology. Modern molecular medicine includes gene therapy and molecular drugs that target genes or gene products within human cells.

Cancer is a complex disease, involving uncontrolled growth and spread of tumor cells (Fig. 15-12). Cancer development depends on the acquisition and selection of specific characteristics that set the tumor cell apart from normal somatic cells. Cancer cells have defects in regulatory circuits that govern normal cell proliferation and homeostasis. Many lines of evidence indicate that tumorigenesis in humans is a multistep process and that these steps reflect genetic alterations that drive the progressive transformation of normal human cells into highly malignant derivatives. The genomes of tumor cells are invariably altered at multiple sites, having suffered disruption through lesions as subtle as point mutations and as obvious as changes in chromosome complement. A succession of genetic changes, each conferring one or another type of growth advantage, leads to the progressive conversion of normal human cells into cancer cells.

Cancer research in the past 20 years has generated a rich and complex body of knowledge, revealing cancer to be a disease involving dynamic changes in the genome. The causes of cancer include genetic predisposition, environmental influences, infectious agents, and aging. These transform normal cells into cancerous ones by derailing a wide spectrum of regulatory pathways including signal transduction pathways, cell cycle machinery, or apoptotic pathways.^{15,16} The early notion that cancer was caused by mutations in genes critical for the control of cell growth implied that genome stability is important for preventing oncogenesis. There are two classes of cancer genes in which alteration has been identified in human and animal cancer cells: oncogenes, with dominant gain-of-function mutations, and tumor suppressor genes, with recessive loss-of-function mutations. In normal cells, oncogenes promote cell growth by activating cell cycle progression, whereas tumor suppressors counteract oncogenes' functions. Therefore, the balance between oncogenes and tumor suppressors maintains a well-controlled state of cell growth.

During the development of most types of human cancer, cancer cells can break away from primary tumor masses, invade adjacent tissues, and hence travel to distant sites where they form new colonies. This spreading process of tumor cells, called *metastasis*, is the cause of 90% of human cancer deaths. Metastatic cancer cells that enter the bloodstream can reach virtually all tissues of the body. Bones are one of the most common places for these cells to settle and start growing again. Bone

Figure 15-12. Tumor clonal evolution and metastasis. A tumor develops from mutant cells with multiple genetic mutations. Through repeated alterations in the genome, mutant epithelial cells are able to develop into a cluster of cells (called a *tumor clone*) that proliferates in an uncontrollable fashion. Further changes in the genome can transform the tumor cells into a population of cells that can enter the blood vessels and repopulate in a new location.

metastasis is one of the most frequent causes of pain in people with cancer. It also can cause bones to break and create other symptoms and problems for patients.

The progression in the knowledge of cancer biology has been accelerating in recent years. All of the scientific knowledge

acquired through hard work and discovery has made it possible for cancer treatment and prevention. As a result of explosive new discoveries, some modern treatments were developed. The success of these therapies, together with traditional treatments such as surgical procedures, is further underscored by the fact that in 2002 the cancer rate was reduced in the United States. Current approaches to the treatment of cancer involve killing cancer cells with toxic chemicals, radiation, or surgery. Alternatively, several new biologic- and gene-based therapies are aimed at enhancing the body's natural defenses against invading cancers. Understanding the biology of cancer cells has led to the development of designer therapies for cancer prevention and treatment. Gene therapy, immune system modulation, genetically engineered antibodies, and molecularly designed chemical drugs are all promising fronts in the war against cancer.

Immunotherapy. The growth of the body is controlled by many natural signals through complex signaling pathways. Some of these natural agents have been used in cancer treatment and have been proven effective for fighting several cancers through the clinical trial process. These naturally occurring biologic agents, such as interferons, interleukins, and other cytokines, can now be produced in the laboratory. These agents, as well as the synthetic agents that mimic the natural signals, are given to patients to influence the natural immune response agents either by directly altering the cancer cell growth or by acting indirectly to help healthy cells control the cancer. One of the most exciting applications of immunotherapy has come from the identification of certain tumor targets called *antigens* and the aiming of an antibody at these targets. This was first used as a means of localizing tumors in the body for diagnosis and was more recently used to attack cancer cells. Trastuzumab (Herceptin) is an example of such a drug.¹⁷ Trastuzumab is a monoclonal antibody that neutralizes the mitogenic activity of cell-surface growth factor receptor HER-2, which is overexpressed in approximately 25% of breast cancers. HER-2–overexpressing tumors tend to grow faster and generally are more likely to recur than tumors that do not overproduce HER-2. Trastuzumab is designed to attack cancer cells that overexpress HER-2 by slowing or preventing the growth of these cells, resulting in increased survival of HER-2–positive breast cancer patients. Another significant example is the administration of interleukin-2 (IL-2) to patients with metastatic melanoma or kidney cancer, which has been shown to mediate the durable regression of metastatic cancer. IL-2, a cytokine produced by human helper T lymphocytes, has a wide range of immune regulatory effects, including the

expansion of lymphocytes following activation by a specific antigen. Although IL-2 has no direct impact on cancer cells, the impact of IL-2 on cancers *in vivo* derives from its ability to expand lymphocytes with antitumor activity. The expanded lymphocyte pool enables recognition of the antigen on cancer cells. Thus, the molecular identification of cancer antigens has opened new possibilities for the development of effective immunotherapies for patients with cancer. Clinical studies using immunization with peptides derived from cancer antigens have shown that high levels of lymphocytes with antitumor activity can be produced in cancer-bearing patients. Highly avid antitumor lymphocytes can be isolated from immunized patients and grown *in vitro* for use in cell-transfer therapies.

Chemotherapy. The primary function of anticancer chemicals is to block different steps involved in cell growth and replication. These chemicals often block a critical chemical reaction in a signal transduction pathway or during DNA replication or gene expression. For example, STI571, also known as *Gleevec*, is one of the first molecularly targeted drugs based on the changes that cancer causes in cells.¹⁸ STI571 offers promise for the treatment of chronic myeloid leukemia (CML) and may soon surpass interferon- γ as the standard treatment for the disease. In CML, STI571 is targeted at the Bcr-Abl kinase, an activated oncogene product in CML (Fig. 15-13). Bcr-Abl is an overly activated protein kinase resulting from a specific genetic abnormality generated by chromosomal translocation that is found in the cells of patients with CML. STI571-mediated inhibition of Bcr-Abl kinase activity not only prevents cell growth of Bcr-Abl–transformed leukemic cells, but also induces apoptosis. Clinically, the drug quickly corrects the blood cell abnormalities caused by the leukemia in a majority of patients, achieving a complete disappearance of the leukemic blood cells and the return of normal blood cells. Additionally, the drug appears to have some effect on other cancers including certain brain tumors and gastrointestinal (GI) stromal tumors, a very rare type of stomach cancer.

Gene Therapy. Gene therapy is an experimental treatment that involves genetically altering a patient's own tumor cells or lymphocytes (cells of the immune system, some of which can attack cancer cells). For years, the concept of gene therapy has held promise as a new, potentially potent weapon to attack cancer. Although a rapid progression in the understanding of the molecular and clinical aspects of gene therapy has been witnessed in the past decade, gene therapy treatment has not yet been shown to be superior to standard treatments in humans.

Figure 15-13. Mechanism of STI571 as a molecular drug. Bcr-Abl is an overly activated oncogene product resulting from a specific genetic abnormality generated by chromosomal translocation that is found in cells of patients with chronic myeloid leukemia. Bcr-Abl is an activated protein kinase and thus requires adenosine triphosphate (ATP) to phosphorylate substrates, which in turn promote cell proliferation. STI571 is a small molecule that competes with the ATP-binding site and thus blocks the transfer of phosphoryl group to substrate. PO₄ = phosphate; Tyr = tyrosine.

Several problems must be resolved to transform it into a clinically relevant form of therapy. The major issues that limit its translation to the clinic are improving the selectivity of tumor targeting, improving the delivery to the tumor, and the enhancement of the transduction rate of the cells of interest. In most gene therapy trials for malignant diseases, tumors can be accessed and directly injected (in situ gene therapy). In situ gene therapy also offers a better distribution of the vector virus throughout the tumor. Finally, a combination of gene therapy strategies will be more effective than the use of a single gene therapy system. An important aspect of effective gene therapy involves the choice of appropriate genes for manipulation. Genes that promote the production of messenger chemicals or other immune-active substances can be transferred into the patient's cells. These include genes that inhibit cell cycle progression, induce apoptosis, enhance host immunity against cancer cells, block the ability of cancer cells to metastasize, and cause tumor cells to undergo suicide. Recent development of RNAi technology, which uses a loss-of-function approach to block gene functions, ensures a new wave of hopes for gene therapy. Nonetheless, gene therapy is still experimental and is being studied in clinical trials for many different types of cancer. The mapping of genes responsible for human cancer is likely to provide new targets for gene therapy in the future. The preliminary results of gene therapy for cancer are encouraging, and as advancements are made in the understanding of the molecular biology of human cancer, the future of this rapidly developing field holds great potential for treating cancer.

It is noteworthy that the use of multiple therapeutic methods has proven more powerful than a single method. The use of chemotherapy after surgery to destroy the few remaining cancerous cells in the body is called *adjuvant* therapy. Adjuvant therapy was first tested and found to be effective in breast cancer. It was later adopted for use in other cancers. A major discovery in chemotherapy is the advantage of multiple chemotherapeutic agents (known as *combination* or *cocktail chemotherapy*) over single agents. Some types of fast-growing leukemias and lymphomas (tumors involving the cells of the bone marrow and lymph nodes) responded extremely well to combination chemotherapy, and clinical trials led to gradual improvement of the drug combinations used. Many of these tumors can be cured today by combination chemotherapy. As cancer cells carry multiple genetic defects, the use of combination chemotherapy, immunotherapy, and gene therapies may be more effective in treating cancers.

Stem Cell Research

Stem cell biology represents a cutting-edge scientific research field with potential clinical applications.¹⁹ It may have an enormous impact on human health by offering hope for curing human diseases such as diabetes mellitus, Parkinson's disease, neurologic degeneration, and congenital heart disease. Stem cells are endowed with two remarkable properties (Fig. 15-14). First, stem cells can proliferate in an undifferentiated but pluripotent state and, as a result, can self-renew. Second, they have the ability to differentiate into many specialized cell types. There are two groups of stem cells: embryonic stem (ES) cells and adult stem cells.

Human ES cells (hESCs) are derived from early preimplantation embryos called *blastocysts* (5 days postfertilization) and are capable of generating all differentiated germ layers in the body by chimera assays or 2-D/3-D differentiation in a

Figure 15-14. Stem cells. A stem cell is capable of self-renewal (unlimited cell cycle) and differentiation (becoming nondividing cells with specialized functions). Differentiating stem cells often undergo additional cell divisions before they become fully mature cells that carry out specific tissue functions.

dish—ectoderm, mesoderm, and endoderm—and therefore are considered pluripotent. There are two pluripotent states associated with hESCs, one of which is the classic culture with bFGF (basic fibroblast growth factor) and knock out replacer (KSR), termed as “primed” pluripotent state. More recently, “naive” hESC culture methods have been introduced based on mouse studies, by supplementing 2i inhibitors (MEK1 and GSK3 β inhibitors) into the medium in addition to bFGF.

Adult stem cells are present in and can be isolated from adult tissues. They often are tissue specific and only can generate the cell types comprising a particular tissue in the body; therefore, they are considered multipotent. However, in some cases, they can transdifferentiate into cell types found in other tissues, called transdifferentiation. For example, hematopoietic stem cells are adult stem cells. They reside in bone marrow and are capable of generating all cell types of the blood and immune system. Another example is mesenchymal stem cells (MSCs), which is initially identified in the bone marrow (BM) to support hematopoietic stem cell homeostasis. In addition to BM, MSCs are also present in adipose tissue, umbilical cord, placenta, amniotic fluid, dental pulp, skeletal muscle, tendons, and synovial, etc., and are reported to obtain the ability to differentiate into osteogenic, chondrogenic, and adipogenic lineages *in vitro*. Due to their characteristics of easy acquisition (from adipose tissue, for example), strong *ex vivo* proliferation, immunomodulatory function, and ability to migrate to damaged tissue, MSCs have been utilized in regenerative medicine.

Stem cells can be grown in culture and be induced to differentiate into a particular cell type, either *in vitro* or *in vivo*. With the recent and continually increasing improvement in culturing stem cells, scientists are beginning to understand the molecular mechanisms of stem cell self-renewal and differentiation in response to environmental cues. It is believed that discovery of the signals that control self-renewal vs differentiation will be extremely important for the therapeutic use of stem cells in treating disease. It is possible that success in the study of the changes in signal transduction pathways in stem cells will lead to the development of therapies to replace diseased or damaged cells in the body using stem cell derivatives. Recently, stem cell research has been transformed by the discovery from the Shinya Yamanaka group and the James Thomson group, who have found that a simple genetic manipulation can reprogram adult differentiated cells back into pluripotent stem cells.^{20,21} This exciting discovery not only bypasses the ethical issues of using early embryos to generate ES cells, but also ensures a

potentially limitless source of patient-specific stem cells for tissue engineering and regenerative medicine.

The Atomic Theory of Disease²²

As early as the 5th century B.C., the ancient Greek Democritus first proposed that matter is composed of indivisible particles called “atoms.” In the 17th and 18th centuries, Isaac Newton described the expansion of gases as rushed atoms into empty space. The existence of atoms was doubted until the discovery of subatomic particles in the 20th century, which demonstrated that the atom was actually divisible into protons, neutrons, and electrons.

Over 100 years after this discovery, direct impacts from utilizing subatomic particles were revealed. This began with the discovery of the X-ray. The most advanced and well-applied atomic technologies include accurate imaging such as X-ray computed tomography (CT) scan, magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT), and positron emission tomography (PET). Additional applications include radiation oncology, which utilizes ionizing particles to treat malignant diseases by inducing double-strand DNA breaks resulting in programmed cell death.

The staggering advances in anatomy, physiology, and molecular biology over the past centuries have led us to our current state in which the atom is now the anatomy of the 21st century. As 99% of the body is composed of six elements (oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus), the next great advance in medicine will be bridging the subatomic, molecular, and genomic levels by forming an atomic theory of disease, which states that alterations in the composition of subatomic particles are the root cause of disease. The atomic theory of disease would include genetic alterations at the atomic/subatomic level that are akin to single nucleotide polymorphisms (SNPs), in which alleles for a gene differ on the exact nucleotide in a single location, which can change the ultimate protein structure. This can lead to subtle changes in function or dramatic results that cause pathology. We hypothesize that on a subatomic level, there could potentially be polymorphisms as well, in which there are subtle changes in the sea of subatomic particles. Isotopes, discovered 100 years ago, would fall into this category of subatomic polymorphism, as they differ in the number of neutrons present in the atom. Differences in other particles may not change the mass of the atom, but may alter some of the characteristics of the atom. This is where the basic human variations originate because an atomic polymerism would result in particular genetic change. Remarkably, somatic point mutations of *KRAS* and *P53* are caused by a single proton shift in cytosine, which is known as tautomerization of cytosine. In turn, the tautomerized cytosine binds with adenine, and not guanine, thus leading to point mutations in *KRAS* and *P53*, which are well known driver mutations for many cancers. This is another example of alterations in subatomic particles that directly cause disease.

A known example of a change in the subatomic milieu of an element leading to a disease process is that of methemoglobinemia, a disorder characterized by an overabundance of methemoglobin. Methemoglobin contains an oxidized form of iron (carrying an extra electron), as opposed to the reduced form in normal hemoglobin. This results in a shift in the oxygen-hemoglobin dissociation curve to the left, causing hypoxia. Methemoglobinemia can be congenital, due to a defect in an enzyme that normally reduces methemoglobin back to hemoglobin, or

acquired, caused by breakdown products of drugs that can oxidize hemoglobin. Although there is less than 1% of methemoglobin normally present in human tissues, affecting local blood flow and inflammation through its effects on nitric oxide and heme, large quantities can lead to respiratory failure and death.

Another example would be exposure to external energy such as radiation that leads to instability of nuclear genome. In Chernobyl and Fukushima, radiolabeled food was metabolized and incorporated into body cells and decay to emit gamma radiation, causing DNA damage. This radiation damage occurs primarily at a subatomic level from a radiobiologic point of view with a direct or indirect ionization of atoms. The clinical results depend on the tissue characteristics and the equilibrium between the damage applied to normal and diseased tissues.

TECHNOLOGIES OF MOLECULAR AND CELL BIOLOGY

DNA Cloning

Since the advent of recombinant DNA technology three decades ago, hundreds of thousands of genes have been identified. Recombinant DNA technology is the technology that uses advanced enzymatic and microbiologic techniques to manipulate DNA.²³ Pure pieces of any DNA can be inserted into bacteriophage DNA or other carrier DNA such as plasmids to produce recombinant DNA in bacteria. In this way, DNA can be reconstructed, amplified, and used to manipulate the functions of individual cells or even organisms. This technology, often referred to as *DNA cloning*, is the basis of all other DNA analysis methods. It is only with the awesome power of recombinant DNA technology that the completion of the Human Genome Project was possible. It also has led to the identification of the entire gene complements of organisms such as viruses, bacteria, worms, flies, and plants.

Molecular cloning refers to the process of cloning a DNA fragment of interest into a DNA vector that ultimately is delivered into bacterial or mammalian cells or tissues^{24,25} (Fig. 15-15). This represents a very basic technique that is widely used in almost all areas of biomedical research. DNA vectors often are called *plasmids*, which are extrachromosomal molecules of DNA that vary in size and can replicate and be transmitted from bacterial cell to cell. Plasmids can be propagated either in the cytoplasm or after insertion, as part of the bacterial chromosome in *Escherichia coli*. The process of molecular cloning involves several steps of manipulation of DNA. First, the vector plasmid DNA is cleaved with a restriction enzyme to create compatible ends with the foreign DNA fragment to be cloned. The vector and the DNA fragment are then joined *in vitro* by a DNA ligase. Alternatively, DNA cloning can be simply done through the so-called *Gateway Technology* that allows for the rapid and efficient transfer of DNA fragments between different cloning vectors while maintaining reading frame and orientation, without the use of restriction endonucleases and DNA ligase. The technology, which is based on the site-specific recombination system of bacteriophage λ , is simple, fast, robust, and automatable and thus compatible for high-throughput DNA cloning.

Finally, the ligation product or the Gateway reaction product is introduced into competent host bacteria; this procedure is called *transformation*, which can be done by either calcium/heat shock or electroporation. Precautions must be taken in every step of cloning to generate the desired DNA construct.

Figure 15-15. Generation of recombinant DNA. The vector is a circular DNA molecule that is capable of replicating in *Escherichia coli* cells. Insert DNA (often your favorite gene) is ligated to the vector after ends of both DNA are properly treated with restriction enzymes. Ligated DNA (i.e., the recombinant plasmid DNA) is then transformed into *E. coli* cells, where it replicates to produce recombinant progenies. *E. coli* cells carrying the recombinant plasmid can be propagated to yield large quantities of plasmid DNA.

The vector must be correctly prepared to maximize the creation of recombinants; for example, it must be enzymatically treated to prevent self-ligation. Host bacteria must be made sufficiently competent to permit the entry of recombinant plasmids into cells. The selection of desired recombinant plasmid-bearing *E. coli* normally is achieved by the property of drug resistance conferred by the plasmid vectors. The plasmids encoding markers provide specific resistance to (i.e., the ability to grow in the presence of) antibiotics such as ampicillin, kanamycin, and tetracycline. The foreign component in the plasmid vector can be a mammalian expression cassette, which can direct expression of foreign genes in mammalian cells. The resulting plasmid vector can be amplified in *E. coli* to prepare large quantities of DNA for its subsequent applications such as transfection, gene therapy, transgenics, and knockout mice.

Detection of Nucleic Acids and Proteins

Southern Blot Hybridization. Southern blotting refers to the technique of transferring DNA fragments from an electrophoresis gel to a membrane support and the subsequent analysis of the fragments by hybridization with a radioactively or chemiluminescently labeled probe (Fig. 15-16).²⁶ Southern blotting is named after E. M. Southern, who in 1975 first described the technique of DNA analysis. It enables reliable and efficient analysis of size-fractionated DNA fragments in an immobilized membrane support. Southern blotting is composed of several steps. It normally begins with the digestion of the DNA samples with appropriate restriction enzymes, which will discriminate wild-type and mutant DNA by size and the separation of DNA samples in an agarose gel by electrophoresis with appropriate DNA size markers, called the DNA ladder. The DNA gel is stained with a dye, usually ethidium bromide, and photographed with a ruler laid alongside the gel so that band positions can later be identified on the membrane. The DNA gel then is treated so the DNA fragments are denatured (i.e., strand separation). The DNA then is transferred onto a nitrocellulose membrane by capillary diffusion or under electricity. After immobilization, the DNA can be subjected to hybridization analysis, enabling bands with sequence similarity to a radioactively or chemiluminescently labeled probe to be identified.

The development of Southern transfer and the associated hybridization techniques made it possible for the first time to obtain information about the physical organization of single and multicopy sequences in complex genomes. The later application of Southern blotting hybridization to the study of restriction fragment length polymorphisms opened up new possibilities

such as genetic fingerprinting and prenatal diagnosis of genetic diseases.

Northern Blot Hybridization. Northern blotting refers to the technique of size fractionation of RNA in a gel and the transferring of an RNA sample to a solid support (membrane) in such a manner that the relative positions of the RNA molecules are maintained. The resulting membrane then is hybridized with a labeled probe complementary to the mRNA of interest. Signals generated from detection of the membrane can be used to determine the size and abundance of the target RNA. In principle,

Figure 15-16. Southern blotting. Restriction enzymatic fragments of DNA are separated by agarose gel electrophoresis, transferred to a membrane filter, and then hybridized to a radioactive probe.

Northern blot hybridization is similar to Southern blot hybridization (and hence its name), with the exception that RNA, not DNA, is on the membrane. Although reverse-transcriptase PCR has been used in many applications (described in the next section, “Polymerase Chain Reaction”), Northern analysis is the only method that provides information regarding mRNA size and has remained a standard method for detection and quantitation of mRNA. The process of Northern hybridization involves several steps, as does Southern hybridization, including electrophoresis of RNA samples in an agarose-formaldehyde gel, transfer to a membrane support, and hybridization to a radioactively labeled DNA probe. Data from hybridization allow

quantification of steady-state mRNA levels and, at the same time, provide information related to the presence, size, and integrity of discrete mRNA species. Thus, Northern blot analysis, also termed *RNA gel blot analysis*, commonly is used in molecular biology studies relating to gene expression.

Polymerase Chain Reaction. PCR is an *in vitro* method for the polymerase-directed amplification of specific DNA sequences using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA (Fig. 15-17).²⁷ One cycle of PCR reaction involves template denaturation, primer annealing, and the extension of

Figure 15-17. Amplification of DNA using the polymerase chain reaction (PCR) technique. Knowledge of the DNA sequence to be amplified is used to design two synthetic DNA oligonucleotides, each complementary to the sequence on one strand of the DNA double helix at opposite ends of the region to be amplified. These oligonucleotides serve as primers for *in vitro* DNA synthesis, which is performed by a DNA polymerase, and they determine the segment of the DNA that is amplified. **A.** PCR starts with a double-stranded DNA, and each cycle of the reaction begins with a brief heat treatment to separate the two strands (*Step 1*). After strand separation, cooling of the DNA in the presence of a large excess of the two primer DNA oligonucleotides allows these primers to hybridize to complementary sequences in the two DNA strands (*Step 2*). This mixture is then incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that DNA is synthesized, starting from the two primers (*Step 3*). The entire cycle is then begun again by a heat treatment to separate the newly synthesized DNA strands. **B.** As the procedure is performed over and over again, the newly synthesized fragments serve as templates in their turn, and, within a few cycles, the predominant DNA is identical to the sequence bracketed by and including the two primers in the original template. Of the DNA put into the original reaction, only the sequence bracketed by the two primers is amplified because there are no primers attached anywhere else. In the example illustrated in **B**, three cycles of reaction produce 16 DNA chains, eight of which (boxed in brown) are the same length as and correspond exactly to one or the other strand of the original bracketed sequence shown at the far left; the other strands contain extra DNA downstream of the original sequence, which is replicated in the first few cycles. After three more cycles, 240 of the 256 DNA chains correspond exactly to the original bracketed sequence, and after several more cycles, essentially all of the DNA strands have this unique length.

the annealed primers by DNA polymerase. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies nearly doubles at each cycle. Thus, a repeated series of cycles result in the exponential accumulation of a specific fragment in which the termini are sharply defined by the 5' ends of the primers. The introduction of the thermostable DNA polymerase (e.g., Taq polymerase) transforms the PCR into a simple and robust reaction. The reaction components (e.g., template, primers, Taq polymerase, 2'-deoxynucleoside 5'-triphosphates, and buffer) could all be assembled and the amplification reaction carried out by simply cycling the temperatures within the reaction tube. The specificity and yield in amplifying a particular DNA fragment by PCR reaction are affected by the proper setting of the reaction parameters (e.g., enzyme, primer, and Mg^{2+} concentration, as well as the temperature cycling profile). Modifying various PCR parameters to optimize the specificity of amplification yields more homogenous products, even in rare template reactions.

The emergence of the PCR technique has dramatically altered the approach to both fundamental and applied biologic problems. The capability of amplifying a specific DNA fragment from a gene or the whole genome greatly advances the study of the gene and its function. It is simple, yet robust, speedy, and most of all, flexible. As a recombinant DNA tool, it underlies almost all of molecular biology. This revolutionary technique enabled the modern methods for the isolation of genes, construction of a DNA vector, introduction of alterations into DNA, and quantitation of gene expression, making it a fundamental cornerstone of genetic and molecular analysis.

Immunoblotting and Immunoprecipitation. Analyses of proteins are primarily carried out by antibody-directed immunologic techniques. For example, Western blotting, also called *immunoblotting*, is performed to detect protein levels in a population of cells or tissues, whereas immunoprecipitation is used to concentrate proteins from a larger pool. Using specific antibodies, microscopic analysis called *immunofluorescence* and *immunohistochemistry* is possible for the subcellular localization and expression of proteins in cells or tissues, respectively.

Immunoblotting refers to the process of identifying a protein from a mixture of proteins (Fig. 15-18). It consists of five steps: (a) sample preparation; (b) electrophoresis (separation of a protein mixture by sodium dodecyl sulfate-polyacrylamide gel electrophoresis); (c) transfer (the electrophoretic transfer of proteins from gel onto membrane support [e.g., nitrocellulose, nylon, or polyvinylidene difluoride]); (d) staining (the subsequent immunodetection of target proteins with specific antibody); and (e) development (colorimetric, chemiluminescent, and recently fluorescent visualization of the antibody-recognized protein). Thus, immunoblotting combines the resolution of gel electrophoresis with the specificity of immunochemical detection. Immunoblotting is a powerful tool used to determine a number of important characteristics of proteins. For example, immunoblotting analysis will determine the presence and the quantity of a protein in a given cellular condition and its relative molecular weight. Immunoblotting also can be used to determine whether posttranslational modification such as phosphorylation has occurred on a protein. Importantly, through immunoblotting analysis, a comparison of the protein levels and modification states in normal vs diseased tissues is possible.

Figure 15-18. Immunoblotting. Proteins are prepared from cells or tissues, separated according to size by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a membrane filter. Detection of a protein of interest can be done by sequential incubation with a primary antibody directed against the protein, and then with an enzyme-conjugated secondary antibody that recognizes the primary antibody. Visualization of the protein is carried out by using colorimetric or luminescent substrates for the conjugated enzyme.

Immunoprecipitation, another widely used immunochemical technique, is a method that uses antibody to enrich a protein of interest and any other proteins that are associated with it (Fig. 15-19). The principle of the technique lies in the property of a strong and specific affinity between antibodies and their antigens to locate and pull down target proteins in solution. Once the antibody-antigen (target protein) complexes are formed in the solution, they are collected and purified using small agarose beads with covalently attached protein A or protein G. Both protein A and protein G specifically interact with the antibodies,

Figure 15-19. Immunoprecipitation. Proteins prepared from cells or tissues can be enriched using an antibody directed against them. The antibody is first conjugated to agarose beads and then incubated with protein mixture. Due to the specific high-affinity interaction between antibody and its antigen (the protein), the antigen-antibody complex can be collected on beads by centrifugation. The immunoprecipitated protein can then be analyzed by immunoblotting. Alternatively, if proteins are radiolabeled in cells or tissues, detection of immunoprecipitated proteins can be achieved by simple sodium dodecyl sulfate-polyacrylamide gel electrophoresis followed by autoradiography.

thus forming a large immobilized complex of antibody-antigen bound to beads. The purified protein can then be analyzed by a number of biochemical methods. When immunoprecipitation is combined with immunoblotting, it can be used for the sensitive detection of proteins in low concentrations, which would otherwise be difficult to detect. Moreover, combined immunoprecipitation and immunoblotting analysis is very efficient in analyzing the protein-protein interactions or determining the posttranslational modifications of proteins. In addition, immunoprecipitated proteins can be used as preparative steps for assays such as intrinsic or associated enzymatic activities. The success of immunoprecipitation is influenced by two major factors: (a) the abundance of the protein in the original preparation and (b) the specificity and affinity of the antibody for this protein.

Recently, *immunoprecipitation* is even used to enrich modified DNA (for example, 5-methylcytosine) for bisulfite sequencing. Besides proteins of interest, specific antibodies can also be raised against specially modified DNA. Like the protein immunoprecipitation, modified DNA can be pulled down, taking advantage of the specificity and affinity of antibody to antigen.

DNA Microarray. Now that the human genome sequence is completed, the primary focus of biologists is rapidly shifting toward gaining an understanding of how genes function. One of the interesting findings about the human genome is that there are only approximately 25,000 to 30,000 protein-encoding genes. However, it is known that genes and their products function in a complicated and yet orchestrated fashion and that the surprisingly small number of genes from the genome sequence is sufficient to make a human being. Nonetheless, with the tens of thousands of genes present in the genome, traditional methods in molecular biology, which generally work on a one-gene-in-one-experiment basis, cannot generate the whole picture of genome function. In the past several years, a new technology called *DNA microarray* has attracted tremendous interest among biologists as well as clinicians. This technology promises to monitor the whole genome on a single chip so researchers can have a better picture of the interactions among thousands of genes simultaneously.

DNA microarray, also called *gene chip*, *DNA chip*, and *gene array*, refers to large sets of probes of known sequences orderly arranged on a small chip, enabling many

hybridization reactions to be carried out in parallel in a small device (Fig. 15-20).²⁸ Like Southern and Northern hybridization, the underlying principle of this technology is the remarkable ability of nucleic acids to form a duplex between two strands with complementary base sequences. DNA microarray provides a medium for matching known and unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. Microarrays require specialized robotics and imaging equipment that spot the samples on a glass or nylon substrate, carry out the hybridization, and analyze the data generated. DNA microarrays containing different sets of genes from a variety of organisms are now commercially available, allowing biologists to simply purchase the chips and perform hybridization and data collection. The massive scale of microarray experiments requires the aid of computers. They are used during the capturing of the image of the hybridized target, the conversion of the image into usable measures of the extent of hybridization, and the interpretation of the extent of hybridization into a meaningful measure of the amount of the complementary sequence in the target. Some data-analysis packages are available commercially or can be found in the core facility of certain institutions.

DNA microarray technology has produced many significant results in quite different areas of application. There are two major application forms for the technology: identification of sequence (gene/gene mutation) in multiple regions of a genome and determination of expression level (abundance) of large numbers of genes simultaneously. For example, analysis of genomic DNA detects amplifications and deletions found in human tumors. Differential gene expression analysis also has uncovered networks of genes differentially present in cancers that cannot be distinguished by conventional means. Significantly, recent advancements in next-generation sequencing (e.g., Solexa and 454 technology) have demonstrated the precision and speed to analyze gene expression in any genome.

Next-Generation Sequencing.^{29,30} First-generation sequencing, also termed *Sanger's sequencing*, requires a single-stranded DNA template, a specific DNA primer, a DNA polymerase, normal deoxynucleoside triphosphates (dNTPs), and modified dideoxynucleotidetriphosphates (ddNTPs). In the process of DNA sequencing, DNA polymerase adds random dNTP or ddNTP

Figure 15-20. DNA microarrays. DNA microarrays, also referred to as *gene chips*, have arrayed oligonucleotides or complementary DNAs (cDNAs) corresponding to tens or hundreds of distinct genes. DNA microarray is used to comparatively analyze gene expression in different cells or tissues. Messenger RNAs (mRNAs) extracted from different sources are converted into cDNAs, which are then labeled with different fluorescent dyes. The two fluorescent cDNA probes are mixed and hybridized to the same DNA microarrays. The ratio of red to green fluorescence at each spot on the chip represents the relative expression of levels of that gene between two different cells. In the example shown in the figure, cDNA from cell #1 is labeled with red fluorescence and that from cell #2 is labeled with green fluorescence. On the microarray, red spots demonstrate that the gene in the cell sample #1 is expressed at a higher level than the corresponding gene in cell sample #2. The green spots indicate that the gene in the cell sample #2 is expressed at a higher level than the corresponding gene in the cell sample #1. Yellow spots represent equal expression of the gene in both cell samples.

after the primer. If ddNTP is incorporated at the end of the chain, it terminizes the reaction and results in DNA fragments of different sizes. The ddNTPs could be radioactively or fluorescently labeled for auto-machine detection. Usually, Sanger's sequencing is able to read sequence below 1 kb with the quality deteriorating after 700 bp. The accuracy and success rate largely depends on the DNA polymerase used.

Recombinant DNA technology greatly impacts the completion of the Human Genome Project due to the invention of shotgun sequencing, which includes breaking the genome DNA into small pieces and randomly cloning those pieces into DNA vectors that are easily sequenced. Based on the overlapping sequence of each clone, computer analysis can be programmed to map and align the DNA sequence that will ultimately cover the whole human genome.

Based on shotgun sequencing, as the sequencing technologies advance, next-generation sequencing (NGS), also called second-generation sequencing, has become one of the most powerful tools to analyze DNA mutation, identify epigenetic modification, and profile gene expression or ncRNA expression.³¹ The next-generation sequencing process usually includes library construction, sequencing, and data analysis. There are three major NGS platforms: Roche 454, Life Technologies Ion Torrent, and Illumina Solexa. Take the Illumina next-generation sequencing as an example: DNA are shared or digested into small pieces and then used to generate a DNA library with adapters on both ends of each DNA piece. Then, the DNA library is diluted and loaded on a chamber of a slide, called a *lane*, for cluster amplification. Cycled fluorescent deoxyribonucleotide triphosphates (dNTPs) are then added to the chamber to enable DNA polymerization, resulting in different fluorescent emission representing different dNTP reading on different clusters, into a microscope. The fluorescent signal is transformed into sequencing data that will be aligned and mapped to a standard genome database. The advantages of next-generation sequencing include the following: no necessity of DNA cloning; fast and cost-effective; and a huge amount of data to give good depth and accuracy of the sequence.

Based on the applications, the most common next-generation sequencing technologies for whole-genome sequencing are whole-genome DNA sequencing, whole-genome bisulfite sequencing (BS-seq), RNA sequencing (RNA-seq), and chromatin immunoprecipitation (ChIP) sequencing (ChIP-seq). Whole-genome DNA sequencing is purely to sequence the DNA sequence of a genome without any preprocessing of the DNA, reflecting any deletions, replications, and mutations within the genomic DNA. Given that the genomic information for human is enormous, to achieve great depth and accuracy the genome needs to be sequenced multiple times to reach statistic significance and pass quality control. Therefore, whole-genome DNA sequencing is still considered to be costly for diagnosis as well as for research purposes. Under clinical settings, one of the most applied DNA sequencing technologies is whole-exome sequencing, i.e., using techniques to capture and analyze exons in all coding genes, given that most known diseases are due to mutations in spliced-in regions of coding genes. Whole-exome sequencing is mostly used for detecting single nucleotide variants and is less reliable in detecting insertion-deletion variants or small copy number variants.

BS-seq is commonly used to identify DNA methylation on the genome (5-methylcytosine [5mC]). The process always involves a bisulfite treatment of DNA before library

construction, during which the unmethylated cytosine will be transformed to a uracil, resulting in reading as a thymine in data output, whereas 5mC is protected and remains as cytosine in data output. Thus, 5mC and cytosine are distinguished this way. To perform whole-genome BS-seq, the library construction starts with a decent amount of DNA followed by a complete conversion of unmethylated cytosine. Because it is also counted as whole-genome sequencing, a certain depth of data needs to be achieved for accurate and convincing results. To develop an affordable genome-wide DNA methylation analysis, the reduced representation bisulfite sequencing (RRBS) approach has been applied to enrich CpG-dense regions of the genome by digesting genomic DNA using a methylation-insensitive restriction enzyme, usually MspI. This method covers a majority of promoters as well as some repetitive regions in the genome.

RNA-seq is usually performed to analyze transcription for the same purpose as performing a microarray. However, RNA-seq is more accurate and provides more information such as splicing variants than traditional microarray. Usually, cDNA that is reversely transcribed from extracted RNA is used to generate libraries. Depending on the needs, mRNA and ncRNA can be enriched in different protocols for RNA extraction. Currently, techniques have been improved to perform RNA profiling on a single cell level. Single-cell RNA sequencing (scRNA-seq) allows expression analysis of individual cells in a population. One use is to examine heterogeneity in tumor cells. Although low copy number genes are usually poorly detected, scRNA-seq on a large number of cells can reveal rare cell subpopulations and uncommon RNA expression patterns among different subpopulations.

ChIP-seq is always used to map the location of a DNA-binding protein in the genome. Prior to library construction, ChIP is performed to enrich DNA bound by the protein of interest (POI). First, POI and DNA are cross-linked before sonication. Then, a specific antibody is used to pull down POI and attached DNA fragments. After the protein and DNA are reverse cross-linked, DNA is purified to make the ChIP-seq library. If using an antibody against particular transcription factor (TF), DNA sequences bound by this TF are pulled down

and examined. The TF binding consensus sequences is then predicted, and if the TF binds to a promoter region, it is likely that the gene using this promoter is regulated by this TF. If using an antibody against an epigenetic modification, the modified regions are marked up into the genome to facilitate identification of potential epigenetic regulating mechanisms.

By using next-generation sequencing technology, any potential mutations in a patient can be scrutinized as well as any defects in epigenetic modification. By combining data from different kinds of sequencing (DNA-seq, RNA-seq, ChIP-seq), better understanding of mutation or transcription-caused diseases aligning with epigenetic regulation can be achieved, which will greatly facilitate the diagnosis of patients and personalization of medicine in a fast and economic way by preventing unnecessary medical costs and procedures.

Third-generation sequencing has emerged rapidly at the research level to involve single molecule real-time sequencing (SMRT). Although first developed and marketed by Pacific Biosciences (Pac Bio), Roche is now leading this technology. Third-generation sequencing allows amplification-free single-molecule sequencing with read length extension up to megabases and reduced sequencing coverage bias. It can be used to build the gap in the human genome (for example, low complexity regions), provide access to structural genomic variants, and simultaneously analyze genome-wide single-nucleotide methylation. So far, clinical application and research is heavily dependent on NGS, especially standardizing and reducing the cost of post-NGS analysis. Third-generation sequencing is under fast development and has been adapted to aid and append NGS.

Cell Manipulations

Cell Culture. Cell culture has become one of the most powerful tools in biomedical laboratories, as cultured cells are being used in a diversity of biologic fields ranging from biochemistry to molecular and cellular biology.³² Through their ability to be maintained *in vitro*, cells can be manipulated by the introduction of genes of interest (cell transfection) and be transferred into *in vivo* biologic receivers (cell transplantation) to study the biologic effect of the interested genes (Fig. 15-21). In common

Figure 15-21. Cell culture and transfection. **A.** Primary cells can be isolated from tissues and cultured in medium for a limited period of time. After genetic manipulations to overcome the cell aging process, primary cells can be immortalized into cell lines for long-term culture. **B.** DNA can be introduced into cells to produce recombinant gene products or to analyze the biologic functions of the gene.

laboratory settings, cells are cultured either as a monolayer (in which cells grow as one layer on culture dishes), considered 2-D, or in suspension or biomedical material skeleton such as hydrogel, considered 3-D.

It is important to know the wealth of information concerning cell culturing before attempting the procedure. For example, conditions of culture will depend on the cell types to be cultured (e.g., origins of the cells such as epithelial or fibroblasts, or primary vs immortalized/transformed cells). It is also necessary to use a cell type-specific culture medium that varies in combination of growth factors and serum concentrations. If primary cells are derived from human patients or animals, some commercial resources have a variety of culture media available for testing. Generally, cells are manipulated in a sterile hood, and the working surfaces are wiped with 70% to 80% ethyl alcohol solution. Cultured cells are usually maintained in a humidified 5% carbon dioxide incubator at 37°C (98.6°F) to maintain a Ph value ranging from 7.2 ~ 7.4 and need to be examined daily under an inverted microscope to check for possible contamination and confluency (the area cells occupy on the dish). In some cases, cells need to be maintained in hypoxia, and the oxygen input could be reduced to as low as 1%. As a general rule, cells should be fed with fresh medium every 2 to 3 days and split when they reach confluency. Depending on the growth rate of cells, the actual time and number of plates required to split cells in two varies from cell line to cell line. Splitting a monolayer requires the detachment of cells from plates by using a trypsin or collagenase treatment, of which concentration and time period vary depending on cell lines. If cultured cells grow continuously in suspension, they are split or subcultured by dilution.

Because cell lines may change their properties when cultured, it is not possible to maintain cell lines in culture indefinitely. Therefore, it is essential to store cells at various time passages for future use. The common procedure to use is cryopreservation. The solution for cryopreservation is usually fetal calf serum containing 10% dimethyl sulfoxide or glycerol, stored in liquid nitrogen (−196°C [−320.8°F]) for years of preservation. However, the viability and health of cells when thawed will decrease over time even in liquid nitrogen.

Cell Transfection. Cells are cultured for two reasons: to maintain and to manipulate them (see Fig. 15-21). The transfer of foreign macromolecules, such as nucleic acid, into living cells provides an efficient method for studying a variety of cellular processes and functions at the molecular level. DNA transfection has become an important tool for studying the regulation and function of genes. The cDNA to be expressed should be in a plasmid vector, behind an appropriate promoter working in mammalian cells (e.g., the constitutively active cytomegalovirus promoter or inducible promoter). Depending on the cell type, many ways of introducing DNA into mammalian cells have been developed. Commonly used approaches include calcium phosphate, electroporation, liposome-mediated transfection, the nonliposomal formulation, and the use of viral vectors. These methods have shown variable success when attempting to transfect a wide variety of cells. Transfection can be performed in the presence or absence of serum. It is suggested to test the transfection efficiency of cell lines of interest by comparing transfection with several different approaches. For a detailed transfection protocol, it is best to follow the manufacturer's instructions for the particular reagent. General considerations for a successful transfection depend on several parameters, such

as the quality and quantity of DNA and cell culture (type of cell and growth phase). To minimize variations in both of these in transfection experiments, it is best to use cells that are healthy, proliferate well, and are plated at a constant density.

Depending on the transfection method, DNA expression can be transient or stable. Using calcium phosphate and liposome-mediated transfection, after DNA is introduced into the cells it is normally maintained epigenetically in cells and will be diluted while host cells undergo cell division. Therefore, functional assays should be performed 24 to 72 hours after transfection, also termed *transient transfection*. In many applications, it is important to study the long-term effects of DNA in cells by stable transfection. Thus, electroporation and viral vector are often used in these situations to enable integration of ectopic DNA into the host genome. Stable cell clones can be selected when plasmids carry an antibiotic-resistant marker. In the presence of antibiotics, only those cells that continuously carry the antibiotic-resistant marker (after generations of cell division) can survive. One application of stable transfection is the generation of transgenic or knockout mouse models, in which the transgene has to be integrated in the mouse genome in the ES cells, followed by microinjection of those transgenic ES cells into blastocysts to generate chimera mice. Stable cells also can be transplanted into host organs to test the effect of transgenic cells *in vivo*.

Genetic Manipulations

Understanding how genes control the growth and differentiation of the mammalian organism has been the most challenging topic of modern research. It is essential for us to understand how genetic mutations and chemicals lead to the pathologic condition of human bodies. The knowledge and ability to change the genetic program will inevitably make a great impact on society and have far-reaching effects on how we think of ourselves.

The mouse has become firmly established as the primary experimental model for studying how genes control mammalian development. Genetically altered mice are powerful tools to study the function and regulation of genes as well as modeling human diseases.³³ The gene function can be studied by creating mutant mice through homologous recombination (gene knockout). A gene of interest (GOI) also can be introduced into the mouse (transgenic mouse) to study its effect on development or diseases. Because mouse models do not precisely represent human biology, genetic manipulations of human somatic or ES cells provide a great means for the understanding of the molecular networks in human cells in addition to mouse models. In all cases, the gene to be manipulated must first be cloned. Gene cloning has been made easy by recombinant DNA technology and the availability of human and mouse genomes (see “Human Genome”). The following section briefly describes the technologies and the principles behind combining both mouse genetics and human cell culture to explore gene function and disease mechanisms.

Transgenic Mice. During the past 20 years, DNA cloning and other techniques have allowed the introduction of new genetic material into the mouse germline. As early as 1980, the first genetic material was successfully introduced into the mouse germline by using pronuclear microinjection of DNA (Fig. 15-22). These animals, called *transgenic*, contain foreign DNA within their genomes. In simple terms, a transgenic mouse is created by the microinjection of ectopic DNA into the one-celled mouse embryo to induce integration, allowing the

Figure 15-22. Transgenic mouse technology. DNA is microinjected into a pronucleus of a fertilized egg, which is then transplanted into a foster mother. The microinjected egg develops offspring mice. Incorporation of the injected DNA into offspring is indicated by the different coat color of offspring mice.

efficient introduction of cloned genes into the following developing mouse somatic tissues, as well as into the germline.

Designs of a Transgene The transgenic technique has proven to be extremely important for basic investigations of gene regulation, creation of animal models of human disease, and genetic engineering of livestock. The design of a transgene construct is a simple task. Like constructs used in cell transfection, a simple transgene construct consists of a protein-encoding gene and a promoter that precedes it. The most common applications for the use of transgenic mice are similar to those in the cell culture system: (a) to study the functions of proteins encoded by the transgene, (b) to analyze the tissue-specific and developmental-stage-specific activity of a gene promoter, and (c) to generate reporter lines to facilitate biomedical studies. Examples of the first application include overexpression of oncogenes, growth factors, hormones, and other key regulatory genes, as well as genes of viral origins. Overexpression of the transgene normally represents gain-of-function mutations. The tissue distribution or expression of a transgene is determined primarily by *cis*-acting promoter enhancer elements within or in the immediate vicinity of the genes themselves. Thus, controlled expression of the transgene can be made possible by using an inducible or tissue-specific promoter. Furthermore, transgenic mice carrying dominant negative mutations of a regulatory gene also have been generated. For example, a truncated growth factor receptor that can bind to the ligand, but loses its catalytic activity when expressed in mice, can block the growth factor binding to the endogenous protein. In this way, the transgenic mice exhibit a loss of function of phenotype, possibly resembling the knockout of the endogenous gene. The second application of the transgenic expression is to analyze the gene promoter of interest. The gene promoter of interest normally is fused to a reporter gene that encodes β -galactosidase (also called *LacZ*), luciferase, or green fluorescence protein. Chemical staining of *LacZ* activity or detection of chemiluminescence/fluorescence can easily visualize the expression of the reporter gene. The third application originates from the second: when the activity of the promoter is known, a fluorescent reporter gene (such as *GFP*) will be driven by the tissue-specific promoter, therefore labeling a particular type of cells at a particular stage. This application is generally used to isolate a special cell type expressing the *GFP* reporter by fluorescence-activated cell sorting (FACS), as well as lineage-tracing experiments.

Production of Transgenic Mice The success of generating transgenic mice is largely dependent on the proper quality and concentration of the DNA supplied for microinjection. For DNA

to be microinjected into mouse embryos, it should be linearized by restriction digestion to increase the chance of proper transgene integration. Concentration of DNA should be accurately determined. Mice that develop from injected eggs often are termed *founder mice*.

Genotyping of Transgenic Mice The screening of founder mice and the transgenic lines derived from the founders is accomplished by determining the integration of the injected gene into the genome. This normally is achieved by performing PCR or Southern blot analysis with a small amount of DNA extracted from the mouse tail. Once a given founder mouse is identified to be transgenic, it will be mated to begin establishing a transgenic line. Usually, for a given gene, more than one transgenic line is generated to assure that the phenotype is due to transgene but not to the interruption of the gene where the transgene integrates into.

Analysis of Phenotype of Transgenic Mice Phenotypes of transgenic mice are dictated by both the expression pattern and biologic functions of the transgene. Depending on the promoter and the transgene, phenotypes can be predictable or unpredictable. Elucidation of the functions of the transgene-encoded protein *in vitro* often offers some clue to what the protein might function to do *in vivo*. When a constitutively active promoter is used to drive the expression of transgenes, mice should express the gene in every tissue; however, this mouse model may not allow the identification and study of the earliest events in disease pathogenesis. Ideally, the use of tissue-specific or inducible promoter allows one to determine if the pathogenic protein leads to a reversible or irreversible disease process in a cell-autonomous manner. For example, rat insulin promoter can target transgene expression exclusively in the β -cells of pancreatic islets. The phenotype of insulin promoter-mediated transgenic mice is projected to affect the function of human β -cells.

Gene Knockout in Mice. The first recorded knockout mouse was created by Mario R. Capecchi, Sir Martin J. Evans, and Oliver Smithies in 1989. They were awarded the 2007 Nobel Prize in Physiology or Medicine. The isolation and genetic manipulation of mouse ES cells represents one of the most important milestones for modern genetic technologies.³⁴ Several unique properties of ES cells, such as the pluripotency to differentiate into all germ layers in an embryo, including the germline, make them an efficient vehicle to introduce genetic alterations in mice. An important breakthrough from this idea is to generate gene-targeted mutation in mice, first by introducing the targeting vector into the ES cells, allowing selection

Figure 15-23. Knockout mouse technology. Summary of the procedures used for making gene replacements in mice. In the first step (**A**), an altered version of the gene is introduced into cultured embryonic stem (ES) cells. Only a few rare ES cells will have their corresponding normal genes replaced by the altered gene through a homologous recombination event. Although the procedure is often laborious, these rare cells can be identified and cultured to produce many descendants, each of which carries an altered gene in place of one of its two normal corresponding genes. In the next step of the procedure (**B**), these altered ES cells are injected into a very early mouse embryo; the cells are incorporated into the growing embryo, and a mouse produced by such an embryo will contain some somatic cells that carry the altered gene. Some of these mice also will contain germline cells that contain the altered gene. When bred with a normal mouse, some of the progeny of these mice will contain the altered gene in all of their cells. If two such mice are in turn bred (not shown), some of the progeny will contain two altered genes (one on each chromosome) in all of their cells. If the original gene alteration completely inactivates the function of the gene, these mice are known as *knockout mice*. When such mice are missing genes that function during development, they often die with specific defects long before they reach adulthood. These defects are carefully analyzed to help decipher the normal function of the missing gene. (Reproduced with permission from Alberts B, Johnson A, Lewis J, et al: *Molecular Biology of the Cell*, 6th ed. New York, NY: WW Norton Company; 2015.)

for successful homologous recombination in a dish, then introducing the selected ES clone into the blastocysts, and finally recovering animals bearing the mutant allele from the germline (Fig. 15-23). This not only makes mouse genetics a powerful approach to address important gene functions, but also identifies the mouse as a great system to model human disease.

Targeting Vector The basic concept in building a target vector to knock out a gene is to use two segments of homologous

sequence to a GOI that flank a part of the gene essential for functions (e.g., the coding region). In the targeting vector, a positive selectable marker (e.g., the *neo* gene) is placed between the homology arms. Upon the homologous recombination between the arms of the vector and the corresponding genomic regions of the GOI in ES cells, the positive selectable marker will replace the essential segment of the target gene, thus creating a null allele. In addition, a negative selectable marker also can

be used alone or in combination with the positive selectable marker, but must be placed outside of the homologous arms to enrich for homologous recombination. To create a conditional knockout (i.e., gene knockout in a spatiotemporal fashion), site-specific recombinases such as the popular cre-loxP system are used. If the consensus loxP sequences that are recognized by cre recombinases are properly designed into targeting loci, controlled expression of the recombinase as a transgene can result in the site-specific recombination at the right time and in the right place (i.e., cell type or tissue). This method, often referred to as *conditional knockout*, is markedly useful to prevent developmental compensations and to introduce null mutations in the adult mouse that would otherwise be lethal. To bring in additional control to tissue-specific cre, an inducible cre could be adopted on top of the tissue-specific promoter. The most popular inducible cre includes CreER: CreER encodes a cre fused with estrogen receptor located to cytosol. With the signaling of tamoxifen, CreER is released and then translocates into the nucleus to induce the recombination of loxP. Therefore, the timing of recombination could be precisely determined by controlling the time of administering tamoxifen. Overall, this cre-loxP system allows for spatial and temporal control over transgene expression and takes advantage of inducers with minimal pleiotropic effects.

Introduction of the Targeting Vector into ES Cells ES cell lines can be obtained from other investigators or commercial sources or established from blastocyst-stage embryos. To maintain ES cells at their full developmental potential, optimal growth conditions should be provided in culture. If culture conditions are inappropriate or inadequate, ES cells may acquire genetic lesions or alter their gene expression patterns and consequently decrease their pluripotency. Excellent protocols are available in public domains or in mouse facilities in most institutions.

To alter the genome of ES cells, the targeting vector DNA then is transfected into ES cells. Electroporation is the most widely used and the most efficient transfection method for ES cells. Similar procedures for stable cell transfection are used for selecting ES cells that carry the targeting vector. High-quality, targeting-vector DNA free of contaminating chemicals is first linearized and then electroporated into ES cells. Stable ES cells are selected in the presence of a positive selectable antibiotic drug. After a certain period of time and depending on the type of antibiotics, all sensitive cells die, and the resistant cells grow into individual colonies of the appropriate size for subcloning by picking. It is extremely important to minimize the time during which ES cells are in culture between selection and injection into blastocysts. Before injecting the ES cells, DNA is prepared from ES colonies to screen for positive ES cells that exhibit the correct integration or homologous recombination of the targeting vector. Positive ES colonies are then expanded and used for creation of chimeras.

Creation of the Chimera A chimeric organism is one in which cells originate from more than one embryo source. Here, chimeric mice are denoted as those that contain some tissues from the ES cells with an altered genome. When these ES cells give rise to the lineage of the germ layer, the germ cells carrying the altered genome can be passed on to the offspring, thus creating the germline transmission from ES cells. There are two methods for introducing ES cells into preimplantation-stage embryos: injection and aggregation. The injection of embryonic cells

directly into the cavity of blastocysts is one of the fundamental methods for generating chimeras, but aggregation chimeras also have become an important alternative for transmitting the ES cell genome into mice. Since every tissue type of a chimera should contain cells from different origins, the mixture of recognizable markers (e.g., coat color) that are specific to the donor mouse and the ES cells can be used to identify chimeric mice. However, most experimenters probably use existing mouse core facilities already established in some institutions or contract a commercial vendor for the creation of a chimera.

Genotyping and Phenotyping of Knockout Animals The next step is to analyze whether germline transmission of targeted mutation occurs in mice. DNA from a small amount of tissue from offspring of the chimera is extracted and subjected to genomic PCR or Southern blot DNA hybridization. Positive mice (i.e., those with properly integrated targeting vector into the genome) will be used for the propagation of more knockout mice for phenotype analysis. When the knockout genes are crucial for early embryogenesis, mice often die in utero, an occurrence called *embryonic lethality*. When this happens, only the phenotype of the homozygous (both alleles ablated) knockout mouse embryos and the phenotype of the heterozygous (only one allele ablated) adult mice can be studied. Because most researchers are interested in the phenotype of adult mice, in particular when using mice as disease models, it is recommended to create the conditional knockout using the cre-loxP system so that the GOI can be knocked out at will.

To date, more than 5000 genes have been disrupted by homologous recombination and transmitted through the germline. The phenotypic studies of these mice provide ample information about the functions of these genes in growth and differentiation of organisms and during development of human diseases.

RNA Interference. Although gene ablation in animal models provides an important means to understand the in vivo functions of GOI, animal models may not adequately represent human biology. Alternatively, gene targeting can be used to knock out genes in human cells, including human ES cells. Gene targeting in human ES cells by homologous recombination has extremely low efficiency, although there are more new techniques emerging aimed at increasing the targeting efficiency. A number of recent advances have made gene targeting in somatic cells as easy as in murine ES cells.³³ However, gene targeting (knocking out both alleles) in somatic cells is a time-consuming process.

Development of RNAi technology in the past few years has provided a more promising approach to understanding the biologic functions of human genes in human cells.³⁵ RNAi is an ancient natural mechanism by which small, double-stranded RNA (dsRNA) acts as a guide for an enzyme complex that destroys complementary RNA and downregulates gene expression in a sequence-specific manner. Although the mechanism by which dsRNA suppresses gene expression is not entirely understood, experimental data provide important insights. In nonmammalian systems such as *Drosophila*, it appears that longer dsRNA is processed into 21–23 nt dsRNA (called *small interfering RNA* or *siRNA*) by an enzyme called *Dicer* containing RNase III motifs. The siRNA apparently then acts as a guide sequence within a multicomponent nuclease complex to target complementary mRNA for degradation. Because long dsRNA induces a potent antiviral response pathway in mammalian cells, short siRNAs are used to perform gene silencing experiments in mammalian cells (Fig. 15-24).

Figure 15-24. RNA interference in mammalian cells. Small interfering RNA (siRNA) can be produced from a polymerase III–driven expression vector. Such a vector first synthesizes a 19–29 nt double-stranded (ds)RNA stem and a loop (labeled as *shRNA* in the figure), and then the RNase complex called *Dicer* processes the hairpin RNA into a small dsRNA (labeled as *siRNA* in the figure). siRNA can be chemically synthesized and directly introduced into the target cell. In the cell, through RNA-induced silencing complex (RISC), siRNA recognizes and degrades target messenger RNAs (mRNAs).

For siRNA studies in mammalian cells, researchers have used two 21-mer RNAs with 19 complementary nucleotides and 3' terminal noncomplementary dimers of thymidine or uridine. The antisense siRNA strand is fully complementary to the mRNA target sequence. Target sequences for an siRNA are identified visually or by software.

The target 19 nucleotides should be compared to an appropriate genome database to eliminate any sequences with significant homology to other genes. Those sequences that appear to be specific to the GOI are the potential siRNA target sites. A few of these target sites are selected for siRNA design. The antisense siRNA strand is the reverse complement of the target sequence. The sense strand of the siRNA is the same sequence as the target mRNA sequence. A deoxythymidine dimer is routinely incorporated at the 3' end of the sense strand siRNA, although it is unknown whether this noncomplementary dinucleotide is important for the activity of siRNAs.

There are two ways to introduce siRNA to knock down gene expression in human cells:

1. **RNA transfection:** siRNA can be made chemically or using an in vitro transcription method. Like DNA oligos, chemically synthesized siRNA oligos can be commercially ordered. However, synthetic siRNA is expensive, and several siRNAs may have to be tried before a particular gene is successfully silenced. In vitro transcription provides a more economic approach. Both short and long RNA can be synthesized using bacteriophage RNA polymerase T7, T3, or SP6. In the case of long dsRNAs, RNase such as recombinant Dicers will be used to process the long dsRNA into a mixture of 21–23 nt siRNA. siRNA oligos or mixtures can be transfected into a few characterized cell lines such as HeLa (human cervical carcinoma) and 293T cells (human kidney carcinoma). Transfection of siRNA directly into primary cells may be difficult.
2. **DNA transfection:** Expression vectors for expressing siRNA have been made using RNA polymerase III promoters such as U6 and H1. These promoters precisely transcribe a hairpin

structure of dsRNA, which will be processed into siRNA in the cell (see Fig. 15-24). Therefore, properly designed DNA oligos corresponding to the desired siRNA will be inserted downstream of the U6 or H1 promoter. There are two advantages of the siRNA expression vectors over siRNA oligos. First, it is easier to transfect DNA into cells. Second, stable populations of cells can be generated that maintain the long-term silencing of target genes. Furthermore, the siRNA expression cassette can be incorporated into a retroviral or adenoviral vector to provide a wide spectrum of applications in gene therapy.

There has been a fast and fruitful development of RNAi tools for in vitro and in vivo use in mammals. These novel approaches, together with future developments, will be crucial to put RNAi technology to use for effective disease therapy or to exert the awesome power of mammalian genetics. Therefore, the applications of RNAi to human health are enormous. siRNA can be applied as a new tool for sequence-specific regulation of gene expression in functional genomics and biomedical studies. With the availability of the human genome sequences, RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes.

Practical applications of RNAi will possibly result in new therapeutic interventions. In 2002, the concept of using siRNA in battling infectious diseases and carcinogenesis was proven effective. These include notable successes in blocking replication of viruses, such as HIV, hepatitis B virus, and hepatitis C virus, in cultured cells using siRNA targeted at the viral genome or the human gene encoding viral receptors. RNAi has been shown to antagonize the effects of hepatitis C virus in mouse models. In cancers, silencing of oncogenes such as *c-Myc* or *Ras* can slow down the proliferation rate of cancer cells. Finally, siRNA also has potential applications for some dominant genetic disorders.

The 21st century, already heralded as the “century of the gene,” carries great promise for alleviating suffering from disease and improving human health. On the whole, completion of

the human genome blueprint, the promise of gene therapy and molecular therapies, and the existence of stem cells have captured the imagination of the public and the biomedical community. Aside from their potential in curing human diseases, these emerging technologies also have provoked many political, economic, religious, and ethical discussions. As more is discerned about the technologic scientific advances, more attention must also be paid to concerns for their inherent risks and social implications. It is important for surgeons to play a leadership role in the emergence of personalized medicine and surgery, as surgeons have access to the diseased tissues. Surgeons should be establishing collaborations with the genomic and molecular scientists to develop genomic biobanks in order to study the genome and molecular signaling of the disease tissues that will help with an understanding of the underlying cause of an individual's disease and ultimately lead to effective, targeted therapies. Surgeons must take this enormous opportunity to

5▶ collaborate with basic and clinical scientists to develop the field of precision medicine and surgery this century.

Bifunctional RNAi Technology.³⁶ Over the last 20 years, the field has worked to define oncogene and nononcogene addiction, discriminate between driver and passenger genes, and appreciate the complexity of complex, robust, network interactions. These insights have led to a preliminary understanding of therapeutically relevant sensitivity and resistance pathway signal patterns requiring *multiple* target modulation. However, this knowledge has not been effectively or reproducibly clinically translated. Clinical response is usually far greater when a combination of single-target molecular therapy is administered. However, it must also be realized that targeting two or more pathways may also increase the toxicity profile, particularly if target specificity is limited. When attempted, off-target toxicity has been demonstrated with combination small-molecule therapy. In contrast, multitargeting bifunctional short hairpin (bi-shRNA) DNA vectors are designed to limit off-target effect given the high specificity for the genes they are designed to target.

Exogenously applied hairpin constructs can be designed to be incorporated into cleavage-dependent RISC or cleavage-independent RISC complexes, or both. The concept of a bifunctional shRNA³⁷ is to increase knockdown efficiency without loss of sequence specificity by engaging both siRNA and miRNA-like (i.e., common biogenic pathway but complementary to target sequence) RISCs, thereby concurrently activating nucleolytic (Ago2-RISC) and nonnucleolytic (Ago1, 3, 4 ± Ago2-RISC) processes.³⁸ Each bi-shRNA contains both a matched stem sequence to promote Ago2-mediated passenger strand cleavage and a second partial mismatched stem sequence for cleavage-independent passenger strand departure. Thus, functionality of the effectors is set by programmed passenger strand guided RISC loading rather than Ago subset distribution in the cancer cell. Both component Ago2 and Ago (1, 2, 4 ± 3) RNAi moieties are fully complementary to the mRNA target sequence. Preliminary data indicate reduced “off-target effects” by shRNA compared with target-identical siRNAs. More than two mismatches in sequences within the target region drastically reduce knockdown effect to undetectable levels (unpublished results). The design process involves *in silico* scanning of the entire human mRNA RefSeq database to avoid any potential sequence-related “off-target effects.” Published data also indicate persistent susceptibility to shRNA-mediated gene

knockdown despite recent evidence of reduced Dicer expression in human cancer cells.³⁹

The first clinical experience with the bi-shRNA platform involved the *ex vivo* knockdown of furin, a Ca²⁺-dependent, nonredundant proprotein convertase that is essential for proteolytic maturational processing of immunosuppressive TGF- β isoforms (β 1 and β 2). An autologous whole-cell cancer vaccine, FANGTM (*furin-knockdown and GMCSF-augmented*),⁴⁰ was produced based on a dual function immunosensitization principle of augmenting tumor antigen expression, presentation, and processing via granulocyte-macrophage colony-stimulating factor (GMCSF) cytokine transgene expression and attenuating secretory immunosuppressive TGF- β . Harvested, autologous cancer cells are transfected with the GMCSF/bi-shRNA^{furin} (FANG) expression plasmid via electroporation. A phase I clinical trial (BB-IND 14205) involving 52 cancer patients was recently completed. Results demonstrated better than 90% knockdown of the bi-shRNA target, furin, and better than 90% knockdown of furin-regulated proteins TGF- β 1 and TGF- β 2, thereby confirming the mechanistic expectation of this novel RNAi platform. Moreover, predicted extensive GMCSF expression verified our ability to successfully construct multi-cassette vectors with good manufacturing practice techniques fulfilling Food and Drug Administration requirements for clinical testing.

Twenty-seven patients received one or more vaccine dose, and 23 patients achieved stable disease as their best response. No toxic effect was identified. Median survival of the FANGTM-treated patients from time of procurement was 554 days and has not been reached from time of treatment. Expected survival of similar patients is historically less than 1 year. Sequential enzyme-linked immunosorbent spot (ELISPOT) analysis revealed a dramatic and significant increase in immune response from baseline to month 4 in half of the FANGTM-treated patients. Comparison of survival between ELISPOT-positive and ELISPOT-negative patients demonstrated a statistically significant increase in survival from time of procurement ($P = .045$) and time of treatment ($P = .025$).

These phase I study results demonstrated mechanism, safety, and effectiveness of the bi-shRNA technology and clinical functionality of a multitargeting (dual) DNA expression vector. Further utilization of bi-shRNAi technology is under way clinically (targeting STMN1, a microtubule modulation critical to cancer program) and preclinically targeting PDX1⁴¹ (an oncogene-like transcription factor for pancreatic embryogenesis using nonviral nanoparticle delivery mechanisms).⁴²

Precision Medicine and Surgery⁴³

Genes determine our susceptibility to diseases and direct our body's response to medicine. Because an individual's genes differ from those of another, the determination of each individual's genome has the potential to improve the prediction, prevention, and treatment of disease. Sequencing of individual genomes holds the key to realize this revolution called *precision medicine and surgery*. Next-generation sequencing, such as Illumina sequencing and 454 pyrosequencing technology, is promising to reduce the time and cost so that genome sequencing can be affordable within healthcare systems. The goal of precision medicine and surgery is to identify the gene variations in each individual and to target the specific gene variations causing the disease by choosing personalized treatments that effectively work in association with the individual's genomic profile. The importance of surgeons in this transformational field of

biomedical science is that surgeons have access to the diseased tissues on a daily basis. Surgeons should partner with the genomic scientists to develop genomic biobanks in order to study the genome of the disease tissues and determine how this information can improve the outcomes of surgery, i.e., precision surgery. These discovery studies are rapidly leading to the uncovering of mutations and SNPs that are the underlying cause of an individual's disease and ultimately lead to targeted therapies. Although precision medicine and surgery holds the potential to revolutionize the practice of modern medicine, there currently exists a gap between our ability to sequence any given individual's genome and how clinicians can apply this information to guide care. There is a rapidly growing list of single genes that are currently guiding care, and these genes are listed as

6▶ type 1 precision genes. Examples of these genes are *BRCA1*, *RET* proto-oncogene, and *CHD1* mutation, which guide potential use of mastectomy, thyroidectomy, and gastrectomy, respectively; however, the great challenge before the scientific and medical community this century is to learn to use the entire genome to guide precision care.

Targeted Genome Editing Using the CRISPR-Cas9 System

Conventional genetic manipulations have proven their value in biomedical research. Researchers today depend on the manipulation of genetic materials in cells or in animal models in almost every project they work on. These genetic manipulation techniques (see “Genetic Manipulations”), though sufficient for general research purposes, suffer from disadvantages. Transfection of target genes into cells is quick and specific, but nonnative. RNA interference (RNAi) is easy to perform and targets native genes, but RNAi never fully eliminates the target gene, and off-target effects are commonly seen using RNAi. Gene knockout mice provide an ideal platform to study native genes with clean background, but conventional knockout methods are time-consuming and costly.

An entirely new gene-editing method now known as the CRISPR-Cas9 system has emerged since 2013⁴⁴⁻⁴⁶ and has 7▶ quickly gained popularity among biologists for gene editing. This new method is easy to perform, can work specifically on the desired gene or DNA sequence, and can generate gene knockout, knock-in, point mutation, or the insertion of an epitope tag in almost any cell line or animal models with high efficiencies.

CRISPR stands for Clustered Regularly Interspaced Short Palindromic Repeats.⁴⁷ It is a region on the genomic DNA first discovered in the microbes as an adapted immune system against exogenous DNA. A typical CRISPR region contains a cluster of short (21–48 bp) DNA repeats (ranging from 2 to hundreds) interspaced by nonrepetitive sequences called spacers.⁴⁷ Within a CRISPR region, while each spacer has its unique sequence, the sequence of the repeats is highly conserved. Several genes, called the CRISPR-associated (Cas) genes, are almost always found directly flanking the CRISPR region.

Extensive studies in the past decade revealed the function of the CRISPR-cas system in DNA-interfering. When bacteria or archaea carrying the CRISPR-cas system are invaded by phage or plasmid DNA, a new spacer can be added to the CRISPR region with its sequence identical to the “proto-spacer,” a fragment of the invading DNA.⁴⁷ It was found that the proto-spacer must be followed by a recognition sequence (NGG in the case of Cas9) called proto-spacer associated motif

(PAM).⁴⁶ With constitutive transcription, the CRISPR region is transcribed as mRNA, and cut by Cas proteins to generate RNA fragments minimally containing one spacer and parts of the repetitive sequence.⁴⁷ This fragment associates with target DNA through Watson-Crick base-pairing and directs the cutting of target DNA by Cas proteins with nuclease activity.

Several CRISPR-Cas systems have been characterized, with a variety of Cas proteins found in these systems. Cas9 in the type II system from *Streptococcus pyogenes* is the most commonly used Cas for gene editing.^{46,48} Cas9 contains one RuvC-like nuclease domain near its N-terminal and one HNH-like nuclease domain in the middle of the protein. The RuvC-like domain cuts the proto-spacer strand (the strand with PAM), and the HNH-like domain cuts the strand pairing with the spacer,⁴⁹ resulting in a double-strand break (DSB) on the target DNA. It is known that Cas9 cuts a blunt end 3 bp 5' to the PAM sequence.⁴⁶ The specificity provided by the spacer, or so-called “guide RNA,” and the ability of Cas9 to cut double-stranded DNA means that this system can specifically target anywhere in a genome with a known sequence.

CRISPR-Cas9–Guided Gene Editing. The CRISPR-Cas9 system was made suitable for gene editing in mammalian cell lines and in animal models through several years of optimization. The key concept for CRISPR-Cas9–mediated gene editing is to introduce DNA strand break and let the cell repair the break. Through the repair process, sequence deletions, insertions, and mutations can be applied to the target gene.

Two DNA repair pathways are utilized in CRISPR-Cas9–mediated gene editing: the nonhomologous end-joining (NHEJ) pathway and the homology-directed repair (HDR).⁴⁹ When a homologous repair template is unavailable, the NHEJ pathway joins the ends of the DSB together, usually with random insertion/deletion (indel) mutations. Such mutations within an open reading frame can cause frameshift and/or premature stop codons. When a repair template is available, however, the cell may choose HDR and repair the DSB through pairing with the template. The HDR pathway can introduce longer insertion/deletion mutations than NHEJ and can specify the mutated sequence (by contrast, NHEJ creates random mutations). However, HDR is usually only active in dividing cells and is of a lower efficiency than NHEJ. Its efficiency also depends on gene location, cell type, and the repair template.⁵⁰ Therefore, the choice of the pathway depends on the need of the outcome: to simply create a gene knockout, NHEJ is much simpler and highly efficient; to achieve precise gene editing (introduce a specific mutation, add or delete a specific sequence), HDR must be used. The two pathways have similar protocols, but they differ in certain details in experimental designs.

Gene Editing Through NHEJ Tools for NHEJ-mediated gene editing can be incorporated onto one simple plasmid, including a single-guide RNA (sgRNA) sequence containing the guide RNA, a U6 promoter driving the expression of the sgRNA, and an expression cassette including codon-optimized Cas9 fused with nuclear localization sequences (NLS) and an optional selection marker (puromycin resistance or a GFP).⁴⁶ NHEJ is usually used to knock out a target gene (Fig. 15-24). Generally, a 20 bp sequence preceding a PAM sequence (NGG for Cas9) is selected as the guide RNA sequence. This sequence can be chosen within the first couple of exons through running online search engines against the target genome to minimize off-target probabilities. The guide RNA sequence is then inserted into the

Figure 15-25. CRISPR-Cas9–mediated gene editing through NHEJ or HDR. The Cas9 protein cleaves target DNA through its RuvC-like and HNH-like domains, guided by the sgRNA. The cell repairs the double-strand break through either NHEJ or HDR. In NHEJ, the broken ends are recognized, bound, and tethered by end-binding protein complexes. The ends are then processed and ligated but may result in random insertion/deletion (experimentally, deletions are more commonly seen) mutations at the break site. The repair process in HDR, however, generates no random error due to the presence of a homologous repair template. During the repair, the broken strands find the homologous template and proceed with DNA synthesis using the template. This results in a repaired DNA that has the same sequence as the repair template. Therefore, point mutations, insertions, or deletions carried on the template will be inherited by the repaired DNA and thus achieve precise gene editing.

designed site within the sgRNA, and the constructed plasmid is transfected into target cells. Expressed Cas9 proteins would associate with expressed sgRNAs to mediate DSB directed by the guide RNA sequence. For cell lines, pure mutant clones can be generated by separating single colonies. Knockout mutations can be confirmed through PCR amplification of the target region and sequencing. If antibodies against the target protein are available, western blotting can be used as a supplemental method to DNA sequencing results to confirm the knockout of the gene.

Gene Editing Through HDR HDR requires a homologous template to repair the DSB. Therefore, apart from the guide RNA, another sequence homologous to the flanking regions of the DSB needs to be present (Fig. 15-25). The homologous sequence can carry insertions, deletions, and mutations to replace the sequence at the DSB, thus achieving precise gene editing on the target. The homologous sequence can be introduced into the cell either as a template on a plasmid or as a single-stranded oligonucleotide.⁴⁶ After the induction of the DSB, the homologous template pairs with the flanking regions of the DSB and serves as the template for the repair of the break site. HDR happens at lower efficiency than NHEJ and therefore is of lower success rate than NHEJ-mediated gene editing. Therefore, HDR is only recommended when precise mutations are desired. Fast screen of positive mutant clones can be achieved by incorporating restriction enzyme cutting sites within the homologous template.

Reducing Off-Target Effects Using Cas9 Nickase The CRISPR-Cas9 system uses a 20 bp guide RNA for sequence recognition. Due to the similar length of recognition sequence to RNAi techniques, CRISPR-Cas9 system also suffers from off-target effects. Because CRISPR-Cas9 requires a PAM site directly following the guide RNA sequence, one way to reduce off-targets is to run through online databases against the genome of the target cell to select a target sequence with the least number

of possible off-targets (CRISPR-Cas9 system tolerates no more than three mismatches). On the other hand, a mutant version of the Cas9 called *Cas9 nickase* can be used to minimize the risk of off-targets.

As mentioned, Cas9 contains one RuvC-like and one HNH-like nuclease domain, each responsible for cutting one strand.⁴⁹ The D10A mutant Cas9 (Cas9 nickase) lacks the activity of the RuvC-like domain, leaving the proto-spacer strand intact and a nick on the antisense strand.⁴⁶ Using two properly spaced (0–20 bp apart), oppositely oriented guide RNA, the Cas9 nickase will leave two single-strand nicks on both strands in close proximity, creating a double-strand break with 5' overhangs on both strands. This leads to NHEJ or HDR at this breaking site, while other off-target single-strand nicks will be repaired without impact. This strategy doubles the number of base pairs required for site recognition, reducing off-target possibilities almost to zero (from about 1 off-target in 30 million bp to 1 in 1000 trillion bp).

Application of the CRISPR-Cas9 System in Biomedical Sciences The biggest advantage of the CRISPR-Cas9 system is its ability to edit genes in almost any cell type and any animal model with high efficiency and accuracy. Plus, it is easy to design and easy to use. Within a couple of years, successful gene editing in *C. elegans*,⁵¹ zebrafish,⁵² fruit fly,⁵³ mouse,⁵⁴ dogs,⁵⁵ and even nonhuman primates⁵⁶ was achieved. CRISPR-Cas9 was also reported to be successful in a variety of cell types including stem cells.

Currently, CRISPR-Cas9 is most used for editing single genes, through gene knockout, gene mutation, or the addition of an epitope tag to a native gene, for functional characterization of the gene of interest. For example, oncogenes or tumor suppressor genes can be knocked out to identify the causative gene for a particular cancer type; point mutations in functional domains

may illustrate the mechanism of action of a protein; for proteins without available antibodies, epitope tags can be inserted onto the native gene for the detection of the native protein.

Apart from single gene editing, CRISPR-Cas9 can be used for large scale loss-of-function gene screen. Multiple lentiviral guide RNA libraries have been established covering the whole human/mouse genome or particular subsets.

Owing to its ability to bind to specific nucleotide sequences, CRISPR-Cas9 has also been used for non-gene-editing purposes. To achieve this, both the RuvC-like and the HNH-like domains are mutated to give a catalytically inactive Cas9 (dCas9). Directed by guide RNA, this dCas9 can bind to particular genes to reversibly suppress or activate gene transcription by the fusion of transcription activators or suppressors with dCas9. Epigenetic modulators (e.g., DNA methylase) can also be fused with dCas9 to achieve controlled epigenetic modulations. Moreover, dCas9 can also be fused with fluorescent markers such as GFP to track a particular DNA region in live cells.

The most exciting potential application of the CRISPR-Cas9 system is perhaps the correction or modification of disease-causing genes in human embryos or in human patients to eradicate disease-causing genes. However, extension of this application may lead to the creation of the so called “perfect human,” hence raising huge ethical concerns and controversies.⁵⁷ Because of such ethical considerations, gene editing in human embryos should be cautiously conducted. Nonetheless, reports have shown the great potential of this powerful gene-editing technique in correcting gene mutations.⁵⁸⁻⁶⁰

In conclusion, the CRISPR-Cas9 system is the most powerful gene-editing system characterized so far, showing its strong ability to edit genes efficiently and precisely. Its applications greatly benefit biomedical researches and, with a solution to ethical issues, can greatly benefit clinical medicine as well.

INTRODUCTION

The skin is a complex organ encompassing the body's surface and is continuous with the mucous membranes. Accounting for approximately 15% of total body weight, it is the largest organ in the human body. Enabled by an array of tissue and cell types, intact skin protects the body from external insults. However, the skin is also the source of a myriad of pathologies that include inflammatory disorders, mechanical and thermal injuries, infectious diseases, and benign and malignant tumors. The intricacies and complexities of this organ and associated pathologies are reasons the skin and subcutaneous tissue remain of great interest and require the attention of various surgical disciplines that include plastic surgery, dermatology, general surgery, and surgical oncology.

ANATOMY AND HISTOLOGY

Background

It is important that surgeons understand completely the cutaneous anatomy and its variability as they play an enormous role in patient health and satisfaction. The skin is made up of tissues derived from both the ectodermal and mesodermal germ cell layers.¹ Three distinct tissue layers comprise the organ, and differ in composition based on location, age, sex, and ethnicity, among other variables. The outermost layer is the epidermis, which is predominantly characterized by a protective, highly keratinized

layer of cells. The next layer is the dermis, which is made up of an organized collagen network to support the numerous epidermal appendages, neurovascular structures, and supportive cells within the skin. The fatty layer below the dermis is collectively known as the hypodermis and functions in body processes of thermoregulation and energy storage, among others. These three distinct layers function together harmoniously and participate in numerous activities essential to life.²

Epidermis

The epidermis is the outermost layer of the cutaneous tissue, and consists primarily of continually regenerating keratinocytes. The tissue is also stratified, forming four to five histologically distinct layers, depending on the location in the body. These layers are, from deep to superficial, the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum and stratum corneum (Fig. 16-1). The different layers of the epidermis represent layers of keratinocytes at differing stages of their approximately thirty-day life cycle. A minority of other cell types are found in different layers of the epidermis as well. Some of these cells are permanent residents, while others are visitors from other parts of the body. All the epidermal appendages, such as sweat glands and pilosebaceous follicles, are derived from this tissue. The thickness of the epidermis is quite variable with regard to location and age, ranging from 75 to 150 μm in thin skin (eyelids) to 0.4 to 1.5 mm in thick skin (palms and soles).² The epidermis lacks any vascular

Key Points

- 1▶ The epidermis consists of continually regenerating stratified epithelium, and 90% of cells are ectodermally derived keratinocytes.
- 2▶ Pilosebaceous units are lined by the germinal epithelium of the epidermis and thus serve as an important source of epidermal regeneration after partial-thickness injury or split-thickness skin graft.
- 3▶ Dermal fibers are predominantly made of type I and III collagen in a 4:1 ratio. They are responsible for the mechanical resistance of skin.
- 4▶ The drugs most commonly associated with epidermal necrolysis include aromatic anticonvulsants, sulfonamides, allopurinol, oxicams (nonsteroidal anti-inflammatory drugs), and nevirapine.
- 5▶ In wounds being allowed to heal secondarily, negative pressure wound therapy can increase the rate of granulation tissue formation.
- 6▶ *Staphylococcus aureus* is the most common isolate of all skin infections. Impetigo, cellulitis, erysipelas, folliculitis, furuncles, and simple abscesses are examples of uncomplicated infections, whereas deep-tissue infections, extensive cellulitis, necrotizing fasciitis, and myonecrosis are examples of complicated infections.
- 7▶ Hemangiomas arise from benign proliferation of endothelial cells surrounding blood-filled cavities. They most commonly present after birth, rapidly grow during the first year of life, and gradually involute in most cases.
- 8▶ Basal cell carcinoma represents the most common tumor diagnosed in the United States, and the nodular variant is the most common subtype. The natural progression of basal cell carcinoma is one of local invasion rather than distant metastasis.
- 9▶ Squamous cell carcinoma is the second most common skin cancer, and typically arises from an actinic keratosis precursor. Primary treatment modalities are surgical excision and Mohs microsurgery. Cautery and ablation, cryotherapy, drug therapy, and radiation therapy are alternative treatments.
- 10▶ Tumor thickness, ulceration, and mitotic rate are the most important prognostic indicators of survival in melanoma. Sentinel lymph node biopsy is often used to stage individuals with biopsy-proven high risk melanoma and clinically node-negative disease.

structures and obtains all nutrients from the dermal vasculature by diffusion.³

Epidermal Components

Keratinocytes. Keratinocytes typically make up about 90% of the cells of the epidermis. These cells have four to five distinct stages in their life cycle, each visibly different under light microscopy. The stratum basale, or germinative layer, is a deep, single layer of asynchronous, continuously replicating cuboidal to columnar epithelial cells and is the

beginning of the life cycle of the keratinocytes of the epidermis. This layer is bound to its basement membrane by complexes made of keratin filaments and anchoring structures called hemidesmosomes. They are bound to other keratinocytes by structures called desmosomes. High mitotic activity and thus large nuclei and basophilic staining characterize the stratum basale on light microscopy. This layer also lines the epidermal appendages that reside largely within the substance of the dermis and later serves as a regenerative source of epithelium in the event of partial thickness wounds.

Figure 16-1. Schematic representation of the skin and its appendages. Note that the root of the hair follicle may extend beneath the dermis into the subcutis.

The next layer is the stratum spinosum, or “spiny” layer. This layer is from five to fifteen cells in thickness and is so named due to the spinous appearance of the intercellular desmosomal attachments under light microscopy. The production of keratin in this cell layer is responsible for their eosinophilic appearance on hematoxylin and eosin (H&E) staining.

As the keratinocytes continue to migrate superficially, they begin to flatten and develop basophilic keratohyalin granules. There are also structures called lamellar granules within these cells that contain the lipids and glycolipids that will ultimately undergo exocytosis to produce the lipid layer around the cells. It is in this layer that the keratinocytes manufacture many of the structures that will eventually serve to protect the skin and underlying tissues from environmental insult.⁴ At the superficial aspect of this layer, the keratinocytes begin to undergo programmed cell death, losing all cellular structures except for the keratin filaments and their associated proteins. In thick skin, such as that found on the palms and soles, there is a layer of flat, translucent keratinocytes called the stratum lucidum.

The final stage of the keratinocyte life cycle results in the layer of the epidermis known as the stratum corneum, or cornified layer. The protein-rich, flattened keratinocytes are now anucleate and surrounded by a lipid-rich matrix. Together the cells and surrounding matrix of this layer serve to protect the tissue from mechanical, chemical, and bacterial disruption while preventing insensible water losses through the skin.^{4,5}

Langerhans Cells. Of the cells in the epidermis, 3% to 6% are immune cells known as Langerhans cells.⁶ Typically found within the stratum spinosum, these mobile, dendritic cells interdigitate between keratinocytes of the epidermis to create a dense network, sampling any antigens that attempt to pass through the cutaneous tissue. Through use of their characteristic rod- or racket-shaped Birbeck granules, they take up antigens for presentation to T-cells.⁷ These monocyte-derived cells represent a large part of the skin’s adaptive immunity. Because of the effectiveness of their antigen presentation, Langerhans cells could be utilized as vaccine vehicles in the future.⁸ The Langerhans cells are functionally impaired by UV radiation, specifically UVB radiation, and may play a role in the development of cutaneous malignancies after UV radiation exposure.⁹

Melanocytes. Within the stratum basale are melanocytes, the cells responsible for production of the pigment melanin in the skin. These neural crest-derived cells are present in a density of four to ten keratinocytes per melanocytes, and about 500 to 2000 melanocytes per mm² of cutaneous tissue. This density varies based on location in the body, but differences in skin pigmentation are based on the activity of individual melanocytes and not the number of melanocytes. In darker-skinned ethnicities, melanocytes create and store melanosomes in keratinocytes at a higher rate, but still have a pale-staining cytoplasm on light microscopy. Hemidesmosomes also attach these cells to the basement membrane, but the intercellular desmosomal connections are not present. The melanocytes interact with keratinocytes of the stratum basale and spinosum via long cytoplasmic extensions leading to invaginations in several keratinocytes. Tyrosinase is created and distributed into melanosomes, and these organelles travel along the dendritic processes to eventually become phagocytized by keratinocytes and distributed in a supranuclear orientation. This umbrella-like cap then serves to protect the nuclear material from damage by radiation; this could explain why light-skinned ethnicities are more prone to

the development of cutaneous malignancies.^{10,11} Melanocytes express the bcl-2 protein, S100 protein, and vimentin, which are important in the pathology and histologic diagnosis of disorders of melanocytes.

Merkel Cells. Merkel cells are slow-adapting mechanoreceptors of unclear origin essential for light touch sensation. Thus, they typically aggregate among basal keratinocytes of the skin in areas where light tactile sensation is warranted, such as the digits, lips, and bases of some hair follicles.¹²⁻¹⁴ They are joined to keratinocytes in the basal layer by desmosomes and have dense neurosecretory granules containing peptides. These neurosecretory granules allow communication with the CNS via afferent, unmyelinated nerve fibers that contact the basolateral portion of the cell via expanded terminal discs.³ The clinical significance of Merkel cells arises in the setting of Merkel cell carcinoma, a rare, but difficult-to-treat malignancy.

Lymphocytes. Less than 1% of the cells in the epidermis are lymphocytes, and these are found primarily within the basal layer of keratinocytes. They typically express an effector memory T-cell phenotype.^{15,16}

Toker Cells. Toker cells are found in the epidermis of the nipple in 10% of both males and females and were first described in 1970. While distinct from Paget’s cells, immunohistochemical studies have implicated them as a possible source of Paget’s disease of the nipple.¹⁷⁻²⁰

Epidermal Appendages

Sweat Glands. Sweat glands, like other epidermal appendages, are derived from the embryologic ectoderm, but the bulk of their substance resides within the dermis. Their structure consists of a tubular-shaped exocrine gland and excretory duct. Eccrine sweat glands make up a majority of the sweat glands in the body and are extremely important to the process of thermoregulation. Solutes are released into the gland via exocytosis. They are present in greatest numbers on the palms, soles, axillae, and forehead. Collectively they produce approximately 10 L/d in an adult. These glands are the most effective means of temperature regulation in humans via evaporative heat loss.

A second type of sweat gland, known as the apocrine sweat gland, is found around the axilla, anus, areola, eyelid, and external auditory canal. The cells in this gland undergo an excretion process that involves decapitation of part of the cell. These apocrine glands are typically activated by sex hormones and thus activate around the time of puberty. The secretion from apocrine glands is initially odorless, but bacteria in the region may cause an odor to develop. Pheromone production may have been a function of the apocrine glands, but this may now be vestigial. While eccrine sweat glands are activated by the cholinergic system, apocrine glands are activated by the adrenergic system.

There is also a third type of sweat gland called apoecrine. This is similar to an apocrine gland but opens directly to the skin surface and does not present until puberty.²¹ Both types of glands are surrounded by a layer of myoepithelial cells that can contract and assist in the excretion of glandular contents to the skin surface.

Pilosebaceous Units. A pilosebaceous unit is a multicomponent unit made up of a hair follicle, sebaceous gland, an erector pili muscle, and a sensory organ. These units are responsible for the production of hair and sebum and are present almost entirely

throughout the body, sparing the palms, soles, and mucosa. They are lined by the germinal epithelium of the epidermis and thus serve as an important source of epidermal regeneration after partial-thickness injury or split-thickness skin graft. The sebaceous glands secrete sebum into the follicle and skin via a duct. The lipid-secreting glands are largely influenced by androgens and become functionally active during puberty. They are present in greatest numbers on the face and scalp.

Nails. The nails are keratinaceous structures overlying the distal phalanges of the fingers and toes. The nail is made of three main parts. The proximal portion of the nail, continuous with the germinal nail matrix, is the nail root. The root is an adherence point for the nail. The nail plate is the portion of the nail that lies on top of the nail bed, the shape of which is determined by the underlying phalanx. The third part of the nail is the free edge, which overlies a thickened portion of epidermis known as the hyponychium. The nail functions to protect the distal digits and augment the function of the pulp of the digits as a source of counter-pressure.

Dermal Components

Architecture. The dermis is a mesoderm-derived tissue that protects and supports the epidermis while anchoring it to the underlying subcutaneous tissue. It consists primarily of three unique components: a fibrous structure, the ground substance that surrounds those fibers, and the cell population that is supported by the dermis. In addition, the dermis houses the neurovasculature that supports the epidermis and facilitates interaction with the outward environment, as well as the epidermal appendages previously described. The dermis varies in thickness based upon body region, thinnest in the eyelids and reaching a thickness of up to 4 mm on the back, and is composed of two distinct layers, the papillary layer and the reticular layer. The papillary layer is made up of papillae that interdigitate with the rete ridges of the deep portion of the epidermis. This structure increases the surface area between the dermis and epidermis, increasing the resistance to shear forces as well as facilitating greater diffusion of nutrients across the dermal-epidermal junction. The papillary layer is characterized by a greater density of cells, and the reticular layer is almost entirely made up of a coarse network of fibers and the ground substance that surrounds it.

Fibers and Ground Substance. Ninety-eight percent of the dry weight of the dermis is made up of collagen, typically 80% to 90% type I collagen and 8% to 12% type III collagen. Collagen types IV and VII are also found in much smaller quantities in the dermo-epidermal junction. The structure of the fibers varies along the depth of the dermis. At the superficial part of the dermis, in the papillary layer, the collagen bundles are arranged more loosely and are primarily made up of type III collagen.²² Deeper in the reticular layer of the dermis, the collagen fibrils are larger in diameter and organized into interwoven bundles surrounded by elastic fibers all within the hydrated ground substance. In a healthy adult, these dermal fibers are in a constant state of breakdown and production, dictated by the activity of matrix metalloproteases and fibroblasts, respectively. The activity of the MMPs is induced by UV radiation, thus leading to increased degradation and disorganization of the collagen fibers, resulting in wrinkling and weakening of the dermis in sun-exposed areas.

The retractile properties of skin are due in part to elastic fibers found throughout the dermis. These fibers, like the

collagen fibers, are thinner and more perpendicularly oriented in the papillary dermis and become thicker and parallel in the reticular dermis. These elastic fibers are also produced by fibroblasts, but they are unique in that they can stretch to twice their original length, and return to their original configuration. The elastic fibers are also in a constant state of turnover that can be negatively impacted by the effects of UV radiation.

The fibrous network of the dermis lies within a hydrated amorphous ground substance made of a variety of proteoglycans and glycosaminoglycans, molecules that can contain up to 1000 times their weight in water. This ground substance facilitates the development of the structure of the dermis and cell migration within the dermis. It also assists in redistributing forces placed on the cutaneous tissues.

Cells

Fibroblasts. Fibroblasts, like most cells in the dermis, are found in the loose, papillary layer, and are the fundamental cells of the dermis. They are responsible for producing all dermal fibers and the ground substance within which those fibers reside. They are typically spindle- or stellate-shaped and have a well-developed rough endoplasmic reticulum, typical of cells engaging in active protein production. The fibroblasts can also differentiate into myofibroblasts, cell types that harbor myofilaments of smooth muscle actin and, more rarely, desmin, which help to decrease the surface area of the wound by contraction.²³ Because of these fundamental functions of fibroblasts, they are the workhorses of wound healing, while macrophages are the orchestrators.

Dermal Dendrocytes. Dermal dendrocytes are comprised of a variety of mesenchymal dendritic cells recognizable mainly by immunohistochemistry. They are responsible for antigen uptake and processing for presentation to the immune system, as well as the orchestration of processes involved in wound healing and tissue remodeling. They are typically found in the papillary dermis around vascular structures as well as sweat glands and pilosebaceous units.

Mast Cells. Mast cells are effector secretory cells of the immune system that are responsible for immediate type I hypersensitivity reactions. When primed with IgE antibodies, encounter with a provoking antigen causes the release of histamine and cytokines, leading to vasodilation and dermatitis commonly seen in allergic reactions.

Cutaneous Vasculature

While the epidermis is void of any vasculature structures, the dermis has a rich supply of blood and nutrients supported by paired plexuses connected by a system of arteriovenous shunts. The superficial, subpapillary plexus is located between the papillary and reticular dermis and provides a vascular loop to every papilla of the papillary dermis.²⁴ The deep dermal plexus is located at the junction of the reticular dermis and hypodermis, and it derives its blood supply from perforating arteries of larger vessels below the cutaneous tissues. The arteriovenous shunts connecting the two horizontal plexuses can divert blood flow to or away from the skin when necessary to conserve or release body heat, or to divert blood flow to vital organs when needed. Associated with the vascular loops of the dermal papillae are the blind-ended beginnings of lymphatic vessels, which serve to transport extravasated fluid and proteins from the soft tissues back into the venous circulatory system.

Cutaneous Innervation

The skin is a highly specialized tool for interacting with our environment and, as such, carries a rich network of nervous tissue to facilitate this purpose. An afferent component made up of free nerve endings and specialized corpuscular receptors is responsible for conveying to our brain information about the environment, while numerous functions of the cutaneous tissues, such as AV-shunting, piloerection, and sweat secretion are controlled by the myelinated and unmyelinated fibers of an efferent component of the CNS.²⁵

Hypodermis

The hypodermis, or subcutaneous tissue, is a richly vascularized loose connective tissue that separates and attaches the dermis to the underlying muscle and fascia. It is made up primarily of pockets of lipid-laden adipocytes separated by septae that contain cellular components similar to the dermis, neurovascular structures supplying the cutaneous tissue, and the deepest parts of sweat glands.²⁶ The hypodermis serves multiple functions—namely insulation, storage of energy, and protection from mechanical forces, allowing the skin to glide over the underlying tissues.

INFLAMMATORY CONDITIONS

Hidradenitis Suppurativa

Hidradenitis suppurativa, also known as acne inversa, is a painful skin condition typically affecting areas of the body bearing apocrine glands—typically the axillae, perineum, and the inframammary and inguinal folds. It is characterized by tender, deep nodules that can expand, coalesce, spontaneously drain, and form persistent sinus tracts in some cases leading to significant scarring and hyperkeratosis. There can be superimposed bacterial infection during episodic flares of the disease as well. In women, flares often occur premenstrually.

Hidradenitis suppurativa typically affects females (female to male ratio of 3:1), most commonly during the third decade of life and has demonstrated associations with smoking and obesity.²⁷ While the etiology of hidradenitis is incompletely understood, it is thought to be the consequence of a genetic predisposition exacerbated by environmental factors. About one-third of affected patients endorse a family history of the disease. A specific gene locus has not been identified, but mutations in the γ -secretase gene have been linked to the disease in some familial cases.²⁸ The histologic progression of the disease is characterized by atrophy of the sebaceous gland, followed by inflammation of the pilosebaceous unit from both the innate and adaptive immune systems, causing hyperkeratosis and eventual granuloma formation.²⁹ Some studies have shown involvement of the IL12-IL23 pathway and TNF- α , supporting the theory that the disease is at least in part caused by an inflammatory disorder.^{30,31}

The diagnosis of hidradenitis is clinical, and the presentation is most commonly categorized by the Hurley classification system, divided into three stages. Single or multiple nodules or abscesses without any sinus tracts or scarring would be classified as stage 1 disease. As abscesses recur and sinus tracts and scarring form, the disease is classified as Hurley stage 2. Stage 3 is the most advanced stage, with diffuse disease and interconnected sinus tracts and abscesses.

Treatment is typically based on Hurley staging, with topical and systemic antibiotics (typically clindamycin) being used

for stage I and II disease,³² while radical excision, laser treatment, and biologic agents are reserved for more advanced stage II and III disease.³³⁻³⁶ Even with complete surgical resection, recurrence rates are still high, reaching up to 50% in the inframammary and inguino-perineal regions. Because of increased risks of recurrence with primary closure, it is preferable to pursue other methods of wound closure, like split-thickness skin grafting, local or regional flaps, and healing by secondary intention. Topical antimicrobial creams should be used during the healing process.

Pyoderma Gangrenosum

Pyoderma gangrenosum is an uncommon inflammatory condition of the skin characterized by the development of sterile pustules which progress to painful, ulcerating lesions with purple borders. This disease is typically diagnosed between the ages of 40 and 60 years and has a slightly higher prevalence in females. Although the exact etiology is currently unknown, it typically arises in individuals with a hematologic malignancy or inflammatory disorder, such as inflammatory bowel disease or rheumatoid arthritis. The most commonly affected sites are the legs, but lesions can occur anywhere. Extracutaneous manifestations are also possible, and it can affect mucosal tissue and solid organs. While the initial pathology is sterile, it can easily become secondarily infected. The diagnosis of this condition is based upon history and clinical presentation after the exclusion of infectious etiologies. There are five distinct types of pyoderma gangrenosum described: vegetative, pustular, peristomal, ulcerative, and bullous. The pathogenesis of this disease is incompletely understood, but it is thought to be a genetic predisposition that is triggered by an environmental influence. An inciting cutaneous injury can often be identified preceding the ulceration. Histopathologic studies have demonstrated significantly elevated levels of inflammatory cytokines, as well as neutrophils exhibiting aberrant chemotactic signaling.³⁷⁻³⁹ Treatment of pyoderma gangrenosum generally involves treatment of the underlying disorder (i.e., management of Crohn's disease) as well as systemic anti-inflammatory medications such as steroids or immunosuppressants like calcineurin inhibitors. Patients with Crohn's disease and PG treated with infliximab (tumor necrosis factor [TNF]- α inhibitor) and etanercept (TNF- α antagonist) had a marked improvement in their PG.^{40,41} In cases of peristomal pyoderma gangrenosum, topical calcineurin inhibitors have been shown to be useful.⁴² Concurrent treatment with systemic and topical antimicrobials, as well as local wound care, including the debridement of purulent exudate and devitalized tissue, is also beneficial. Surgical therapy without proper systemic treatment will generally result in recurrent disease. Final wound closure can be achieved with primary closure or grafts.

Epidermal Necrolysis

Epidermal necrolysis (EN) is a rare mucocutaneous disorder characterized by cutaneous destruction at the dermoepidermal junction. EN is commonly referred to as either Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN) depending on the extent of skin involvement present. SJS refers to cases in which <10% of total body surface area is involved, while cases with >30% involvement are considered TEN, with an SJS-TEN overlap syndrome referring to all cases in between. These two disorders are now considered to be the same clinical entity that vary simply on the extent of cutaneous involvement. Erythema multiforme was once considered as part of the clinical subgroup

Figure 16-2. Blisters on the forearm of a patient several days after exposure to vancomycin. Note the clear antishear dressing and the dark silver-impregnated antimicrobial dressing (Acticoat).

encompassing SJS and TEN, but it is now thought to be a separate entity related to herpetic or *Mycoplasma* infections.

The clinical presentation usually occurs within 8 weeks of initiation of a new drug treatment and is characterized by a macular rash beginning in the face and trunk and progressing to the extremities within hours to days. A positive Nikolsky sign is often present, in which lateral pressure on the skin causes separation of the epidermis from the dermis. (Fig. 16-2). The macular rashes then begin to blister and coalesce, forming bullae that eventually burst, leaving partial thickness wounds with exposed dermis. Mucous membrane involvement is seen in 90% of cases and can involve the oral, genital, and ocular mucosa, as well as the respiratory and gastrointestinal tracts. The cutaneous manifestations can also be associated with high fever and pain. It is important to distinguish EN from infectious etiologies like staphylococcal scalded skin syndrome due to their similar clinical presentation.

While the etiology is not entirely clear, it is well documented to be a reaction to various drugs. While over 100 drugs have been implicated as the inciting agent of EN,^{43,44} there are a handful of high-risk drugs that account for a majority of the cases.⁴⁵ The drugs most commonly associated with EN include

4▶ aromatic anticonvulsants, sulfonamides, allopurinol, oximams (nonsteroidal anti-inflammatory drugs), and nevirapine. The pathophysiology is also incompletely understood, but it has generally been accepted that it involves cell-mediated cytotoxicity targeted at keratinocytes and the cytokine-induced expression of “death-receptors” like Fas-L. Recently, studies have demonstrated greatly increased concentrations of granulysin, an apoptotic protein secreted by cytotoxic T cells, within EN lesions, and thus this protein may be implicated in the pathogenesis of EN.⁴⁶ A genetic component may also exist, and genetic testing before carbamazepine treatment is recommended in people of Han Chinese ancestry to exclude carriers of HLA-B1502.⁴⁷

The prognosis of EN is generally related to the surface area affected and secondary complications of extensive cutaneous damage, like secondary infections and loss of hemodynamic stability due to increased insensible losses and third spacing of fluid. Modern burn- and ICU-care has decreased mortality

significantly.⁴⁸ The first principle of management of EN is discontinuation of the offending agent, and in drugs with short half-lives, this can significantly increase chances of survival.⁴⁹ Other management principles include maintenance of euolemia, early enteral feeding, and measures to reduce risk of infection. This includes surgical debridement of devitalized tissue, the use of topical antibiotics or antimicrobial dressings, nonadherent dressings, or temporary biologic or synthetic grafts until the underlying dermis can reepithelialize. The cornea should regularly be inspected with a Wood’s lamp to evaluate for corneal sloughing. The use of systemic corticosteroids in the acute setting is controversial as there have been mixed results. Some studies have shown a slowed disease progression when corticosteroid therapy was administered early,⁵⁰ while others showed increased rates of sepsis and overall mortality with no effect on disease progression. IVIG has also been used in an effort to inhibit the Fas-L cytotoxic pathway, with some mixed results. A 2007 meta-analysis of nine IVIG trials concluded that high-dose IVIG improves survival,⁵¹ while a large retrospective analysis in 2013 concluded that there was no mortality benefit.⁵² Other agents, like cyclosporine A, plasmapheresis and anti-TNF- α have been studied with mixed results.⁴⁸ Recent guidelines out of the United Kingdom confirm that there is still no treatment with clearly demonstrated benefit in the management of EN.⁵³ The cutaneous manifestations of EN generally progress for 7 to 10 days, while reepithelialization generally occurs over 3 weeks.

INJURIES

Radiation-Induced Injuries

Radiation injuries can result from exposure to electromagnetic radiation from industrial/occupation applications or, more commonly, from environmental exposure and medical treatments. This is especially true in the continually evolving role of radiation therapy in the multidisciplinary approach to oncologic disease and other skin conditions. In addition to treatment for lymphomas, head and neck squamous cell carcinomas, and prostate adenocarcinoma, it is often an adjuvant or neoadjuvant component of the surgical treatment of rectal, breast, esophageal, and cervical cancers. Although the new modalities and principles of radiation therapy have allowed for more precise administration of this therapy, there is still collateral damage in the cutaneous and visceral tissues surrounding the treatment site.

Environmental sources of radiation damage are typically from UV radiation. UVC rays are filtered by the ozone layer, so the only UV rays that humans typically encounter are UVA (320–400 nm) and UVB (290–320 nm).⁵⁴ The amount of exposure to UV radiation is dependent on seasonal, temporal, geographic and environmental variables. Ninety-five percent of the UV rays that reach the earth’s surface are UVA rays. This radiation is less energetic (longer wavelength) than UVB rays and affects the cutaneous tissues differently. UVA waves penetrate deeper into the tissues, with 20% to 30% reaching the deep dermis. UVB rays are mostly absorbed in the epidermis, with 70% reaching the stratum corneum, 20% reaching the deep epidermis, and only 10% reaching the papillary dermis. Major chromophores in the cutaneous tissue include nucleic acids, aromatic amino acids, and melanin.

The short-term effects of solar radiation include erythema and pigmentation. The resultant erythema peaks at 6 to 24 hours

after exposure. The pigmentation occurs differently for UVA and UVB rays. Pigmentation occurs because of photooxidation of melanin by UVA radiation. Partial fading of this pigment change occurs within an hour after exposure, but with higher and repeated doses of UVA, stable residual pigmentation is observed. UVB waves induce neomelanization, increasing the total amount of melanin in the epidermal tissues and resulting in an effect that is observable 72 hours after exposure. The increase in melanin as a result of UVB exposure serves as a protective mechanism to defend the nuclei of the basal keratinocytes from further radiation-induced damage by absorbing the high-energy radiation in future exposures. Long-term effects of exposure to UV radiation can lead to chronic skin changes, such as irregular pigmentation, melasma, postinflammatory pigmentation, and actinic lentiginos (sun spots). Lysozyme, an enzyme secreted by cells of the immune system, typically inhibits the activity of collagenase and elastase, playing a role in turnover of the elastin and collagen network of the dermis. Long-term exposure to UV radiation increases the activity of lysozyme, thus impairing the natural turnover of these fibers, resulting in a disorganized accumulation of elastin, and an increase in the ratio of type III to type I collagen. This results in loss of firmness and resilience of the skin, leading to wrinkles and an aged appearance.

The other major source of radiation injury that a surgeon will likely encounter is from therapeutic radiation. The various forms of radiation work to destroy the replicative potential of the target cells via damage to the nucleic acid structures in the cell. This is typically used to treat oncologic disease, but it can also be used to treat benign disease like eczema, psoriasis, and keloid scarring at relatively low exposures. While this goal is accomplished, surrounding tissues are also affected and damaged. The most radiosensitive components of the cutaneous tissue are the basal keratinocytes, hair follicle stem cells, and melanocytes. Exposure to this intense radiation results in disorganized, uncontrolled cell death, leading to the release of reactive oxygen species and further damage and inflammation to the surrounding cellular network. Damage to the basal keratinocytes and fibroblasts hinders the replicative capacity of the epidermis and dermis, respectively.

Acute skin changes to these structures manifest within weeks as erythema, edema, and alopecia. Permanent hyperpigmentation, tightening, thickening, and fibrosis of the skin become apparent as the tissue attempts to heal. In severe radiation injury, there can be complete loss of the epidermis, resulting in partial-thickness wounds and fibrinous exudate. Reepithelialization typically occurs 14 days following initial injury, provided other variables affecting wound healing are optimized (bacterial colonization, nutrition.) Long-term effects include compromise of the functional integrity of the skin secondary to thrombosis and necrosis of capillaries, hypovascularity, telangiectasia, ulceration, fibrosis, poor wound healing, and infection. These can present weeks to years after exposure.

Treatment of minor radiation injury includes skin moisturizers and local wound care when appropriate. Severe radiation injury may warrant surgical excision and reconstruction with free-tissue transfer from a part of the body unaffected by radiation.

Trauma-Induced Injuries

Mechanical Injury. Physical disruption of the skin can occur via numerous mechanisms. Treatment of the wound is dependent on the size of the defect left behind by the insult, any

exposed structures that remain in the wound bed, and the presence of contaminating debris or infection. Clean, simple lacerations can be irrigated, debrided, and closed primarily. There is no systematic evidence to guide the optimal timing of closure within 24 hours,⁵⁵ but many surgeons will close primarily within 6 hours of injury. Grossly contaminated or infected wounds should be allowed to heal by secondary intention or delayed primary closure.⁵⁶ In wounds allowed to heal secondarily, nega-

5▶ tive pressure wound therapy can increase the rate of granulation tissue formation.⁵⁷ Tangential abrasions are treated similarly to burn wounds, with depth of injury dictating management. Partial thickness injuries with preservation of the regenerative pilosebaceous units can be allowed to heal on their own while maintaining a moist, antimicrobial wound environment. Full thickness wounds may require reconstruction with split- or full-thickness skin grafting depending on the size of the defect and the need for future cosmesis and durability. In the setting of devitalization of full thickness tissue, the damaged tissue may be used as a full thickness graft, provided the wound is appropriately cleaned.

Bite Wounds. Dog bites alone recently accounted for 4.5 million bites to humans in a single year. Bites from dogs, humans, and other animals can quickly lead to severe deep-tissue infections if not properly recognized and treated.⁵⁸ The most common location of bite wounds is the hand. This area is of particular importance, as the anatomy of the hand allows for rapid progression of deep infection long relatively avascular structures and can lead to long term morbidity if not adequately treated.⁵⁹ Bite bacteriology is influenced by normal mouth flora, as well as the content of the offending animal's diet. Early presentation bite wounds yield polymicrobial cultures, while cultures from a late infection will typically exhibit one dominant pathogen. Common aerobic bacteria include *Pasteurella multocida*, *Streptococcus*, *Staphylococcus*, *Neisseria*, and *Corynebacterium*; anaerobic organisms include *Fusobacterium*, *Porphyromonas*, *Prevotella*, *Propionibacterium*, *Bacteroides*, and *Peptostreptococcus*. *Capnocytophaga canimorsus* bacteria after a dog bite are rare, and it appears that immunocompromised patients are most susceptible to this type of infection and its complications. The bacterial load in dog bites is heavily influenced by the last meal of the animal, increasing with wet food and shorter time since the last meal⁶⁰ (Fig. 16-3). Cat bite bacteriology is similar, with slightly higher prevalence of *Pasteurella* species. Infections from *Francisella tularensis* (tularemia) and *Yersinia pestis* (human plague) have been reported.

Bacteria colonizing human bites are those present on the skin or in the mouth. These include the gram-positive aerobic organisms *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus* species, and anaerobes including *Peptococcus* species, *Peptostreptococcus* species, *Bacteroides* species, and *Eikenella corrodens* (facultative anaerobe). Human bites are characterized by a higher bacterial load (>10⁵). Antibiotic prophylaxis after a human bite is recommended as it has been shown to significantly decrease the rate of infection.⁶¹ A course of 3 to 7 days of amoxicillin/clavulanate is typically used. Alternatives are doxycycline or clindamycin with ciprofloxacin.

There is controversy over the closure of bite wounds. Typically, in areas of aesthetic importance, the wound is thoroughly irrigated and debrided and primarily closed with a short course of antibiotics and close follow-up to monitor for signs of infection. In areas that are less cosmetically sensitive and bites that look grossly contaminated or infected, the wounds

are allowed to close secondarily. Special consideration should be paid to puncture wounds in areas like the hands, which have multiple small compartments. Some groups have found that as long as wounds are properly irrigated and cleansed with povidone iodine solution while a short course of antibiotics is prescribed, there is no difference in infection rates in dog bite wounds closed primarily.⁶²

Rabies in domestic animals in the United States is rare, and most cases are contracted from bat bites. In developing countries, dog bites remain the most common source of rabies. Management of this is beyond the scope of this chapter.

Caustic Injury

Chemical burns make up to 10.7% of all burns but account for up to 30% of all burn-related deaths.⁶³ The number of cases of

industrial chemical burns is declining while chemical burns in the domestic setting is on the rise. The extent of tissue destruction from a chemical burn is dependent on type of chemical agent, concentration, volume, and time of exposure, among other variables.

Injuries from acidic solutions are typically not as severe as those from basic solutions. This is due to the mechanism of injury of each. Acidic injuries typically result in superficial eschar formation because the coagulative necrosis caused by acids limits tissue penetration. Acids can cause thermal injury in addition to the coagulative necrosis due to exothermic reactions. Without treatment, acid injuries will progress to erythema and ulcers through the subcutaneous tissue. Injuries from basic solutions undergo liquefactive necrosis, unlike acids, and thus have no barrier preventing them from causing deeper tissue injury.

Figure 16-4. Self-inflicted alkali burn with cleaner fluid.

(Fig. 16-4). Common examples of agents that often cause alkaline chemical burns are sodium hydroxide (drain decloggers and paint removers) and calcium hydroxide (cement).

Treatment for acidic or alkaline chemical burns is first and foremost centered around dilution of the offending agent, typically using distilled water or saline for 30 minutes for acidic burns and 2 hours for alkaline injuries. Attempting to neutralize the offending agent is typically discouraged, as it does not offer an advantage over dilution and the neutralization reaction could be exothermic, increasing the amount of tissue damage. After removal of the caustic agent, the burn is treated like other burns and is based on the depth of tissue injury. Topical antimicrobials and nonadherent dressings are used for partial-thickness wounds with surgical debridement and reconstruction if needed for full-thickness injuries. Liposuction and saline dilution have been used in cases where injury to deeper structures was suspected.⁶⁴ Prophylactic use of antibiotics is generally avoided.

There are several chemical agents that have specific treatments, including the use of calcium gluconate for hydrofluoric acid burns and polyethylene glycol for phenol burns. These types of treatments are specific to the offending agent and outside of the scope of this chapter.

One type of caustic injury that is commonly seen in the hospital is extravasation injury, especially in the setting of chemotherapeutic administration. Extravasation is estimated to occur in 0.1% to 0.7% of all cytotoxic drug administrations. Like other chemical burns, extravasation injuries depend on properties of the offending agent, time of exposure, concentration, and volume of drug delivered to the tissues. Extravasation injuries typically cause little damage, but they can cause significant morbidity in

those with thin skin, fragile veins, and poor tissue perfusion, like neonates and the critically ill. (Fig. 16-5).

Initial presentation of extravasation injuries usually involves swelling, pain, erythema, and blistering. It may take days or longer for the extent of tissue damage to demarcate. Thorough evaluation to rule out injury to deeper tissues should be conducted. The treatment for extravasation injuries is usually conservative management with limb elevation, but saline aspiration with a liposuction cannula in an effort to dilute and remove the offending agent has been used soon after injury presentation.⁶⁵ Infiltration of specific antidotes directed toward the offending agent has been described, but it lacks the support of randomized controlled trials, and no consensus in treatment has been reached.⁶⁶ It is best to avoid cold or warm compression because the impaired temperature regulation of the damaged tissue may lead to thermal injury. After the wound demarcates, full-thickness skin death should be surgically debrided and managed like other wounds based on depth of injury.

Thermal Injury

Thermal injury involves the damage or destruction of the soft tissue due to extremes of temperature, and the extent of injury is dependent on the degree temperature to which the tissue is exposed and the duration of exposure. The pathophysiology and management are discussed in detail in a separate chapter. Briefly, the management of thermal wounds is initially guided by the concept of three distinct zones of injury. The focus of thermal injury that has already undergone necrosis is known as the zone of coagulation. Well outside the zone of coagulation is the zone of hyperemia, which exhibits signs of inflammation but

will likely remain viable. In between these two zones is a zone of stasis with questionable tissue viability, and it is this area at which proper burn care can salvage viable tissue and decrease the extent of injury⁶⁷ (Fig. 16-6).

The mechanisms of injury in hypothermic situation differ. Direct cellular damage can occur as a result of the crystallization of intracellular and extracellular components with resultant dehydration of the cell and disruption of lipid protein

Figure 16-6. Scald burn of upper arm, back, and buttock. Pink areas are superficial partial-thickness burn, whereas whiter areas are deeper burns in the dermis.

complexes. During rewarming, further damage occurs because of the shifts of fluid in response to melting ice. Indirect effects of hypothermic injury include microvascular thrombosis and tissue ischemia. This, together with subsequent edema and inflammation upon rewarming, propagates tissue injury even further.⁶⁸ Even so, the standard treatment of frostbite injury begins with rapid rewarming to 40°C to 42°C. In addition, further treatment includes debridement of all devitalized tissue, hydrotherapy, elevation, topical antimicrobials, topical antithromboxanes (aloe vera), and systemic antiprostaglandins (aspirin).

Pressure Injury

A problem that all surgeons will encounter very early in their careers is pressure necrosis. The development of pressure ulcers is increasingly being regarded as a marker of quality of care, and strategies aimed at prevention have been the source of recent study. Pressure ulcers are known to affect the critically ill (22% to 49% of all critically ill patients are affected), but pressure sources can also affect the chronically bed- or wheelchair-bound, patients undergoing surgical procedures, and those with Foley catheters, artificial airways, or other medical equipment (Fig. 16-7).

Pressure ulcers can present in several ways depending on the stage at presentation. They are typically grouped into 4 stages: stage 1, nonblanching erythema over intact skin; stage 2, partial-thickness injury with blistering or exposed dermis; stage 3, full-thickness injury extending down to, but not including, fascia and without undermining of adjacent tissue; and stage 4, full-thickness skin injury with destruction

A

B

Figure 16-7. **A.** Pressure wound after removal of a poorly padded cast. Stage cannot be determined until debridement but is at least a grade 2 lesion. **B.** Decubitus ulcer of the sacral region, stage 4, to the tendinous and bone layers.

or necrosis of muscle, bone, tendon, or joint capsule. Tissue destruction occurs most easily at bony prominences due to the inability to redistribute forces along a greater surface area. The average perfusion pressure of the microcirculation is about 30 mmHg, and pressures greater than that cause local tissue ischemia. In animal models, pressure greater than twice the capillary perfusion pressure produces irreversible tissue necrosis in just 2 hours. The most common areas affected are the ischial tuberosity (28%), greater trochanter (19%), sacrum (17%), and heel (9%). Tissue pressures can measure up to 300 mmHg in the ischial region during sitting and 150 mmHg over the sacrum while lying supine.⁶⁹ Tissues with a higher metabolic demand are

typically susceptible to insult from tissue hypoperfusion more rapidly than tissues with a lower metabolic demand. Because of this, it is possible to have muscle necrosis beneath cutaneous tissue that has yet to develop signs of irreversible damage.

Management of pressure sores first and foremost involves avoidance of prolonged pressure to at-risk areas. Strategies typically employed are pressure-offloading hospital beds or assist devices, patient repositioning every 2 hours, early mobilization, prophylactic silicone dressings, and nursing education.⁷⁰ From a wound healing perspective, patients should be nutritionally optimized and surgically debrided as appropriate.^{71,72} The presence of stage III or IV pressure ulcers is not necessarily an indication for surgery, and fevers in a patient with chronic pressure ulcers are often from a urinary or pulmonary source.⁷³⁻⁷⁵ Goals of surgical intervention are drainage of fluid collections, wide debridement of devitalized and scarred tissue, excision of pseudobursa, ostectomy of involved bones, hemostasis, and tension-free closure of dead space with well-vascularized tissue (muscle, musculocutaneous, or fasciocutaneous flaps). Stage 2 and 3 ulcers may be left to heal secondarily after debridement. Subatmospheric pressure wound therapy devices (vacuum-assisted closure) play a role in wound management by removing excess interstitial fluid, promoting capillary circulation, decreasing bacterial colonization, increasing vascularity and granulation tissue formation, and contributing to wound size reduction.⁵⁷

BIOENGINEERED SKIN SUBSTITUTES

The management of soft tissue defects is more commonly including the use of bioengineered skin substitutes. These products are typically derived from or designed to imitate dermal tissue, providing a regenerative matrix or stimulating autogenous dermal regeneration while protecting the underlying soft tissue and structures. There are generally four types of skin substitutes: (a) autografts, which are taken from the patient and placed over a soft tissue defect (split-thickness and full-thickness skin grafts); (b) allografts, which are taken from human organ donors; (c) xenografts, which are taken from members of other animal species; and (d) synthetic and semisynthetic biomaterials that are constructed de novo and may be combined with biologic materials.⁷⁶ Acellular dermal matrices are one type of skin substitute and are used quite often for wound healing and support of soft tissue reconstruction. They are from allogenic or xenogeneic sources and are composed of collagen, elastin, laminin, and glycosaminoglycans. Tissue incorporation generally occurs within 1 to 2 weeks.⁷⁷ Dermal matrices have been shown to be an effective bridge to split-thickness skin grafting for wounds that have exposed nerves, vessels, tendons, bones, or cartilage.⁷⁸ Bilayered matrices can also be used to promote dermal regeneration in acute or chronic wounds. These products can be temporary, needing to be removed prior to grafting, or permanent, integrating into the host tissue and being grafted directly.

BACTERIAL INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

Introduction

In 1998, the Food and Drug Administration (FDA) categorized infections of the skin and skin structures for the purpose of clinical trials. A revision of this categorization in 2010 excluded specific diagnoses such as bite wounds, decubitus ulcers, diabetic

foot ulcers, perirectal abscesses, and necrotizing fasciitis. The general division into “uncomplicated” and “complicated” skin infections can be applied to help guide management.⁷⁹

The agent most commonly responsible for skin and soft tissue infections is *S aureus* and is isolated in 44% of specimens.⁸⁰ Less common isolates include other gram-positive bacteria such as *Enterococcus* species (9%), β -hemolytic streptococci (4%), and coagulase-negative staphylococci (3%). *S aureus* is more commonly responsible for causing abscesses. Patients with an impaired immune system (diabetic, cirrhotic, or neutropenic patients) are at higher risk of infection from gram-negative species like *Pseudomonas aeruginosa* (11%), *Escherichia coli* (7.2%), *Enterobacter* (5%), *Klebsiella* (4%), and *Serratia* (2%), among others.

Uncomplicated Skin Infections

Uncomplicated infections involve relatively small surface area (<75 cm²) and bacterial invasion limited to the skin and its appendages. Impetigo, erysipelas, cellulitis, folliculitis, and simple abscess fall into this category. Impetigo is a superficial infection, typically of the face, that occurs most frequently in infants or children, resulting in honey-colored crusting. Erysipelas is a cutaneous infection localized to the upper layers of the dermis, while cellulitis is a deeper infection, affecting the deeper dermis and subcutaneous tissue. Folliculitis describes inflammation of the hair follicle, and a furuncle describes a follicle with swelling and a collection of purulent material. These lesions can sometimes coalesce into a carbuncle, an abscess with multiple different draining sinus tracts.

It is recommended to culture infectious lesions to help identify the causative agent, but treatment without these studies is reasonable in typical cases. Minor infections can be safely treated with topical antimicrobials like 2% mupirocin to provide coverage for methicillin-resistant *S aureus* (MRSA). Folliculitis generally resolves with adequate hygiene and warm soaks. Furuncles, carbuncles and other simple abscesses can be incised, drained, and packed, typically without the use of systemic antibiotics. The decision to use systemic antibiotics after incision and drainage of abscess should be made based upon presence or absence of systemic inflammatory response syndrome (SIRS) criteria.⁸¹

For nonpurulent, uncomplicated cellulitis in which there is no drainable collection, systemic antibiotic coverage for β -hemolytic streptococcus is recommended. If there is no improvement in 48 to 72 hours or worsening of symptoms, antibiotic coverage should be added for MRSA. Systemic therapy for purulent cellulitis, which includes cutaneous abscesses, should cover MRSA, and empiric coverage for streptococcus is likely unnecessary. Antibiotic coverage for streptococcus is generally accomplished with β -lactam antibiotics like penicillins or first-generation cephalosporins. MRSA coverage is accomplished with clindamycin, trimethoprim-sulfamethoxazole, linezolid, and tetracyclines. Clindamycin, trimethoprim-sulfamethoxazole, linezolid, or tetracycline combined with a β -lactam can all be used for dual coverage of streptococcus and MRSA.

Complicated Skin Infections

Complicated skin infections include superficial cellulitis encompassing a large surface area (>75 cm²) or deeper infections extending below the dermis. Necrotizing soft tissue infections (NSTIs), including necrotizing fasciitis, can rapidly cause extensive morbidity and mortality, thus their prompt diagnosis and appropriate management is crucial. A thorough history and

exam should be performed to elicit information (e.g., history of trauma, diabetes mellitus, cirrhosis, neutropenia, bites, IV or subcutaneous drug abuse) as well as physical findings such as crepitus (gas-forming organism), fluctuance (abscess), purpura (sepsis in streptococcal infections), bullae (streptococci, *Vibrio vulnificus*), lymphangitis, and signs of a systemic inflammatory response.

Extensive cellulitis is managed in a similar fashion as simple cellulitis. Initial treatment consists of intravenous antibiotics that cover β -hemolytic streptococcus, such as cephalosporins, with the addition of MRSA coverage if there is no improvement in symptoms. Vancomycin is typically the first choice for MRSA coverage, but this drug is inferior to β -lactams for coverage of MSSA. Alternative antibiotics that are typically effective against MRSA are linezolid, daptomycin, tigecycline, and telavancin. Clindamycin is approved for use against MRSA, but resistance rates are increasing, and its use is discouraged if institutional rates of clindamycin resistance are $>15\%$.⁸¹

Necrotizing soft tissue infections occur 500 to 1500 times a year in the United States⁸² and are frequently associated with diabetes mellitus, intravenous drug abuse, obesity, alcohol abuse, immune suppression, and malnutrition.⁸³ Because NSTIs can often present initially with nonspecific findings, the physician should always have a high index of suspicion when evaluating a patient. The threshold for surgical exploration and debridement should be low, particularly in a weakened host. Occasionally an inciting event or point of entry can be identified, but in 20% to 50% of cases, the exact cause is unknown. These infections are associated with a high mortality, ranging from 25% to 40%, with higher rates in the truncal and perineal cases.

NSTIs are classified based on anatomic site, involved tissues, and the offending organisms. NSTIs commonly originate at the genitalia, perineum (Fournier's gangrene), and abdominal wall. Subcutaneous tissue, fascia and muscle can all be affected. Necrotizing fasciitis involves infection of the fascia, and the infection can quickly travel along the easily separable, avascular planes. There are three types of NSTIs when classified by the offending agent. The most common is type 1, which is caused by a polymicrobial source including gram-positive cocci, gram-negative rods, and anaerobic bacteria, specifically *Clostridium perfringens* and *C septicum*. Type 2 is caused by a monomicrobial source of β -hemolytic *Streptococcus* or *Staphylococcus* species, with MRSA contributing to the increasing number of community-acquired NSTIs.⁸⁴ A history of trauma is often elicited and can be associated with toxic shock syndrome. Type 3 is a rare but fulminant subset resulting from a *V vulnificus* infection of traumatized skin exposed to a body of salt-water.

In addition to signs of SIRS, patients can present with skin changes like erythema, bullae, necrosis, pain, and crepitus (Fig. 16-8). They may exhibit signs of hemodynamic instability, and gas within the soft tissues on imaging is pathognomonic. Patients can present with a range of symptoms, from minimal skin change to frank necrosis, and the time of progression to fulminant disease varies in each patient. Laboratory values are nonspecific and resemble values seen in sepsis. There have been attempts at creating scoring systems to assist in the diagnosis of NSTI. One study in 2000 used the criteria of a white blood cell count $>15,400$ and a serum sodium level <135 mmol/L. This test was found to have a negative predictive value of 99%, but a positive predictive value of only 26%.⁸⁵ In 2004, six criteria

A

B

Figure 16-8. A. Initial presentation of necrotizing soft tissue infection in an obese, diabetic patient. B. Following operative debridement to muscle layer.

were used and referred to as the Laboratory Risk Indicator for Necrotizing Fasciitis, or LRINEC, and included C-reactive protein (CRP), white blood cell (WBC) count, hemoglobin, plasma sodium, creatinine, and glucose.⁸⁶ A score of 8 or greater

suggested a high probability of NSTI, 6 or 7 an intermediate probability, and <5 a low probability. This test was internally validated and found to have a PPV of 92% and an NPV of 96%. However, some have criticized this study because of its small sample size and over-reliance on CRP, which can be elevated in multiple other conditions. Blood cultures are not always positive, and tissue samples will demonstrate necrosis, white blood cell infiltration, thrombosis, angiitis, and microorganisms. The use of cross-sectional imaging in the diagnosis of NSTI is limited, and it should not delay appropriate surgical treatment.

Three principles form the foundation of the management of NSTIs: (a) source control with wide surgical debridement, (b) broad-spectrum intravenous antibiotics, and (c) supportive care and resuscitation. As soon as the diagnosis is clear or the suspicion is high, the patient should be taken for operative exploration and debridement. Incisions should be made parallel to neurovascular structures and through the fascial plane, removing any purulent or devitalized tissue until viable, bleeding tissue is encountered. On inspection, the tissue will appear necrotic with dead muscle, thrombosed vessels, the classic “dishwater” fluid, and a positive finger test, in which the tissue layers can be easily separated from one another. In Fournier’s gangrene, one should aim to preserve the anal sphincter as well as the testicles (blood supply is independent of the overlying tissue and is usually not infected). Return to the OR should be planned for the next 24 to 48 hours to verify source control and the extent of damage. Broad spectrum antibiotic therapy should be initiated as soon as possible, with the intent of covering gram positives (including MRSA), gram negatives, and anaerobic organisms. The Infectious Diseases Society of America recommends initiating therapy with intravenous vancomycin and piperacillin/tazobactam, unless a monomicrobial agent is identified, in which case more directed therapy would be appropriate.⁸¹ Antibiotic therapy should continue until the patient requires no further debridement, is clinically improving, and has been afebrile for 48 to 72 hours.

Adjuncts to surgery include topical antimicrobial creams, subatmospheric pressure wound dressings, and optimization of nutrition. Controversial topics include the role of hyperbaric oxygen⁸⁷ (may inhibit infection by creating an oxidative burst, with anecdotally fewer debridements required and improved survival, but limited availability) and IVIG (may modulate the immune response to streptococcal superantigens). Wound closure is performed once bacteriologic, metabolic, and nutritional balances are obtained.

Actinomycosis

Actinomyces is a genus of gram positive rods that inhabit the oropharynx, gastrointestinal tract, and female genital tract. The most commonly isolated species causing disease in humans is *A. israelii*. The cervicofacial form of *Actinomyces* infection is the most common presentation, representing 55% of cases, and typically presenting as an acute pyogenic infection in the submandibular or paramandibular area. Patients can also exhibit chronic soft tissue swelling, fibrosis, and sinus discharge of sulfur granules.⁸⁸ Demonstration of gram-positive filamentous organisms and sulfur granules on histological examination is strongly supportive of a diagnosis of actinomycosis.⁸⁹ These infections are typically treated with high doses of intravenous followed by oral penicillin therapy. Surgical treatment is utilized if there is extensive necrotic tissue, poor response to antibiotics, or the need for tissue biopsy to rule out malignancy.

VIRAL INFECTIONS WITH SURGICAL IMPLICATIONS

Human Papillomavirus Infections

Human papillomaviruses represent a group of over 100 isolated types of small DNA viruses of the *Papovavirus* family that is highly host-specific to humans.⁹⁰ These viruses are transmitted via cutaneous contact with individuals who have clinical or subclinical infection and occur more frequently in immunocompromised individuals. The viruses are responsible for the development of verrucae, or warts. These are histologically characterized by nonspecific findings of hyperkeratosis, papillomatosis, and acanthosis, as well as the hallmark koilocytes (clear halo around nucleus). Clinically, these generally arise as slow-growing papules on the skin or mucosal surfaces. Regression of HPV lesions is frequently an immune-mediated, spontaneous event that is exemplified by the persistent and extensive manifestation of this virus in the immune-compromised patient.

The subtypes are generally grouped, based on their presentation, as cutaneous or mucosal. Cutaneous types most commonly affect the hands and fingers. *Verruca vulgaris*, or common warts, are caused by HPV types 1, 2, and 4, with a prevalence of up to 33% in school children and 3.5% in adults, and a higher prevalence in the immunosuppressed population.⁹¹ Plantar and palmar warts (HPV-1 and -4) typically occur at points of pressure and are characterized by a keratotic plug surrounded by a hyperkeratotic ring with black dots (thrombosed capillaries) on the surface. Plane warts occur on the face, dorsum of hands, and shins. They are caused by HPV-3 and -10 and tend to be multiple, flat-topped lesions with a smooth surface and light brown color. Cutaneous warts typically regress spontaneously in the immunocompetent patient. Epidermodysplasia verruciformis is a rare, autosomal recessive inherited genetic skin disorder that confers increased susceptibility to certain types of HPV. This presents with difficult-to-treat and often widespread verrucae that carry a higher risk of malignant transformation (30%–50% risk of squamous cell carcinoma), especially when caused by HPV types 5 and 8.⁹² A similar clinical picture has been described in human immunodeficiency virus (HIV) and transplant patients.^{93,94}

Mucosal HPV types cause lesions in the mucosal or genital areas and behave like sexually transmitted infections. The most common mucosal types are HPV-6, -11, -16, -18, -31 and -33. These lesions present as condylomata acuminata, genital or venereal warts, papules that occur on the perineum, external genitalia, anus, and can extend into the mucosal surfaces of the vagina, urethra and rectum. These lesions are at risk for malignant transformation, with types 6 and 11 conferring low risk, and types 16, 18, 31 and 33 conferring a high risk. The recently developed quadrivalent HPV vaccine, targeting HPV types -6, -11, -16, and -18, is now available to both males and females age 9 to 26 and is associated with an up to 90% reduction of infections from those HPV types.⁹⁵

Treatment is aimed at physical destruction of the affected cells. Children often require no treatment as spontaneous regression is common. In cases causing physical or emotional discomfort, or in cases of immunocompromise or risk of transmission, treatment may be indicated. Cryotherapy using liquid nitrogen is an effective treatment for most warts, but care must be taken not to damage underlying structures.⁹⁶ Topical preparations of salicylic acid, silver nitrate, and glutaraldehyde may also be

used. Treatment of recalcitrant lesions includes a variety of therapeutic options aimed at physically destroying the lesions by electrodesiccation, cryoablation, and pulsed dye laser therapy. Additional modalities such as H2-antagonists and zinc sulfate may have a role in augmenting the immune response and reducing recurrence rates.

Cutaneous Manifestations of Human Immunodeficiency Virus

The HIV-infected patient is significantly more susceptible to infectious and inflammatory skin conditions than the rest of the population.⁹⁷ These skin disorders may be due to the HIV infection itself or from opportunistic infections secondary to immunosuppression. During early stages, nonspecific cutaneous manifestations may occur. Acute retroviral syndrome occurs following inoculation in one-half to two-thirds of patients, and 30% to 50% of these patients can present with an acute viral exanthem.⁹⁸ This is usually a morbilliform rash affecting the face, trunk, and upper extremities. Other skin changes, as well as common skin disorders with atypical features, can occur, including recurrent varicella zoster, hyperkeratotic warts, and seborrheic dermatitis. Condylomata acuminata and verrucae appear early; however, their frequency and severity do not change with disease progression.

Late-presenting cutaneous manifestations include chronic herpes simplex virus (HSV), cytomegalovirus, and, to a lesser extent, molluscum contagiosum, which is typically treatable with imiquimod. HSV is the most common viral infection in the patient with HIV, and is more likely to display atypical features and less likely to spontaneously resolve in these patients.⁹⁹ Mycobacterial infections and mucocutaneous candidiasis also occur. Bacterial infections such as impetigo and folliculitis may be more persistent and widespread.

Malignant lesions such as Kaposi's sarcoma occur in less than 5% of HIV-infected patients in the United States, although the worldwide prevalence in acquired immunodeficiency syndrome (AIDS) patients exceeds 30%. Kaposi's sarcoma is a vascular neoplasm that can affect cutaneous and visceral tissues. While the rates of Kaposi's sarcoma development have sharply declined since the widespread use of antiretroviral therapy, the rates of other cutaneous malignancies have remained stable. The risk of an HIV-infected patient developing a cutaneous malignancy is about 5.7%, with basal cell carcinoma being the most common type encountered.¹⁰⁰

With regard to general surgical considerations in HIV patients, contributing related morbidities such as malnutrition, decreased CD4 count, and presence of opportunistic infection may result in delayed and attenuated wound healing capacity.¹⁰¹

BENIGN TUMORS

Hemangioma

Hemangiomas are benign vascular tumors that arise from the proliferation of endothelial cells that surround blood-filled cavities. They occur in about 4% of children by 1 year of age. Their natural history is typically presentation shortly after birth, a period of rapid growth during the first year, and then gradual involution over childhood in more than 90% of cases. These hemangiomas are generally managed nonsurgically prior to involution. Occasionally, during the rapid growth phase, the lesions can obstruct the airway, GI tract, vision, and musculoskeletal function. In these cases, surgical resection is indicated

prior to the involution phase. Hemangiomas can sometimes consume a large percentage of cardiac output, resulting in high-output heart failure or a consumptive coagulopathy, which may also necessitate resection. These lesions characteristically express the GLUT-1 glucose transporter protein, which is absent in cells of the normal cutaneous vasculature.¹⁰² First-line therapy for these infantile hemangiomas is propranolol, which causes cessation of growth and, in most cases, actual regression of the lesions.^{103,104} Systemic corticosteroids and interferon- α can impede tumor progression, and laser therapy has been used as well. If tumors persist into adolescence leaving a cosmetically undesirable defect, surgical resection may be considered. When surgical resection or debulking is considered, upfront selective embolization can help with planned resection.

Nevi

Nevi (singular, nevus) are areas of melanocytic hyperplasia or neoplasia. These collections can be found in the epidermis (junctional), partially in the dermis (compound), or completely within the dermis (dermal). They commonly develop in childhood and young adulthood, and will sometimes spontaneously regress. Exposure to UV radiation is associated with increased density of these lesions.¹⁰⁵ Nevi are typically symmetric and small. Congenital nevi are the result of abnormal development of melanocytes. The events leading to this abnormal development may also affect the surrounding cells, resulting in longer, darker hair. Congenital nevi are found in less than 1% of neonates, and when characterized as giant congenital nevi, they have up to a 5% chance of developing into a malignant melanoma, and may do so even in the first years of childhood.^{106,107} Treatment, therefore, consists of surgical excision of the lesion as early as is feasible. For larger lesions, serial excision and tissue expansion may be required, with the goal of lesion excision being maintenance of function and form while decreasing oncologic risk.

Cystic Lesions

Cutaneous cysts are benign lesions that are characterized by overgrowth of epidermis towards the center of the lesion, resulting in keratin accumulation. Epidermoid cysts (often mistakenly referred to as sebaceous cysts) are classically the result of keratin-plugged pilosebaceous units. They commonly affect adult men and women, and present as a dermal or subcutaneous cyst with a single, keratin-plugged punctum at the skin surface, often at or above the upper chest and back. Epidermoid cysts are the most common cutaneous cyst and are histologically characterized by mature epidermis complete with granular layer. Another type of cystic lesion is known as a trichilemmal cyst. These cysts are derived from the outer sheath of hair follicles, and, in contrast to epidermoid cysts, lack a granular layer. They are almost always found on the scalp and more commonly in women. A third type of cutaneous cyst is a dermoid cyst. Dermoid cysts are congenital variants that occur as the result of persistent epithelium within embryonic lines of fusion. They occur most commonly between the forehead and nose tip, and the most frequent site is the eyebrow. They can lie in the subcutaneous tissue or intracranially, and often communicate with the skin surface via a small fistula. These cystic structures contain epithelial tissue, hair, and a variety of epidermal appendages. Treatment for these cystic structures includes surgical excision with care taken to remove the cyst lining to prevent recurrence.

Actinic Keratosis. Actinic keratoses are neoplasms of epidermal keratinocytes that represent a range in a spectrum of disease from sun damage to squamous cell carcinoma. They typically occur in fair-skinned, elderly individuals in primarily sun-exposed areas, and UV radiation exposure is the greatest risk factor. There are multiple variants, and they can present as erythematous and scaly to hypertrophic, keratinized lesions. They can become symptomatic, causing bleeding, pruritis and pain. They can regress spontaneously, persist without change, and transform into invasive squamous cell carcinoma. It is estimated that approximately 10% of actinic keratoses will transform into invasive squamous cell carcinoma, and that progression takes about 2 years on average.¹⁰⁸ About 60% to 65% of squamous cell carcinomas are believed to originate from actinic keratoses. The presence of actinic keratoses also serves as a predictor of development of other squamous cell and basal cell carcinomas.¹⁰⁹ Treatment options are excision, fluorouracil, cauterization and destruction, and dermabrasion.^{110,111}

Seborrheic Keratosis. Seborrheic keratoses are benign lesions of the epidermis that typically present as well-demarcated, “stuck on” appearing papules or plaques over elderly individuals. Clonal expansion of keratinocytes and melanocytes make up the substance of these lesions. They carry no malignant potential and treatment is primarily for cosmetic purposes.

Soft Tissue Tumors

Acrochordons. Acrochordons, also known as skin tags, are benign, pedunculated lesions on the skin made up of epidermal keratinocytes surrounding a collagenous core. Although they can become irritated or necrotic, their removal is generally cosmetic.

Dermatofibromas. Dermatofibromas are benign cutaneous proliferations that appear most commonly on the lower extremities of women. They appear as pink to brown papules that pucker or dimple in the center when the lesion is pinched. It remains unclear whether these lesions have a neoplastic etiology or if they are the result of minor trauma or infection.¹¹² These lesions are typically asymptomatic, and treatment is only indicated for cosmetic concerns or when a histologic diagnosis is required. Surgical excision is the recommended treatment, although cryotherapy and laser treatment may be used.¹¹³ In rare cases, a basal cell carcinoma may develop within a dermatofibroma.

Lipomas. Lipomas are the most common subcutaneous neoplasm and have no malignant potential.¹¹⁴ They present as a painless, slow-growing, mobile mass of the subcutaneous tissue. Usually less than 5 cm in diameter, these neoplasms can reach much larger sizes. Lipomas are largely asymptomatic but may cause pain due to regional nerve deformation. Surgical resection is indicated in cases of local pain, mass effect, or cosmetically sensitive areas. The tumors are usually well circumscribed and amenable to surgical resection. Liposarcoma is a malignant fatty tumor that can mimic a lipoma, but is often deep-seated, rapidly growing, painful, and invasive. In these cases, cross-sectional imaging is recommended prior to any surgical resection.

Neural Tumors

Neuromas. Neuromas do not represent a true clonal proliferation of neural tissue, but rather disordered growth of Schwann cells and nerve axons, often at the site of previous trauma. They

can present within surgical scar lines or at the site of previous trauma as flesh-colored papules or nodules and are typically painful.

Schwannomas. A schwannoma is a benign proliferation of the Schwann cells of the peripheral nerve sheath, and can arise sporadically or in association with type 2 neurofibromatosis. It contains no axons, but may displace the affected nerve and cause pain along the distribution of the nerve.

Neurofibromas. Neurofibromas, in contrast, are benign proliferations that are made up of all nerve elements, and arise as fleshy and nontender, sessile or pedunculated masses on the skin. They can arise sporadically or in association with type 1 neurofibromatosis, and in these cases, are associated with café-au-lait spots and Lisch nodules. They are often asymptomatic, but may be pruritic. The development of pain at the site of a previously asymptomatic neurofibroma may indicate a rare malignant transformation and requires surgical excision and biopsy.

MALIGNANT TUMORS

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common tumor diagnosed in the United States, with an estimated one million new cases occurring each year. It represents 75% of non-melanoma skin cancers and 25% of all cancers diagnosed each year.¹¹⁵ BCC is seen slightly more commonly in males and individuals over the age of 60, though the incidence in younger age groups is increasing. The primary risk factor for disease development is sun exposure (UVB rays more than UVA rays), particularly during adolescence. The pathogenesis of BCC stems from mutations of genes involved in tumor suppression, often caused by ionizing radiation. The p53 tumor suppressor gene is defective in approximately 50% of cases.¹¹⁶ There is a latency period of 20 to 50 years.

BCC tends to occur on sun-exposed areas of the skin, most commonly the nose and other parts of the face. A malignant lesion on the upper lip is almost always BCC, and BCC is the most common malignant eyelid tumor. Because of the photoprotective effect of melanin, dark-skinned individuals are far less commonly affected. Other risk factors for development of BCC include immune suppression, chemical exposure, and ionizing radiation exposure. There are also genetic susceptibilities to development of BCC in conditions such as xeroderma pigmentosa, unilateral basal cell nevus syndrome, and nevoid BCC syndrome.¹¹⁵ The natural history of BCC is typically one of local invasion rather than distant metastasis, but untreated BCC can often result in significant morbidity.

There are multiple variants of BCC, and presentation can range from red, flesh-colored, or white macule or papule, to nodules and ulcerated lesions. Growth patterns of these lesions can either be well-circumscribed or diffuse and the most common types of BCC are nodular and micronodular, superficial spreading, and infiltrative.¹¹⁷ The most common subtype is the nodular variant, characterized by raised, pearly pink papules with telangiectasias and occasionally a depressed tumor center with raised borders giving the classic “rodent ulcer” appearance. Superficial spreading BCC is confined to the epidermis as a flat, pink, scaling or crusting lesion, often mistaken for eczema, actinic keratosis, fungal infection, or psoriasis. This subtype typically appears on the trunk or extremities and the mean age of diagnosis is 57 years. The infiltrative form appears on the

head and neck in the late 60s, often at embryonic fusion lines,¹¹⁷ with an opaque yellow-white color that blends with surrounding skin and has no raised edges.¹¹⁸ The morpheiform subtype represents 2% to 3% of all BCC and is the most aggressive subtype. It usually presents as an indurated macule or papule with the appearance of an enlarging scar. The clinical margins are often indistinct, and the rate of positive margins after excision is high. There is also a pigmented variant of BCC that can be difficult to distinguish from certain melanoma subtypes.

Treatment of BCC varies according to size, location, type, and high- or low-risk. Treatment options include surgical excision, medical, or destructive therapies. Surgical excision should include 4 mm margins for small, primary BCC on cosmetically sensitive areas, and 10 mm margins otherwise.¹¹⁹ Mohs microsurgical excision is sequential horizontal excision and has been shown to be cost-effective and associated with low recurrence rates for BCC (1%).^{120,121} It is the treatment of choice for morpheiform or other BCC with aggressive features, poorly delineated margins, recurrent tumors, or cosmetically sensitive areas, especially in the midface. A common approach used by dermatologists for very small (<2 mm) and low risk lesions is cautery and destruction, although it should be kept in mind that the local cure rates can be operator and institution dependent. Other destructive techniques include cryosurgery and laser ablation. Radiation therapy can be used as adjuvant therapy following surgery, or as primary therapy in poor surgical candidates with low-risk lesions. The practitioner must be aware of the potential consequences of radiation therapy, including poor cosmetic outcomes and future cancer risk.

Superficial medical therapies are generally reserved for patients in whom surgical and radiation treatment is not an option. Topical imiquimod or 5-fluorouracil have been used for periods of 6 to 16 weeks for small, superficial BCC of the neck, trunk or extremities.¹²²⁻¹²⁶ Lastly, topical photodynamic therapy has shown some benefit in treatment of premalignant or superficial low-risk lesions as well.

Patients with BCC need to have regular follow-up with full skin examinations every 6 to 12 months. Sixty-six percent of recurrences develop within 3 years, and with a few exceptions occurring decades after initial treatment, the remaining recur within 5 years of initial treatment.^{121,127} A second primary BCC may develop after treatment and, in 40% of cases, presents within the first 3 years after treatment.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the second most common skin cancer and accounts for approximately 100,000 cases each year. The primary risk factor for the development of SCC is UV radiation exposure¹²⁸; however, other risks include light Fitzpatrick skin type (I or II), environmental factors such as chemical agents, physical agents (ionizing radiation), psoralen, HPV-16 and -18 infections, immunosuppression, smoking, chronic wounds, burn scars, and chronic dermatoses. Heritable risk factors include xeroderma pigmentosum, epidermolysis bullosa, and oculocutaneous albinism.

SCC classically appears as a scaly or ulcerated papule or plaque, and bleeding of the lesion with minimal trauma is not uncommon, but pain is rare. It can exhibit in situ (confined to the epidermis) or invasive subtypes. The most common in situ variant of SCC is actinic keratosis, described previously in this chapter. Invasive squamous cell carcinomas may arise de novo, but more commonly evolve from these precursors. Another in

situ variant is known as Bowen disease. This is characterized by full-thickness epidermal dysplasia and clinically appears as a scaly, erythematous patch often with pigmentation and fissuring. When it occurs on the glans penis, it is known as erythroplasia of Queyrat. Ten percent of these cases will eventually become invasive.¹²⁹ Outside of these instances, most in situ cases grow slowly and do not progress to invasive disease.

Invasive SCC is characterized by invasion through the basement membrane into the dermis of the skin. It usually arises from an actinic keratosis precursor, but de novo varieties do occur and are higher risk. De novo invasive SCC commonly occurs in organ transplant and immunocompromised patients, and has a metastatic rate as high as 14%.¹³⁰ De novo invasive SCC arising in areas of chronic wounds or burn scars are known as Marjolin's ulcers, and have a higher metastatic potential (Fig. 16-9). Keratoacanthoma is now being accepted as a subtype of SCC that is characterized by a rapidly growing nodule with a central keratin plug.¹³¹ The natural history of invasive disease depends on location and inherent tumor characteristics. Clinical risk factors for recurrence include presentation with neurologic symptoms, immunosuppression, tumor with poorly defined borders, and tumor that arises at a site of prior radiation. Perineural involvement also has a poorer survival with increased local recurrence and lymph node metastasis. Grades of differentiation are based on the ratio of differentiated to undifferentiated cells, with a lower ratio associated with a greater metastatic and recurrent potential. Large (>2 cm) lesions, depth of invasion >4 mm, rapid growth, and location on the ear, lips, nose, scalp, or genitals are all also indicators of worse prognosis.

When feasible, wide surgical excision including subcutaneous fat is the treatment of choice for SCC. Margins of 4 mm are recommended for low-risk lesions and 6 mm for high-risk lesions.¹²⁸ Mohs microsurgical excision is indicated for positive margins, recurrent tumors, sites where cosmesis or function preservation is critical, poorly differentiated tumors, invasive lesions, and verrucous tumors. Using this modality often results in lower recurrence rates.^{127,130} It has also found use in nail bed lesions and in those arising in a background of osteomyelitis. The role of lymph node dissection in the setting of SCC continues to evolve. Lymphadenectomy is indicated following fine-needle aspiration or core biopsy for clinically palpable lymph nodes or nodes detected on cross-sectional imaging. Nodes

Figure 16-9. Squamous cell carcinoma forming in a chronic wound.

should also be removed from susceptible regional lymph node basins in patients with SCC in the setting of chronic wounds. Patients with parotid disease benefit from a superficial or total parotidectomy (with facial nerve preservation) and adjuvant radiotherapy. Sentinel lymph node dissection may be used in high risk cases with clinically negative nodal disease. Radiation therapy is typically reserved as primary therapy for those who are poor surgical candidates, and as adjuvant therapy after surgical resection for large, high-risk tumors. When used as primary therapy, cure rates may approach 90%.¹²¹

Melanoma

Background. In 2017, an estimated 87,110 new cases of melanoma were diagnosed, as well as 9730 melanoma-related deaths. The incidence of melanoma is rising faster than most other solid malignancies, and these numbers likely represent an underestimation given the many in situ and thin melanoma cases that are underreported. These tumors primarily arise from melanocytes at the epidermal-dermal junction but may also originate from mucosal surfaces of the oropharynx, nasopharynx, eyes, proximal esophagus, anorectum, and female genitalia. Melanoma characteristically metastasizes quite often, and can travel to most other tissues in the body. This metastasis confers a poor prognosis in patients, with a median life span of 6 to 8 months after diagnosis.¹³²

The most important risk factor for the development of melanoma is exposure to UV radiation. It was recently reported that greater than 10 tanning bed sessions by adolescents and young adults increased their relative risk of developing melanoma twofold,¹³³ and there is a positive association with intermittent childhood sunburns and melanoma development.¹³⁴ There is also an association with residence at high altitudes or in close proximity to the equator. Both personal and family history of melanomas increase the risk of primary melanoma development. Individuals with dysplastic nevi have a 6% to 10% overall lifetime risk of melanoma, with tumors arising from preexisting nevi or de novo. Individuals with familial atypical multiple-mole melanoma syndrome have numerous melanocytic nevi and a greatly increased risk of cutaneous melanoma. Congenital nevi increase the risk for melanoma proportionally with size, and giant congenital nevi (generally considered >20 cm in diameter) are associated with a 5% to 8% lifetime risk. Melanoma development is strongly associated with the p16/CDK4,6/Rb and p14ARF/HMD2/p53 tumor suppressor pathways and the RAF-MEK-ERK and PI3K-Akt oncogenic pathways.¹³⁵

Clinical Presentation. The presentation of melanoma is commonly used to determine subtype but often starts as a localized, radial growth phase followed by a more aggressive, vertical growth phase. Approximately 30% of melanoma lesions arise from a preexisting melanocytic nevus. The most common subtype of melanoma is superficial spreading (Fig. 16-10). This accounts for 50% to 70% of melanomas and typically arises from a precursor melanocytic nevus. Nodular subtype accounts for 15% to 30% of melanomas, and typically arises de novo, most commonly in men and on the trunk (Figs. 16-11 and 16-12). This subtype is aggressive with an early vertical growth pattern and is often diagnosed at a later stage. Up to 5% of these lesions will lack melanin and can be mistaken for other cutaneous lesions. Lentigo maligna represents 10% of melanoma cases and is a less aggressive subtype of melanoma in situ that typically arises on sun-exposed areas of the head and neck. Acral

Figure 16-10. Primary cutaneous melanoma seen in the scalp of a 61-year-old male.

lentiginous melanoma accounts for 29% to 72% of melanomas in dark-skinned individuals, is occasionally seen in Caucasians, and is found on palmar, plantar, and subungual surfaces. This subtype is not thought to be due to sun exposure.

Melanoma most commonly manifests as cutaneous disease, and clinical characteristics of malignant transformation are often remembered by the initialism ABCDE. These lesions are typically Asymmetric with irregular Borders, Color variations, a Diameter greater than 6 mm, and are undergoing some sort of Evolution or change. Other key clinical characteristics include a pigmented lesion that has enlarged, ulcerated, or bled. Amelanotic lesions appear as raised pink, purple, or flesh-colored skin papules and are often diagnosed late.

Diagnosis and Staging. Workup should begin with a history and physical exam. The entire skin should be checked for synchronous primaries, satellite lesions, and in-transit metastases, and all nodal basins should be examined for lymphadenopathy. Suspicious lesions should undergo excisional biopsy with 1- to 3-mm margins; however, tumors that are large or are in a cosmetically or anatomically challenging area can be approached by incisional biopsy, including punch biopsy.¹³⁶

Tissue specimen should include full thickness of the lesion and a small section of normal adjacent skin to aid the pathologist in diagnosis. Clinically suspicious lymph nodes should undergo fine-needle aspiration (FNA), as this has been shown to have

a high sensitivity and specificity for detection of melanoma in large lymph nodes.¹³⁶⁻¹³⁹

Melanoma is characterized according to the American Joint Committee on Cancer (AJCC) as localized disease (stage I and II), regional disease (stage III), or distant metastatic disease (stage IV). The Breslow tumor thickness replaced the Clark's level as the most important prognostic indicator for melanoma staging.^{132,140} The Breslow tumor thickness measures the depth of penetration of the lesions from the top of the granular layer of the epidermis into the dermal layer and is directly related to the risk of disease progression. Tumor ulceration, mitotic rate ≥ 1 per mm^2 , and metastasis are all also associated with worse prognosis. In the presence of regional node metastasis, the number of nodes affected is the most important prognostic indicator. For stage IV disease, the site of metastasis is strongly associated with prognosis, and elevated lactate dehydrogenase (LDH) is associated with a worse prognosis.¹⁴¹

There is no supportive evidence for chest X-ray or computed tomography (CT) in the staging of patients unless there is positive regional lymph node disease, although it can be used to work up specific signs and symptoms when metastatic disease is suspected.¹³⁶ In patients with stage III or greater disease, there is a high risk for distant metastasis, and imaging is recommended for baseline staging. These patients should receive additional imaging that includes CT of the chest, abdomen, and pelvis; whole-body positron emission tomography (PET)-CT; or brain magnetic resonance imaging (MRI).¹³⁶

The sentinel lymph node biopsy (SLNB) technique for melanoma was introduced in 1992 and has become a cornerstone in the management of melanoma, although its role in management continues to be refined. SLNB is a standard staging procedure to evaluate the regional nodes for patients with clinically node-negative malignant melanoma. Detecting subclinical nodal metastasis in may benefit from lymphadenectomy or adjuvant therapy. This technique identifies the first draining lymph node from the primary lesion and has shown excellent accuracy and significantly less morbidity compared to complete resection of nodal basins. It is almost always performed at the time of initial wide excision, as SLN mapping after lymphatic violation from surgical excision could decrease the accuracy of the test. Recently, the results of MSLT-1, an international, multicenter, phase III trial were published. This study randomized clinically node negative patients to either SLNB at the time of primary melanoma excision (and completion lymphadenectomy if positive) or nodal basin monitoring (and delayed complete lymphadenectomy for recurrent lymph node disease).¹⁴² The results of this study demonstrated that SLNB, with immediate lymphadenectomy if positive, improved disease-free survival by 7% and 10% in patients with intermediate thickness (1.2–3.5 mm) and thick (>3.5 mm) lesions respectively. The use of SLNB in lesions <1.2 mm thick did not affect disease-free survival. SLNB should also be offered to thin lesions with high-risk features (thickness >0.75 , ulceration, mitoses ≥ 1 per mm^2).¹³⁶ The SLNB involves preoperative lymphoscintigraphy with intradermal injections of technetium-sulfur colloid to delineate lymphatic drainage and intraoperative intradermal injection of 1 mL of isosulfan or methylene blue dye near the tumor or biopsy site. (Figs. 16-13 and 16-14). The radioactive tracer-dye combination allows the sentinel node to be identified in 98% of cases. An incision over the lymph node basin of interest allows nodes to be excised and studied with hematoxylin and eosin and immunohistochemistry (S100, HMB45, and MART-1/Melan-A) staining (Fig. 16-15).

Figure 16-13. After injection of radioactive technetium-99–labeled sulfur colloid tracer at the primary cutaneous melanoma site, sentinel lymph node basins are identified. **A.** Lymphoscintigraphy of 67-year-old male with a malignant melanoma of the right heel; sentinel lymph nodes in both the right popliteal fossa and inguinal region. **B.** Lymphoscintigraphy of 52-year-old male with a malignant melanoma of the posterior right upper arm; sentinel lymph node in the right axillary region. **C.** Lymphoscintigraphy of 69-year-old male with a facial melanoma; sentinel lymph nodes in the submandibular region. ANT = anterior; INJ = injection; POST = posterior.

Risks of this technique are uncommon but include skin necrosis near the site of injection, anaphylactic shock, lymphedema, surgical site infections, seromas, and hematomas.

Surgical Management of the Primary Tumors and Lymph Nodes. The appropriate excision margin is based on primary tumor thickness. Several retrospective studies suggest that for melanoma in situ, 0.5 to 1 cm margins are sufficient.¹⁴³⁻¹⁴⁵ We believe that 1-cm margins should be obtained in anatomically feasible areas given the possibility of an incidental finding of a small invasive component in permanent sections. Several studies compared 1- to 3-cm margins and 2- to 5-cm margins in melanoma <2 mm thick, and 2- to 4-cm margins in melanoma lesions 1 to 4 mm thick and found no difference.¹⁴⁶⁻¹⁴⁹ A British trial suggested that there is a limit to how narrow margins can be for melanomas >2 mm thick by showing that 1-cm margins provide worse outcomes compared to 3-cm margins.¹⁵⁰ Tumors <1 mm thick require 0.5 to 1 cm margins. Tumors 1 to 2 mm thick require 1 to 2 cm margins, and tumors >2 mm thick require 2-cm margins.

Completion lymphadenectomy is commonly performed in cases of sentinel nodes with metastatic disease, but it has been shown that most of these nodal basins do not have additional disease. Thus, many surgeons do not perform routine completion lymphadenectomy for positive nodes, and data from the MSLT-2 may provide guidance. It has been shown that those patients with nonsentinel lymph node positivity found on completion lymph node dissection after a positive SLN have higher rates of recurrence and lower rates of survival. The therapeutic value, however, has not been clearly demonstrated. In patients with clinically positive lymph nodes but absent signs of distant metastasis on PET-CT, therapeutic lymph node dissection is associated with 5-year survival rates of 30% to 50%. In these cases, resection of the primary melanoma lesion and a completion lymphadenectomy should be performed.

Individuals with face, anterior scalp, and ear primaries who have a positive SLNB should undergo a superficial parotidectomy in addition to a modified radical neck dissection.

Figure 16-14. Technique of sentinel lymph node biopsy for cutaneous melanoma. **A.** After injection of radioactive technetium-99–labeled sulfur colloid tracer at a lower abdominal wall primary cutaneous melanoma site, **B.** sentinel lymph node basins are identified. (Reproduced with permission from Gershenwald JE, Ross MI: Sentinel-lymph-node biopsy for cutaneous melanoma, *N Engl J Med.* 2011 May 5;364(18):1738-1745.)

Figure 16-15. Operation of sentinel lymph node biopsy for cutaneous melanoma. After preoperative injection of radioactive technetium-99–labeled sulfur colloid tracer and intraoperative injection of Lymphazurin blue dye around the primary melanoma excision site, the nodal basin of interest is identified. An incision is made directly overlying the lymph node basin in the posterior axillary space. The sentinel lymph nodes are identified and excised.

Patients with positive sentinel nodes in the inguino-femoral nodal basin should undergo an inguino-femoral lymphadenectomy that includes removal of Cloquet’s node. If Cloquet’s node is positive or the patient has three or more nodes that contain melanoma metastases the probability of clinically occult positive pelvic nodes is increased. The effect of ileo-obturator lymph node dissection on the survival of these patients is unknown.

Surgery for Regional and Distant Metastasis. Nonmetastatic, in-transit disease should undergo excision to clear margins when feasible. However, disease not amenable to complete excision derives benefit from isolated limb perfusion (ILP) and isolated limb infusion (ILI) (Fig. 16-16). These two modalities are used to treat regional disease, and their purpose is to administer high doses of chemotherapy, commonly melphalan, to an affected limb while avoiding systemic drug toxicity. ILI was shown to provide a 31% response rate in one study, while hyperthermic ILP provided a 63% complete response rate in an independent study.¹⁵¹⁻¹⁵⁴

The most common sites of metastasis of melanoma are the lung and liver. These are followed by the brain, gastrointestinal tract, distant skin, and subcutaneous tissue. A limited subset of patients with small-volume, limited distant metastases to the brain, gastrointestinal tract, or distant skin can be treated with surgical resection or directed radiation. Liver metastases are better dealt without surgical resection unless they arise from an ocular primary. Adjuvant therapy after resection of metastatic lesions is not standard of care. However, there are ongoing clinical trials addressing whether drugs and vaccines will be beneficial in this setting.¹¹⁵ Surgery may provide palliation for patients with gastrointestinal obstruction, gastrointestinal hemorrhage, and nongastrointestinal hemorrhage. Radiotherapy for symptomatic bony or brain metastases provides palliation in diffuse disease.

Adjuvant and Palliative Therapies. Eastern Cooperative Oncology Group (ECOG) Trials 1684, 1690, and 1694 were prospective randomized controlled trials that demonstrated

Figure 16-16. Isolated limb infusion. Schematic of isolated limb infusion of lower extremity. (Adapted with permission from Testori A, Verhoef C, Kroon HM, et al: Treatment of melanoma metastases in a limb by isolated limb perfusion and isolated limb infusion, *J Surg Oncol*. 2011 Sep;104(4):397-404.)

disease-free survival advantages in patients with melanoma >4 mm in thickness with or without lymph node involvement if they received adjuvant treatment with high-dose interferon (IFN).¹⁵⁵⁻¹⁵⁷ A European Organization for Research and Treatment of Cancer (EORTC) trial also showed recurrence-free survival benefit with pegylated IFN.¹⁵⁸ It is important to note that IFN therapy is not well tolerated and the pooled analysis of these trials did not show an improvement in overall survival benefit.

Most patients with melanoma will not be surgical candidates. Although medical options for melanoma have historically been poor, several recent studies have shown promise in drug therapy for metastatic melanoma. BRAF inhibitors (sorafenib), anti-PD1 antibodies, CTLA antibodies (ipilimumab), and high-dose interleukin-2 (IL-2) with and without vaccines have been shown in randomized studies to provide survival benefit in metastatic disease.¹⁵⁹⁻¹⁶⁵ Despite the excitement of recent drugs, surgery will likely play an adjunct role in treating individuals who develop resistance to these drugs over time.

Special Circumstances. Special circumstances of note are melanoma in pregnant women, melanoma of unknown primaries, and noncutaneous melanomas. The prognosis of pregnant patients is similar to women who are not pregnant. Extrapolation of studies examining the SLNB technique in pregnant women with breast cancer suggests lymphoscintigraphy may be done safely during pregnancy without risk to the fetus (blue dye is contraindicated). General anesthesia should be avoided during the first trimester, and local anesthetics should be used during this time. It has been suggested by some that after excising the primary tumor during pregnancy, the SLNB may be performed after delivery.

Unknown primary melanoma occurs in 2% to 5% of cases and most commonly occurs in the lymph nodes. In these cases, a thorough search for the primary lesion should be sought, including eliciting a history about prior skin lesions, skin procedures (e.g., curettage and electrodesiccation, excision, laser), and review of any prior “benign” pathology. The surgeon should be aware that melanoma is known to spontaneously regress because of an immune response. Melanoma of unknown primary has survival rates comparable to melanoma diagnosed with a known primary of the same stage.

The most common noncutaneous disease site is ocular melanoma, and treatment of this condition includes photocoagulation, partial resection, radiation, or enucleation.¹⁶⁶⁻¹⁶⁸ Ocular melanomas exclusively metastasize to the liver and not regional lymph nodes, and some patients benefit from liver resection. Melanoma of the mucous membranes most commonly presents in the oral cavity, oropharynx, nasopharynx, paranasal sinus, anus, rectum, and female genitalia. Patients with this presentation have a worse prognosis (10% 5-year survival) than patients with cutaneous melanomas. Management should be excision to negative margins, and radical resections should be avoided because the role of surgery is locoregional control, not cure. Generally speaking, lymph node dissection should be avoided because the benefit is unclear.

Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is an aggressive neuroendocrine tumor of the skin whose incidence has been rapidly increasing. Although it is a much rarer malignancy than melanoma, the prognosis is much worse, with a 5-year survival of 46%.¹⁶⁹ Merkel cells are epidermal appendages involved in the sensation

Figure 16-17. Merkel cell carcinoma seen just above the left knee in a 44-year-old female.

of light touch, and along with Merkel cell carcinoma, are cyto-keratin-20 positive. This stain is now used to confirm the diagnosis. Other risk factors include age >65 years (the median age of diagnosis is 70 years), UV exposure, Merkel cell polyoma virus, and immunosuppression. MCC typically presents as a rapidly growing, flesh-colored to red or purple papule or plaque (Fig. 16-17). Regional nodes are involved in 30% of patients at diagnosis, and 50% will develop systemic disease (skin, lymph nodes, liver, lung, bone, and brain).^{170,171} There are no standardized diagnostic imaging studies for staging, but CT of the chest, abdomen, pelvis and octreotide scans may provide useful information when clinically indicated.

After a thorough skin examination, treatment should begin by evaluating nodal basins. Patients without clinical nodal disease should undergo an SLNB prior to wide local excision because studies suggest a benefit.¹⁷² In patients with sentinel lymph nodes with metastatic disease, completion lymphadenectomy and/or radiation therapy may follow, and in patients with node-negative disease, observation or radiation therapy should be considered.¹⁷² SLNB is important for staging and treatment, and the literature suggests that it predicts recurrence- and relapse-free survival. Elective lymph node dissection may decrease regional nodal recurrence and in-transit metastases. Patients with clinically positive nodes should have an FNA to confirm disease. If positive, a metastatic staging workup should follow, and, if negative, treatment of the primary and nodal basin as managed for sentinel lymph node-positive disease should be considered. A negative FNA and open biopsy-negative disease should be managed by treatment of the primary disease alone.

Patients with metastatic disease should be managed according to consensus from a multidisciplinary tumor board.

Important surgical principles for excision of the primary lesion are to excise with wide margins down to fascia and complete circumferential and peripheral deep-margin assessment. Recommended management for margins is 1 to 3 cm, but there are no randomized trials defining these margins. Chemotherapy and adjuvant radiation are commonly used, but there are no data to support a specific regimen or that demonstrate a definitive survival benefit.

Recurrence of MCC is common. One study of 95 patients showed a 47% recurrence, with 80% of recurrences occurring within 2 years and 96% occurring within 5 years.^{173,174} Regional lymph node disease is common, and 70% of patients will have nodal spread within 2 years of disease presentation. Five-year overall survival of head and neck disease in surgically treated patients is between 40% and 68%.

Kaposi's Sarcoma

Kaposi's sarcoma is characterized by the proliferation and inflammation of endothelial-derived spindle cell lesions. There are five major forms of this angioproliferative disorder: classic (Mediterranean), African endemic, HIV-negative men having sex with men (MSM)-associated, and immunosuppression-associated. They are all driven by the human herpesvirus (HHV-8).¹⁷⁵ Kaposi's sarcoma is diagnosed after the fifth decade of life and predominantly found on the skin but can occur anywhere in the body. In North America, the Kaposi's sarcoma herpes virus is transmitted via sexual and nonsexual routes and predominantly affects individuals with compromised immune systems such as those with HIV and transplant recipients on immune-suppressing medications. Clinically, Kaposi's sarcoma appears as multifocal, rubbery blue-red nodules. Treatment of AIDS-associated Kaposi's sarcoma is with antiviral therapy, and many patients experience a dramatic treatment response.^{176,177} Those individuals who do not respond and have limited mucocutaneous disease may benefit from cryotherapy, photodynamic therapy, radiation therapy, intralesional injections, and topical therapy. Surgical biopsy is important for disease diagnosis, but given the high local recurrence and the fact that Kaposi's sarcoma represents more of a systemic rather than local disease, the benefit of surgery is limited and generally should not be pursued except for palliation.

Dermatofibrosarcoma Protuberans

This rare, low-grade sarcoma of fibroblast origin commonly afflicts individuals during their third decade of life. It has low distant metastatic potential, but it behaves aggressively locally with finger-like extensions. Tumor depth is the most important prognostic variable. Presentation is characteristically a slow-growing, asymptomatic, violaceous plaque involving the trunk, head, neck, or extremities (Fig. 16-18). Nearly all cases are positive for CD34 and negative for factor XIIIa.^{178,179} Treatment is wide local excision with 3-cm margins down to deep underlying fascia or Mohs microsurgery in cosmetically sensitive areas where maximum tissue preservation will benefit.¹⁸⁰ No nodal dissection is needed, and both approaches provide similar local control.¹⁸¹ Some clinicians have used radiation therapy and biologic agents (imatinib) as adjuvant therapy with some success in patients with advanced disease. Local recurrence occurs in 50% to 75% of cases, usually within 3 years of treatment. Thus, clinical follow-up is important. Recurrent tumors should be resected whenever possible.

Figure 16-18. Dermatofibrosarcoma protuberans of the left flank.

Malignant Fibrous Histiocytoma (Undifferentiated Pleomorphic Sarcoma and Myxofibrosarcoma)

This uncommon, cutaneous, spindle-cell, soft tissue sarcoma occurs in the extremities, head, and neck of elderly patients. They present as solitary, soft to firm, skin-colored subcutaneous nodules. Complete surgical resection is the treatment of choice, and adjuvant radiation therapy provides local control; patients with positive margins benefit most from this combination. Nevertheless, patients undergoing complete gross resection will experience recurrence in 30% to 35% of cases.¹³⁵ Up to 50% of patients may present with distant metastasis, and this is a contraindication to surgical resection.

Angiosarcoma

Angiosarcoma is an uncommon, aggressive cancer that arises from vascular endothelial cells and occurs in four variants, all of which have a poor prognosis.¹⁸² The 5-year survival estimate is 15%.¹⁸³ The head and neck variant presents in individuals older than 40 years as an ill-defined red patch on the face or scalp, often with satellite lesions and distant metastasis, and has a median survival of 18 to 28 months. Lymphedema-associated angiosarcoma (Stewart-Treves) develops on an extremity ipsilateral to an axillary lymphadenectomy. It appears on the upper, medial arm as a violaceous plaque in an individual with nonpitting edema and has a poor survival. Radiation-induced angiosarcoma occurs 4 to 25 years after radiation therapy for benign and malignant conditions. Finally, the epithelioid variant of angiosarcoma involves the lower extremities and also has a poor prognosis. Surgical excision with wide margins is the treatment

of choice for localized disease, but the rate of recurrence is high. Adjuvant radiation therapy can be considered in a multidisciplinary fashion. Cases of extremity disease can be considered for amputation. For widely metastatic disease, chemotherapy and radiation may provide palliation, but these modalities do not prolong overall survival.¹¹⁵

Extramammary Paget's Disease

This rare adenocarcinoma of apocrine glands arises in axillary, perianal, and genital regions of men and women.¹⁸⁴ Clinical presentation is that of erythematous or nonpigmented plaques with an eczema-like appearance that often persist after failed treatment from other therapies. An important characteristic and one that the surgeon must be acutely aware of is the high incidence of concomitant other malignancies with this cutaneous disease. Forty percent of cases are associated with primary gastrointestinal and genitourinary malignancies, and a diligent search should be made after a diagnosis of extramammary Paget's disease is made. Treatment is surgical resection with negative microscopic margins, and adjuvant radiation may provide additional locoregional control.

CONCLUSION

The skin is the largest organ in the human body and is composed of three organized layers that are the source of numerous pathologies. Recognition and management of cutaneous and subcutaneous diseases require an astute clinician to optimize clinical outcomes. Improvements in drugs, therapies, and healthcare practices have helped recovery from skin injuries. Skin and subcutaneous diseases are often managed medically, although surgery frequently complements treatment. Benign tumors are surgical diseases, while malignant tumors are primarily treated surgically, and additional modalities including chemotherapy and radiation therapy are sometimes required. The management of melanoma is at an exciting phase, requiring the coordinated multidisciplinary care of medical oncologists, surgical oncologists, radiation oncologists, dermatopathologists, and plastic and reconstructive surgeons. The advent of new drug therapies will redefine the role of surgery in this disease in the coming years.

A BRIEF HISTORY OF BREAST CANCER THERAPY

Breast cancer has captured the attention of surgeons throughout the ages. The Smith Surgical Papyrus (3000–2500 B.C.) is the earliest known document to refer to breast cancer. The cancer was in a man, but the description encompassed most of the common clinical features. In reference to this cancer, the author concluded, “There is no treatment.”¹ There were few other historical references to breast cancer until the first century. In *De Medicina*, Celsus commented on the value of operations for early breast cancer: “None of these may be removed but the cacoethes (early cancer), the rest are irritated by every method of cure. The more violent the operations are, the more angry they grow.”² In the second century, Galen inscribed his classical clinical observation: “We have often seen in the breast a tumor

exactly resembling the animal the crab. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab's legs. We have often cured this disease in its early stages, but after it has reached a large size, no one has cured it. In all operations we attempt to excise the tumor in a circle where it borders on the healthy tissue.”³

The Galenic system of medicine ascribed cancers to an excess of black bile and concluded that excision of a local bodily outbreak could not cure the systemic imbalance. Theories espoused by Galen dominated medicine until the Renaissance. In 1652, Tulp introduced the idea that cancer was contagious when he reported an elderly woman and her housemaid who both developed breast cancer (N. Tulp, *Observationes medicae* 1652). This single incidence was accepted as conclusive

Key Points

- 1▶ The breast receives its principal blood supply from perforating branches of the internal mammary artery, lateral branches of the posterior intercostal arteries, and branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery.
- 2▶ The axillary lymph nodes usually receive >75% of the lymph drainage from the breast, and the rest flows through the lymph vessels that accompany the perforating branches of the internal mammary artery and enters the parasternal (internal mammary) group of lymph nodes.
- 3▶ Breast development and function are initiated by a variety of hormonal stimuli, with the major trophic effects being modulated by estrogen, progesterone, and prolactin.
- 4▶ Benign breast disorders and diseases are related to the normal processes of reproductive life and to involution, and there is a spectrum of breast conditions that ranges from normal to disorder to disease (aberrations of normal development and involution classification).
- 5▶ To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories. This risk score is then compared with an adjusted population risk of breast cancer to determine the woman's individual risk. This model is not appropriate for use in women with a known *BRCA1* or *BRCA2* mutation or women with lobular or ductal carcinoma in situ.
- 6▶ Routine use of screening mammography in women ≥ 50 years of age reduces mortality from breast cancer by 25%. Magnetic resonance imaging (MRI) screening is recommended in women with *BRCA* mutations and may be considered in women with a greater than 20% to 25% lifetime risk of developing breast cancer.
- 7▶ Core-needle biopsy is the preferred method for diagnosis of palpable or nonpalpable breast abnormalities.
- 8▶ When a diagnosis of breast cancer is made, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels before initiating local therapy.
- 9▶ Sentinel node dissection is the preferred method for staging of the regional lymph nodes in women with clinically node-negative invasive breast cancer. Axillary dissection may be avoided in women with one to two positive sentinel nodes who are treated with breast conserving surgery, whole breast radiation, and systemic therapy.
- 10▶ Local-regional and systemic therapy decisions for an individual patient with breast cancer are best made using a multidisciplinary treatment approach. The sequencing of therapies is dependent on patient and tumor related factors including breast cancer subtype.

evidence and started an idea which persisted into the 20th century among some lay people. The majority of respected surgeons considered operative intervention to be a futile and ill-advised endeavor. The Renaissance and the wars of the 16th and 17th centuries brought developments in surgery, particularly in anatomical understanding. However, there were no new theories espoused in relation to cancer. Beginning with Morgagni, surgical resections were more frequently undertaken, including some early attempts at mastectomy and axillary dissection. The 17th century saw the start of the Age of Enlightenment, which lasted until the 19th century. In terms of medicine, this resulted in the abandonment of Galen's humoral pathology, which was repudiated by Le Dran, and the subsequent rise in cellular pathology as espoused by Virchow. Le Dran stated that breast cancer was a local disease that spread by way of lymph vessels to axillary lymph nodes. When operating on a woman with breast cancer, he routinely removed any enlarged axillary lymph nodes.⁴

In the 19th century, Moore, of the Middlesex Hospital, London, emphasized complete resection of the breast for cancer and stated that palpable axillary lymph nodes also should be removed.⁵ In a presentation before the British Medical Association in 1877, Banks supported Moore's concepts and advocated the resection of axillary lymph nodes even when palpable lymphadenopathy was not evident, recognizing that occult involvement of axillary lymph nodes was frequently present. In 1894, Halsted and Meyer reported their operations for treatment of breast cancer.⁶ By demonstrating superior local-regional control rates after radical resection, these surgeons established radical mastectomy as state-of-the-art treatment for that era. Halsted and Meyer advocated complete dissection of axillary lymph node levels I to III. Both routinely resected the long thoracic

nerve and the thoracodorsal neurovascular bundle with the axillary contents. In 1943, Haagensen and Stout described the grave signs of breast cancer, which included: (a) edema of the skin of the breast, (b) skin ulceration, (c) chest wall fixation, (d) an axillary lymph node >2.5 cm in diameter, and (e) fixed axillary lymph nodes. Women with two or more signs had a 42% local recurrence rate and only a 2% 5-year disease-free survival rate.⁷ Based on these findings, they declared that women with grave signs were beyond cure by radical surgery. In 1948, Patey and Dyson of the Middlesex Hospital, London, advocated a modified radical mastectomy for the management of advanced operable breast cancer, explaining, "Until an effective general agent for treatment of carcinoma of the breast is developed, a high proportion of these cases are doomed to die."⁸ Their technique included removal of the breast and axillary lymph nodes with preservation of the pectoralis major muscle. They showed that removal of the pectoralis minor muscle allowed access to and clearance of axillary lymph node levels I to III.

During the 1970s, there was a transition from the Halsted radical mastectomy to the modified radical mastectomy as the surgical procedure most frequently used by American surgeons to treat breast cancer. This transition acknowledged that: (a) fewer patients were presenting with advanced local disease with or without the grave signs described by Haagensen, (b) extirpation of the pectoralis major muscle was not essential for local-regional control in stages I and II breast cancer, and (c) neither the modified radical mastectomy nor the Halsted radical mastectomy consistently achieved local-regional control of stage III breast cancer. Radiation therapy was incorporated into the management of advanced breast cancer and demonstrated improvements in local-regional control. The National Surgical

Adjuvant Breast and Bowel Project (NSABP) conducted a randomized trial in the early 1970s to determine the impact of local and regional treatments on survival in operable breast cancer. In the B-04 trial, 1665 women were enrolled and stratified by clinical assessment of the axillary lymph nodes. The clinically node-negative women were randomized into three treatment groups: (a) Halsted radical mastectomy; (b) total mastectomy plus radiation therapy; and (c) total mastectomy alone. Clinically node-positive women were randomized to Halsted radical mastectomy or total mastectomy plus radiation therapy. This trial accrued patients between 1971 and 1974, an era that predated widespread availability of effective systemic therapy for breast cancer and therefore reflect survival associated with local-regional therapy alone. There were no differences in survival between the three groups of node-negative women or between the two groups of node-positive women. These overall survival equivalence patterns persisted at 25 years of follow-up.⁹

The next major advance in the surgical management of breast cancer was the development of breast conserving surgery. Breast conserving surgery and radium treatment was first reported by Geoffrey Keynes of St Bartholomew's Hospital, London in the *British Medical Journal* in 1937.¹⁰ Several decades later, the NSABP launched the B-06 trial, a phase 3 study that randomized 1851 patients to total mastectomy, lumpectomy alone, or lumpectomy with breast irradiation. The results showed no difference in disease-free, distant disease-free, and overall survival among the three groups; however, the omission of radiation therapy resulted in significantly higher rates of ipsilateral breast tumor recurrence in those who received lumpectomy alone.¹¹ The B-06 trial excluded patients who had palpable axillary lymph nodes, and those patients randomized to breast conserving surgery had frozen sections performed. If on frozen section the margins were involved, the surgeon proceeded to perform a mastectomy, but the patient was included in the analysis as having had a breast conserving operation. Furthermore, in B-06, local in-breast recurrences were regarded as “nonevents” in terms of disease-free survival. Both the NSABP B-04 and B-06 trials were taken to refute the Halstedian concept that cancer spread throughout a region of the breast to lymphatics and then on to distant sites. Bernard Fisher proposed the “alternative hypothesis” that breast cancer was a systemic disease at diagnosis and that tumor cells had access to both the blood and lymphatic systems and that regional lymph nodes were a marker of systemic disease and not a barrier to the dissemination of cancer cells. He proposed that host factors were important in the development of metastasis and that variations in the local-regional approach to breast cancer treatment were not likely to substantially impact survival. This idea was dominant for a number of years but has been challenged by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview analysis, which reported that “the avoidance of recurrence in a conserved breast . . . avoids about one breast cancer death over the next 15 years for every four such recurrences avoided,”¹² indicating that not all breast cancer is a systemic disease at presentation.

During the 1970s, clinical trials were initiated to determine the value of systemic therapy in the postoperative setting as an adjuvant to surgery. The EBCTCG was established in 1985 to coordinate the meta-analysis of data from randomized clinical trials in order to examine the impact of adjuvant treatments for breast cancer on recurrence and mortality. The EBCTCG overview has demonstrated that anthracycline containing

regimens are superior to cyclophosphamide, methotrexate, and 5-fluorouracil (CMF), and more recently, that the addition of a taxane to an anthracycline-based regimen reduces breast cancer mortality by one-third.¹¹ The overview has also demonstrated that tamoxifen is of benefit only in patients with estrogen receptor (ER) positive breast cancer and that tamoxifen may decrease mortality from breast cancer by as much as 30%.¹³ Importantly, the EBCTCG data have shown that proportional reduction in risk was not significantly affected by standard clinical and pathologic factors such as tumor size, ER status, and nodal status.¹⁴ This underscores the importance of stratification of risk in determining adjuvant therapy decisions in order to minimize the toxicities of therapies in those unlikely to benefit, yet realize the substantial benefits gained in local-regional control and survival in those at higher risk.

Many early randomized clinical trials considered all patients similarly in terms of treatment viewing breast cancer as more of a homogeneous disease. Breast cancer has traditionally been defined by pathologic determinants using conventional light microscopy and basic histologic techniques. In the 1980s, immunohistochemistry allowed assessment of the expression of individual tumor markers (most commonly proteins) while DNA was initially assessed in terms of its ploidy status. Subsequently, breast cancer specimens have been interrogated at the level of the DNA by labeling genes of interest and allowing fluorescent dyes to quantify the abundance of a particular gene and comparing a large number of genes simultaneously in a single breast cancer specimen. Gene expression arrays have shown that breast cancers cluster according to their intrinsic gene expression patterns into at least five intrinsic subtypes and these intrinsic subtypes correlate with breast cancer outcomes.¹⁵ Breast cancers are now classified by molecular subtypes and these are being used for risk stratification and decision making in terms of local-regional and systemic therapies.

Currently, 50% of American women will consult a surgeon regarding breast disease, 25% will undergo breast biopsy for diagnosis of an abnormality, and 12% will develop some variant of breast cancer. Considerable progress has been made in the integration of surgery, radiation therapy, and systemic therapy to control local-regional disease, enhance survival, and improve the quality of life of breast cancer survivors. Surgeons are traditionally the first physician consulted for breast care, and it is critical for them to be well trained in all aspects of the breast from embryologic development, to growth and development, to benign and malignant disease processes. This will allow the greatest opportunity to achieve optimal outcomes for patients and their families.

EMBRYOLOGY AND FUNCTIONAL ANATOMY OF THE BREAST

Embryology

At the fifth or sixth week of fetal development, two ventral bands of thickened ectoderm (mammary ridges, milk lines) are evident in the embryo.¹⁶ In most mammals, paired breasts develop along these ridges, which extend from the base of the forelimb (future axilla) to the region of the hind limb (inguinal area). These ridges are not prominent in the human embryo and disappear after a short time, except for small portions that may persist in the pectoral region. Accessory breasts (*polymastia*) or accessory nipples (*polythelia*) may

Figure 17-1. The mammary milk line. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)

occur along the milk line (Fig. 17-1) when normal regression fails. Each breast develops when an ingrowth of ectoderm forms a primary tissue bud in the mesenchyme. The primary bud, in turn, initiates the development of 15 to 20 secondary buds. Epithelial cords develop from the secondary buds and extend into the surrounding mesenchyme. Major (lactiferous) ducts develop, which open into a shallow mammary pit. During infancy, a proliferation of mesenchyme transforms the mammary pit into a nipple. If there is failure of a pit to elevate above skin level, an inverted nipple results. This congenital malformation occurs in 4% of infants. At birth, the breasts are identical in males and females, demonstrating only the presence of major ducts. Enlargement of the breast may be evident, and a secretion, historically referred to as *witch's milk*, may be produced. These transitory events occur in response to maternal hormones that cross the placenta.

The breast remains undeveloped in the female until puberty, when it enlarges in response to ovarian estrogen and progesterone, which initiate proliferation of the epithelial and connective tissue elements. However, the breasts remain incompletely developed until pregnancy occurs. Absence of the breast (*amastia*) is rare and results from an arrest in mammary ridge development that occurs during the sixth fetal week. Poland's syndrome consists of hypoplasia or complete absence of the breast, costal cartilage and rib defects, hypoplasia of the subcutaneous tissues of the chest wall, and brachysyndactyly. Breast hypoplasia also may be iatrogenically induced before puberty by trauma, infection, or radiation therapy. *Symmastia* is a rare anomaly recognized as webbing between the breasts across the midline. Accessory nipples (polythelia) occur in <1% of infants and may be associated with abnormalities of the urinary and cardiovascular systems. Supernumerary breasts may occur in any configuration along the mammary milk line but most frequently occur between the normal nipple location and the symphysis pubis. Turner's syndrome (ovarian agenesis

and dysgenesis) and Fleischer's syndrome (displacement of the nipples and bilateral renal hypoplasia) may have polymastia as a component. Accessory axillary breast tissue is uncommon and usually is bilateral.

Functional Anatomy

The breast is composed of 15 to 20 lobes (Fig. 17-2), which are each composed of several lobules.¹⁷ Fibrous bands of connective tissue travel through the breast (Cooper's suspensory ligaments), insert perpendicularly into the dermis, and provide structural support. The mature female breast extends from the level of the second or third rib to the inframammary fold at the sixth or seventh rib. It extends transversely from the lateral border of the sternum to the anterior axillary line. The deep or posterior surface of the breast rests on the fascia of the pectoralis major, serratus anterior, and external oblique abdominal muscles, and the upper extent of the rectus sheath. The retro-mammary bursa may be identified on the posterior aspect of the breast between the investing fascia of the breast and the fascia of the pectoralis major muscles. The axillary tail of Spence extends laterally across the anterior axillary fold. The upper outer quadrant of the breast contains a greater volume of tissue than do the other quadrants. The breast has a protuberant conical form. The base of the cone is roughly circular, measuring 10 to 12 cm in diameter. Considerable variations in the size, contour, and density of the breast are evident among individuals. The nulliparous breast has a hemispheric configuration with distinct flattening above the nipple. With the hormonal stimulation that accompanies pregnancy and lactation, the breast becomes larger and increases in volume and density, whereas with senescence, it assumes a flattened, flaccid, and more pendulous configuration with decreased volume.

Nipple-Areola Complex. The epidermis of the nipple-areola complex is pigmented and is variably corrugated. During puberty, the pigment becomes darker and the nipple assumes an elevated configuration. Throughout pregnancy, the areola

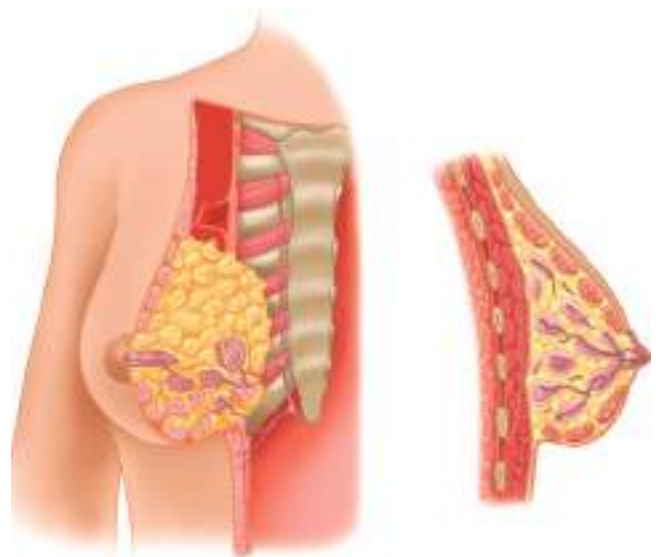

Figure 17-2. Anatomy of the breast. Tangential and cross-sectional (sagittal) views of the breast and associated chest wall. (Reproduced with permission from Bland KI, Copeland EMI: *The Breast: Comprehensive Management of Benign and Malignant Diseases*, 4th ed. Philadelphia, PA: Elsevier/Saunders; 2009.)

enlarges and pigmentation is further enhanced. The areola contains sebaceous glands, sweat glands, and accessory glands, which produce small elevations on the surface of the areola (Montgomery's tubercles). Smooth muscle bundle fibers, which lie circumferentially in the dense connective tissue and longitudinally along the major ducts, extend upward into the nipple, where they are responsible for the nipple erection that occurs with various sensory stimuli. The dermal papilla at the tip of the nipple contains numerous sensory nerve endings and Meissner's corpuscles. This rich sensory innervation is of functional importance because the sucking of the infant initiates a chain of neurohumoral events that results in milk letdown.

Inactive and Active Breast. Each lobe of the breast terminates in a major (lactiferous) duct (2–4 mm in diameter), which opens through a constricted orifice (0.4–0.7 mm in diameter) into the ampulla of the nipple (see Fig. 17-2). Immediately below the nipple-areola complex, each major duct has a dilated portion (lactiferous sinus), which is lined with stratified squamous epithelium. Major ducts are lined with two layers of cuboidal cells, whereas minor ducts are lined with a single layer of columnar or cuboidal cells. Myoepithelial cells of ectodermal origin reside between the epithelial cells in the basal lamina and contain myofibrils. In the inactive breast, the epithelium is sparse and consists primarily of ductal epithelium (Fig. 17-3). In the early phase of the menstrual cycle, minor ducts are cord-like with small lumina. With estrogen stimulation at the time of ovulation, alveolar epithelium increases in height, duct lumina become more prominent, and some secretions accumulate. When the hormonal stimulation decreases, the alveolar epithelium regresses.

With pregnancy, the breast undergoes proliferative and developmental maturation. As the breast enlarges in response to hormonal stimulation, lymphocytes, plasma cells, and eosinophils accumulate within the connective tissues. The minor ducts branch and alveoli develop. Development of the alveoli is asymmetric, and variations in the degree of development may occur within a single lobule (Fig. 17-4). With parturition, enlargement of the breasts occurs via hypertrophy of alveolar

Figure 17-3. Inactive human breast (100x). The epithelium, which is primarily ductal, is embedded in loose connective tissue. Dense connective tissue surrounds the terminal duct lobular units (TDLU). epithelium and accumulation of secretory products in the lumina of the minor ducts. Alveolar epithelium contains abundant endoplasmic reticulum, large mitochondria, Golgi complexes, and dense lysosomes. Two distinct substances are produced by the alveolar epithelium: (a) the protein component of milk, which is synthesized in the endoplasmic reticulum (merocrine secretion); and (b) the lipid component of milk (apocrine secretion), which forms as free lipid droplets in the cytoplasm. Milk released in the first few days after parturition is called *colostrum* and has low lipid content but contains considerable quantities of antibodies. The lymphocytes and plasma cells that accumulate within the connective tissues of the breast are the source of the antibody component. With subsequent reduction in the number of these cells, the production of colostrum decreases and lipid-rich milk is released.

Blood Supply, Innervation, and Lymphatics. The breast receives its principal blood supply from: (a) perforating branches of the internal mammary artery; (b) lateral branches of the posterior intercostal arteries; and (c) branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery (Fig. 17-5). The second, 1▶ third, and fourth anterior intercostal perforators and branches of the internal mammary artery arborize in the breast as the medial mammary arteries. The lateral thoracic artery gives off branches to the serratus anterior, pectoralis major and pectoralis minor, and subscapularis muscles. It also gives rise to lateral mammary branches. The veins of the breast and chest wall follow the course of the arteries, with venous drainage being toward the axilla. The three principal groups of veins are: (a) perforating branches of the internal thoracic vein, (b) perforating branches of the posterior intercostal veins, and (c) tributaries of the axillary vein. Batson's vertebral venous plexus, which invests the vertebrae and extends from the base of the skull to the sacrum, may provide a route for breast cancer metastases to the vertebrae, skull, pelvic bones, and central nervous system. Lymph vessels generally parallel the course of blood vessels.

Figure 17-5. Arterial supply to the breast, axilla, and chest wall. (Reproduced with permission from Bland KI, Copeland EMI: *The Breast: Comprehensive Management of Benign and Malignant Diseases*, 4th ed. Philadelphia, PA: Elsevier/Saunders; 2009.)

Lateral cutaneous branches of the third through sixth intercostal nerves provide sensory innervation of the breast (lateral mammary branches) and of the anterolateral chest wall. These branches exit the intercostal spaces between slips of the serratus anterior muscle. Cutaneous branches that arise from the cervical plexus, specifically the anterior branches of the supraclavicular nerve, supply a limited area of skin over the upper portion of the breast. The intercostobrachial nerve is the lateral cutaneous branch of the second intercostal nerve and may be visualized during surgical dissection of the axilla. Resection of the intercostobrachial nerve causes loss of sensation over the medial aspect of the upper arm.

The boundaries for lymph drainage of the axilla are not well demarcated, and there is considerable variation in the position of the axillary lymph nodes. The six axillary lymph node groups recognized by surgeons (Figs. 17-6 and 17-7) are: (a) the axillary vein group (lateral), which consists of four to six lymph nodes that lie medial or posterior to the vein and receive most of the lymph drainage from the upper extremity; (b) the external mammary group (anterior or pectoral group), which consists of five to six lymph nodes that lie along the lower border of the pectoralis minor muscle contiguous with the lateral thoracic vessels and receive most of the lymph drainage from the lateral aspect of the breast; (c) the scapular group (posterior or subscapular), which consists of five to seven lymph nodes that lie along the posterior wall of the axilla at the lateral border of the scapula contiguous with the subscapular vessels and receive lymph drainage principally from the lower posterior neck, the posterior trunk, and the posterior shoulder; (d) the central group, which consists of three or four sets of lymph nodes that are embedded in the fat of the axilla lying immediately posterior to the pectoralis minor muscle and receive lymph drainage both from the axillary vein, external mammary, and scapular groups of lymph nodes, and directly from the breast; (e) the subclavicular group (apical), which consists of six to twelve sets of lymph nodes that lie posterior and superior to the upper border of the pectoralis minor muscle and receive lymph drainage from all of the other groups of axillary lymph nodes; and (f) the

Figure 17-6. Lymphatic pathways of the breast. Arrows indicate the direction of lymph flow. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)

interpectoral group (Rotter's lymph nodes), which consists of one to four lymph nodes that are interposed between the pectoralis major and pectoralis minor muscles and receive lymph drainage directly from the breast. The lymph fluid that passes

The axillary vein with its major tributaries and the supraclavicular lymph node group are also illustrated. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)

Breast Development and Function

Breast development and function are initiated by a variety of hormonal stimuli, including estrogen, progesterone, prolactin, oxytocin, thyroid hormone, cortisol, and growth hormone.^{17,18} Estrogen, progesterone, and prolactin especially have profound

3► trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development, whereas progesterone is responsible for differentiation of epithelium and for lobular development. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and the postpartum period. It upregulates hormone receptors and stimulates epithelial development. Fig. 17-8 depicts the secretion of neurotrophic hormones from the hypothalamus, which is responsible for regulation of the secretion of the hormones that affect the breast tissues. The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate the release of estrogen and progesterone from the ovaries. In turn, the release of LH and FSH from the basophilic cells of the anterior pituitary is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Positive and negative feedback effects of circulating estrogen and progesterone regulate the secretion of LH, FSH, and GnRH. These hormones are responsible for the development, function, and maintenance of breast tissues (Fig. 17-9A). In the female neonate, circulating estrogen and progesterone levels decrease after birth and remain low throughout childhood because of the sensitivity of

through the interpectoral group of lymph nodes passes directly into the central and subclavicular groups.

As indicated in Fig. 17-7, the lymph node groups are assigned levels according to their anatomic relationship to the pectoralis minor muscle. Lymph nodes located lateral to or below the lower border of the pectoralis minor muscle are referred to as *level I lymph nodes*, which include the axillary vein, external mammary, and scapular groups. Lymph nodes located superficial or deep to the pectoralis minor muscle are referred to as *level II lymph nodes*, which include the central and interpectoral groups. Lymph nodes located medial to or above the upper border of the pectoralis minor muscle are referred to as *level III lymph nodes*, which consist of the subclavicular group. The plexus of lymph vessels in the breast arises in the interlobular connective tissue and in the walls of the lactiferous ducts and communicates with the subareolar plexus of lymph vessels. Efferent lymph vessels from the breast pass around the lateral edge of the pectoralis major muscle and pierce the clavipectoral fascia, ending in the external mammary (anterior, pectoral) group of lymph nodes. Some lymph vessels may travel directly to the subscapular (posterior, scapular) group of lymph nodes. From the upper part of the breast, a few lymph vessels pass directly to the subclavicular (apical) group of lymph nodes. The axillary lymph nodes usually 2► receive >75% of the lymph drainage from the breast. The rest is derived primarily from the medial aspect of the breast, flows through the lymph vessels that accompany the perforating branches of the internal mammary artery, and enters the parasternal (internal mammary) group of lymph nodes.

Figure 17-8. Overview of the neuroendocrine control of breast development and function. ADH = antidiuretic hormone; CRF = corticotropin-releasing factor; GRF = growth hormone-releasing factor; LH-RH = luteinizing hormone-releasing hormone; Oxy = oxytocin; TRH = thyrotropin-releasing hormone. the hypothalamic-pituitary axis to negative feedback from these hormones. With the onset of puberty, there is a decrease in the sensitivity of the hypothalamic-pituitary axis to negative feedback and an increase in its sensitivity to positive feedback from estrogen. These physiologic events initiate an increase in GnRH, FSH, and LH secretion and ultimately an increase in estrogen and progesterone secretion by the ovaries, leading to establishment of the menstrual cycle. At the beginning of the menstrual cycle, there is an increase in the size and density of the breasts, which is followed by engorgement of the breast tissues and epithelial proliferation. With the onset of menstruation, the breast engorgement subsides and epithelial proliferation decreases.

Pregnancy, Lactation, and Senescence

A dramatic increase in circulating ovarian and placental estrogens and progestins is evident during pregnancy, which initiates striking alterations in the form and substance of the breast (see Fig. 17-9B).¹⁷⁻¹⁹ The breast enlarges as the ductal and lobular epithelium proliferates, the areolar skin darkens, and the accessory areolar glands (Montgomery's glands) become prominent.

In the first and second trimesters, the minor ducts branch and develop. During the third trimester, fat droplets accumulate in the alveolar epithelium, and colostrum fills the alveolar and ductal spaces. In late pregnancy, prolactin stimulates the synthesis of milk fats and proteins.

After delivery of the placenta, circulating progesterone and estrogen levels decrease, permitting full expression of the lactogenic action of prolactin. Milk production and release are controlled by neural reflex arcs that originate in nerve endings of the nipple-areola complex. Maintenance of lactation requires regular stimulation of these neural reflexes, which results in prolactin secretion and milk letdown. Oxytocin release results from the auditory, visual, and olfactory stimuli associated with nursing. Oxytocin initiates contraction of the myoepithelial cells, which results in compression of alveoli and expulsion of milk into the lactiferous sinuses. After weaning of the infant, prolactin and oxytocin release decreases. Dormant milk causes increased pressure within the ducts and alveoli, which results in atrophy of the epithelium (Fig. 17-9C). With menopause, there is a decrease in the secretion of estrogen and progesterone by

the ovaries and involution of the ducts and alveoli of the breast. The surrounding fibrous connective tissue increases in density, and breast tissues are replaced by adipose tissues (Fig. 17-9D).

Gynecomastia

Gynecomastia refers to an enlarged breast in the male.²⁰ Physiologic gynecomastia usually occurs during three phases of life: the neonatal period, adolescence, and senescence. Common to each of these phases is an excess of circulating estrogens in relation to circulating testosterone. Neonatal gynecomastia is caused by the action of placental estrogens on neonatal breast tissues, whereas in adolescence, there is an excess of estradiol relative to testosterone, and with senescence, the circulating testosterone level falls, which results in relative hyperestrinism. In gynecomastia, the ductal structures of the male breast enlarge, elongate, and branch with a concomitant increase in epithelium. During puberty, the condition often is unilateral and typically occurs between ages 12 and 15 years. In contrast, senescent gynecomastia is usually bilateral. In the nonobese male, breast tissue measuring at least 2 cm in diameter must be present before a diagnosis of gynecomastia may be made. Mammography and ultrasonography are used to differentiate breast tissues. Dominant masses or areas of firmness, irregularity, and asymmetry suggest the possibility of a breast cancer, particularly in the older male. Gynecomastia generally does not predispose the male breast to cancer. However, the hypoandrogenic state of Klinefelter's syndrome (XXY), in which gynecomastia is usually evident, is associated with an increased risk of breast cancer. Gynecomastia is graded based on the degree of breast enlargement, the position of the nipple with reference to the inframammary fold, and the degree of breast ptosis and skin redundancy: Grade I—mild breast enlargement without skin redundancy; Grade IIa—moderate breast enlargement without skin redundancy; Grade IIb—moderate breast enlargement with skin redundancy; and Grade III—marked breast enlargement with skin redundancy and ptosis.

Table 17-1 identifies the pathophysiologic mechanisms that may initiate gynecomastia: estrogen excess states; androgen deficiency states; pharmacologic causes; and idiopathic causes. Estrogen excess results from an increase in the secretion of estradiol by the testicles or by nontesticular tumors, nutritional alterations such as protein and fat deprivation, endocrine disorders (hyperthyroidism, hypothyroidism), and hepatic disease (nonalcoholic and alcoholic cirrhosis). Refeeding gynecomastia is related to the resumption of pituitary gonadotropin secretion after pituitary shutdown. Androgen deficiency may initiate gynecomastia. Concurrently occurring with decreased circulating testosterone levels is an elevated level of circulating testosterone-binding globulin, which results in a reduction of free testosterone. This senescent gynecomastia usually occurs in men age 50 to 70 years. Hypoandrogenic states can be from primary testicular failure or secondary testicular failure. Klinefelter's syndrome (XXY) is an example of primary testicular failure that is manifested by gynecomastia, hypergonadotropic hypogonadism, and azoospermia. Secondary testicular failure may result from trauma, orchitis, and cryptorchidism. Renal failure, regardless of cause, also may initiate gynecomastia.

Pharmacologic causes of gynecomastia include drugs with estrogenic activity (digitalis, estrogens, anabolic steroids, marijuana) or drugs that enhance estrogen synthesis (human chorionic gonadotropin). Drugs that inhibit the action or synthesis of testosterone (cimetidine, ketoconazole, phenytoin,

spironolactone, antineoplastic agents, diazepam) also have been implicated. Drugs such as reserpine, theophylline, verapamil, tricyclic antidepressants, and furosemide induce gynecomastia through idiopathic mechanisms.

When gynecomastia is caused by androgen deficiency, then testosterone administration may cause regression. When it is caused by medications, then these are discontinued if possible. When endocrine defects are responsible, then these receive specific therapy. As soon as gynecomastia is progressive and does not respond to other treatments, surgical therapy is considered. Techniques include local excision, liposuction or subcutaneous mastectomy. Attempts to reverse gynecomastia with danazol have been successful, but the androgenic side effects of the drug are considerable.

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE BREAST

Infections in the postpartum period remain proportionately the most common time for breast infections to occur. Infections of the breast unrelated to lactation are proportionately less common, however, are still a relatively common presentation to breast specialists. The latter are classified as intrinsic (secondary to abnormalities in the breast) or extrinsic (secondary to an infection in an adjacent structure, e.g., skin, thoracic cavity) the most common being probably periductal mastitis and infected sebaceous cysts, respectively.

Bacterial Infection

Staphylococcus aureus and *Streptococcus* species are the organisms most frequently recovered from nipple discharge from an infected breast.¹⁷ Typically breast abscesses are seen in staphylococcal infections and present with point tenderness, erythema, and hyperthermia. When these abscesses are related to lactation they usually occur within the first few weeks of breastfeeding. If there is progression of a staphylococcal infection, this may result in subcutaneous, subareolar, interlobular (periductal), and retromammary abscesses (unicentric or multicentric). Previously almost all breast abscesses were treated by operative incision and drainage, but now the initial approach is antibiotics and repeated aspiration of the abscess, usually ultrasound-guided aspiration.²¹ Operative drainage is now reserved for those cases that do not resolve with repeated aspiration and antibiotic therapy or cases in which there is some other indication for incision and drainage (e.g., thinning or necrosis of the overlying skin). Preoperative ultrasonography is effective in delineating the required extent of the drainage procedure. While staphylococcal infections tend to be more localized and may be situated deep in the breast tissues, streptococcal infections usually present with diffuse superficial involvement. They are treated with local wound care, including application of warm compresses, and the administration of IV antibiotics (penicillins or cephalosporins). Breast infections may be chronic, possibly with recurrent abscess formation. In this situation, cultures are performed to identify acid-fast bacilli, anaerobic and aerobic bacteria, and fungi. Uncommon organisms may be encountered, and long-term antibiotic therapy may be required.

Biopsy of the abscess cavity wall should be considered at the time of incision and drainage to rule out underlying breast cancer in patients where antibiotics and drainage have been ineffective.

Nowadays hospital-acquired puerperal infections of the breast are much less common, but nursing women who present with milk stasis or noninfectious inflammation may still develop this problem. Epidemic puerperal mastitis is initiated by highly virulent strains of methicillin-resistant *S aureus* that are transmitted via the suckling neonate and may result in substantial morbidity and occasional mortality. Purulent fluid may be expressed from the nipple. In this circumstance, breastfeeding is stopped, antibiotics are started, and surgical therapy is initiated. *Nonepidemic (sporadic) puerperal mastitis* refers to involvement of the interlobular connective tissue of the breast by an infectious process. The patient develops nipple fissuring and milk stasis, which initiates a retrograde bacterial infection. Emptying of the breast using breast suction pumps shortens the duration of symptoms and reduces the incidence of recurrences. The addition of antibiotic therapy results in a satisfactory outcome in >95% of cases.

Zuska's disease, also called *recurrent periductal mastitis*, is a condition of recurrent retroareolar infections and abscesses.^{22,23} Smoking has been implicated as a risk factor for this condition.^{24,25} This syndrome is managed symptomatically by antibiotics coupled with incision and drainage as necessary. Attempts to obtain durable long-term control by wide debridement of chronically infected tissue and/or terminal duct resection have been reported and can be curative, but they can also be frustrated by postoperative infections.²⁶

Mycotic Infections

Fungal infections of the breast are rare and usually involve blastomycosis or sporotrichosis.²⁷ Intraoral fungi that are inoculated into the breast tissue by the suckling infant initiate these infections, which present as mammary abscesses in close proximity to the nipple-areola complex. Pus mixed with blood may be expressed from sinus tracts. Antifungal agents can be administered for the treatment of systemic (noncutaneous) infections. This therapy generally eliminates the necessity of surgical intervention, but occasionally drainage of an abscess, or even partial mastectomy, may be necessary to eradicate a persistent fungal infection. *Candida albicans* affecting the skin of the breast presents as erythematous, scaly lesions of the inframammary or axillary folds. Scrapings from the lesions demonstrate fungal elements (filaments and binding cells). Therapy involves the removal of predisposing factors such as maceration and the topical application of nystatin.

Hidradenitis Suppurativa

Hidradenitis suppurativa of the nipple-areola complex or axilla is a chronic inflammatory condition that originates within the accessory areolar glands of Montgomery or within the axillary sebaceous glands.²⁷ Women with chronic acne are predisposed to developing hidradenitis. When located in and about the nipple-areola complex, this disease may mimic other chronic inflammatory states, Paget's disease of the nipple, or invasive breast cancer. Involvement of the axillary skin is often multifocal and contiguous. Antibiotic therapy with incision and drainage of fluctuant areas is appropriate treatment. Excision of the involved areas may be required. Large areas of skin loss may necessitate coverage with advancement flaps or split-thickness skin grafts.

Mondor's Disease

Mondor's disease is a variant of thrombophlebitis that involves the superficial veins of the anterior chest wall and breast.²⁸ In 1939, Mondor described the condition as "string phlebitis," a thrombosed vein presenting as a tender, cord-like structure.²⁹ Frequently involved veins include the lateral thoracic vein, the thoracoepigastric vein, and, less commonly, the superficial epigastric vein. Typically, a woman presents with acute pain in the lateral aspect of the breast or the anterior chest wall. A tender, firm cord is found to follow the distribution of one of the major superficial veins. Rarely, the presentation is bilateral, and most women have no evidence of thrombophlebitis in other anatomic sites. This benign, self-limited disorder is not indicative of a cancer. When the diagnosis is uncertain, or when a mass is present near the tender cord, biopsy is indicated. Therapy for Mondor's disease includes the liberal use of anti-inflammatory medications and application of warm compresses along the symptomatic vein. The process usually resolves within 4 to 6 weeks. When symptoms persist or are refractory to therapy, excision of the involved vein segment may be considered.

COMMON BENIGN DISORDERS AND DISEASES OF THE BREAST

Benign breast disorders and diseases encompass a wide range of clinical and pathologic entities. Surgeons require an in-depth understanding of benign breast disorders and diseases so that clear explanations may be given to affected women, appropriate treatment is instituted, and unnecessary long-term follow up is avoided.

Aberrations of Normal Development and Involution

The basic principles underlying the aberrations of normal development and involution (ANDI) classification of benign breast conditions are the following: (a) benign breast disorders and diseases are related to the normal processes of reproductive life and to involution; (b) there is a spectrum of breast conditions that ranges from normal to disorder to disease; and (c) the ANDI classification encompasses all aspects of the breast condition, including pathogenesis and the degree of abnormality.³⁰

4▶ The horizontal component of Table 17-2 defines ANDI along a spectrum from normal, to mild abnormality (disorder), to severe abnormality (disease). The vertical component indicates the period during which the condition develops.

Early Reproductive Years. Fibroadenomas are seen and present symptomatically predominantly in younger women age 15 to 25 years (Fig. 17-10).³¹ Fibroadenomas usually grow to 1 or 2 cm in diameter and then are stable but may grow to a larger size. Small fibroadenomas (≤ 1 cm in size) are considered normal, whereas larger fibroadenomas (≤ 3 cm) are disorders, and giant fibroadenomas (>3 cm) are disease. Similarly, multiple fibroadenomas (more than five lesions in one breast) are very uncommon and are considered disease. It is noted that with the introduction of mammographic screening, asymptomatic

Figure 17-10. Fibroadenoma (40x). These benign tumors are typically well circumscribed and are comprised of both stromal and glandular elements. (Used with permission from Dr. Sindhu Menon, Consultant Histopathologist and Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

fibroadenomas are sometimes found in an older screened population. The precise etiology of adolescent breast hypertrophy is unknown. A spectrum of changes from limited to massive stromal hyperplasia (gigantomastia) is seen. Nipple inversion is a disorder of development of the major ducts, which prevents normal protrusion of the nipple. Mammary duct fistulas arise when nipple inversion predisposes to major duct obstruction, leading to recurrent subareolar abscess and mammary duct fistula.

Table 17-2

ANDI classification of benign breast disorders

	NORMAL	DISORDER	DISEASE
Early reproductive years (age 15–25 y)	Lobular development Stromal development Nipple eversion	Fibroadenoma Adolescent hypertrophy Nipple inversion	Giant fibroadenoma Gigantomastia Subareolar abscess Mammary duct fistula
Later reproductive years (age 25–40 y)	Cyclical changes of menstruation Epithelial hyperplasia of pregnancy	Cyclical mastalgia Nodularity Bloody nipple discharge	Incapacitating mastalgia
Involution (age 35–55 y)	Lobular involution Duct involution Dilatation Sclerosis Epithelial turnover	Macrocysts Sclerosing lesions Duct ectasia Nipple retraction Epithelial hyperplasia	— Periductal mastitis — Epithelial hyperplasia with atypia

ANDI = aberrations of normal development and involution.

Later Reproductive Years. Cyclical mastalgia and nodularity usually are associated with premenstrual enlargement of the breast and are regarded as normal. Cyclical pronounced mastalgia and severe painful nodularity are viewed differently than are physiologic discomfort and lumpiness. Painful nodularity that persists for >1 week of the menstrual cycle is considered a disorder. In epithelial hyperplasia of pregnancy, papillary projections sometimes give rise to bilateral bloody nipple discharge.

Involution. Involution of lobular epithelium is dependent on the specialized stroma around it. However, an integrated involution of breast stroma and epithelium is not always seen, and disorders of the process are common. When the stroma involutes too quickly, alveoli remain and form microcysts, which are precursors of macrocysts. The macrocysts are common, often subclinical, and do not require specific treatment. Sclerosing adenosis is considered a disorder of both the proliferative and the involutinal phases of the breast cycle. Duct ectasia (dilated ducts) and periductal mastitis are other important components of the ANDI classification. Periductal fibrosis is a sequela of periductal mastitis and may result in nipple retraction. About 60% of women ≥ 70 years of age exhibit some degree of epithelial hyperplasia (Fig. 17-11). Atypical proliferative diseases

A

B

Figure 17-11. **A.** Ductal epithelial hyperplasia. The irregular intracellular spaces and variable cell nuclei distinguish this process from carcinoma in situ. **B.** Lobular hyperplasia. Table 17-3

Cancer risk associated with benign breast disorders and in situ carcinoma of the breast

ABNORMALITY	RELATIVE RISK
Nonproliferative lesions of the breast	No increased risk
Sclerosing adenosis	No increased risk
Intraductal papilloma	No increased risk
Florid hyperplasia	1.5 to 2-fold
Atypical lobular hyperplasia	4-fold
Atypical ductal hyperplasia	4-fold
Ductal involvement by cells of atypical ductal hyperplasia	7-fold
Lobular carcinoma in situ	10-fold
Ductal carcinoma in situ	10-fold

Data from Dupont WD, Page DL. Risk factors for breast cancer in women with proliferative breast disease. *N Engl J Med.* 1985 Jan 17; 312(3):146-151.

include ductal and lobular hyperplasia, both of which display some features of carcinoma in situ. Women with atypical ductal or lobular hyperplasia have a fourfold increase in breast cancer risk (Table 17-3).

Pathology of Nonproliferative Disorders

Of paramount importance for the optimal management of benign breast disorders and diseases is the histologic differentiation of benign, atypical, and malignant changes.^{32,33} Determining the clinical significance of these changes is a problem that is compounded by inconsistent nomenclature. The classification system originally developed by Page separates the various types of benign breast disorders and diseases into three clinically relevant groups: nonproliferative disorders, proliferative disorders without atypia, and proliferative disorders with atypia (Table 17-4). Nonproliferative disorders of the breast account for 70% of benign breast conditions and carry no increased risk

Table 17-4

Classification of benign breast disorders

Nonproliferative disorders of the breast

- Cysts and apocrine metaplasia
- Duct ectasia
- Mild ductal epithelial hyperplasia
- Calcifications
- Fibroadenoma and related lesions

Proliferative breast disorders without atypia

- Sclerosing adenosis
- Radial and complex sclerosing lesions
- Ductal epithelial hyperplasia
- Intraductal papillomas

Atypical proliferative lesions

- Atypical lobular hyperplasia
- Atypical ductal hyperplasia

Data from Godfrey SE: Is fibrocystic disease of the breast precancerous? *Arch Pathol Lab Med.* 1986 Nov;110(11):991.

for the development of breast cancer. This category includes cysts, duct ectasia, periductal mastitis, calcifications, fibroadenomas, and related disorders.

Breast macrocysts are an involutinal disorder, have a high frequency of occurrence, and are often multiple. Duct ectasia is a clinical syndrome characterized by dilated subareolar ducts that are palpable and often associated with thick nipple discharge. Haagensen regarded duct ectasia as a primary event that led to stagnation of secretions, epithelial ulceration, and leakage of duct secretions (containing chemically irritating fatty acids) into periductal tissue.³⁴ This sequence was thought to produce a local inflammatory process with periductal fibrosis and subsequent nipple retraction. An alternative theory considers periductal mastitis to be the primary process, which leads to weakening of the ducts and secondary dilatation. It is possible that both processes occur and together explain the wide spectrum of problems seen, which include nipple discharge, nipple retraction, inflammatory masses, and abscesses.

Calcium deposits are frequently encountered in the breast. Most are benign and are caused by cellular secretions and debris or by trauma and inflammation. Calcifications that are associated with cancer include microcalcifications, which vary in shape and density and are <0.5 mm in size, and fine, linear calcifications, which may show branching. Fibroadenomas have abundant stroma with histologically normal cellular elements. They show hormonal dependence similar to that of normal breast lobules in that they lactate during pregnancy and involute in the postmenopausal period. Adenomas of the breast are well circumscribed and are composed of benign epithelium with sparse stroma, which is the histologic feature that differentiates them from fibroadenomas. They may be divided into tubular adenomas and lactating adenomas. Tubular adenomas are seen in young nonpregnant women, whereas lactating adenomas are seen during pregnancy or during the postpartum period. Hamartomas are discrete breast tumors that are usually 2 to 4 cm in diameter, firm, and sharply circumscribed. Adenolipomas consist of sharply circumscribed nodules of fatty tissue that contain normal breast lobules and ducts.

Fibrocystic Disease. The term *fibrocystic disease* is nonspecific. Too frequently, it is used as a diagnostic term to describe symptoms, to rationalize the need for breast biopsy, and to explain biopsy results. Synonyms include fibrocystic changes, cystic mastopathy, chronic cystic disease, chronic cystic mastitis, Schimmelbusch's disease, mazoplasia, Cooper's disease, Reclus' disease, and fibroadenomatosis. *Fibrocystic disease* refers to a spectrum of histopathologic changes that are best diagnosed and treated specifically.

Pathology of Proliferative Disorders Without Atypia

Proliferative breast disorders without atypia include sclerosing adenosis, radial scars, complex sclerosing lesions, ductal epithelial hyperplasia, and intraductal papillomas.^{32,33} Sclerosing adenosis is prevalent during the childbearing and perimenopausal years and has no malignant potential. Histologic changes are both proliferative (ductal proliferation) and involutinal (stromal fibrosis, epithelial regression). Sclerosing adenosis is characterized by distorted breast lobules and usually occurs in the context of multiple microcysts, but occasionally presents as a palpable mass. Benign calcifications are often associated with this disorder. Sclerosing adenosis can be managed by observation as long as the imaging features and pathologic findings are

concordant. Central sclerosis and various degrees of epithelial proliferation, apocrine metaplasia, and papilloma formation characterize radial scars and complex sclerosing lesions of the breast. Lesions up to 1 cm in diameter are called *radial scars*, whereas larger lesions are called *complex sclerosing lesions*. Radial scars originate at sites of terminal duct branching where the characteristic histologic changes radiate from a central area of fibrosis. All of the histologic features of a radial scar are seen in the larger complex sclerosing lesions, but there is a greater disturbance of structure with papilloma formation, apocrine metaplasia, and occasionally sclerosing adenosis. Distinguishing between a radial scar and invasive breast carcinoma can be challenging based on core-needle biopsy sampling. Often the imaging features of a radial scar (which can be quite similar to an invasive cancer) will dictate the need for either a vacuum-assisted biopsy or surgical excision in order to exclude the possibility of carcinoma.

Mild ductal hyperplasia is characterized by the presence of three or four cell layers above the basement membrane. Moderate ductal hyperplasia is characterized by the presence of five or more cell layers above the basement membrane. Florid ductal epithelial hyperplasia occupies at least 70% of a minor duct lumen. It is found in >20% of breast tissue specimens, is either solid or papillary, and is associated with an increased cancer risk (see Table 17-3). Intraductal papillomas arise in the major ducts, usually in premenopausal women. They generally are <0.5 cm in diameter but may be as large as 5 cm. A common presenting symptom is nipple discharge, which may be serous or bloody. Grossly, intraductal papillomas are pinkish tan, friable, and usually attached to the wall of the involved duct by a stalk. They rarely undergo malignant transformation, and their presence does not increase a woman's risk of developing breast cancer (unless accompanied by atypia). However, multiple intraductal papillomas, which occur in younger women and are less frequently associated with nipple discharge, are susceptible to malignant transformation.

Pathology of Atypical Proliferative Diseases

The atypical proliferative diseases have some of the features of carcinoma in situ but either lack a major defining feature of carcinoma in situ or have the features in less than fully developed form.³⁴ Atypical ductal hyperplasia (ADH) appears similar to low grade ductal carcinoma in situ (DCIS) histologically and is composed of monotonous round, cuboidal, or polygonal cells enclosed by basement membrane with rare mitoses. A lesion will be considered to be ADH if it is up to 2 or 3 mm in size but would be called DCIS if it is larger than 3 mm. The diagnosis can be difficult to establish with core-needle biopsy specimen alone and many cases will require excisional biopsy specimen for classification. Individuals with a diagnosis of ADH are at increased risk for development of breast cancer and should be counseled appropriately regarding risk reduction strategies.

In 1978, Haagensen et al described lobular neoplasia, a spectrum of disorders ranging from atypical lobular hyperplasia to lobular carcinoma in situ (LCIS).³⁵ Atypical lobular hyperplasia (ALH) results in minimal distention of lobular units with cells that are similar to those seen in LCIS. The diagnosis of LCIS is made when small monomorphic cells that distend the terminal ductal lobular unit are noted. In cases of LCIS, the acini are full and distended while the overall lobular architecture is maintained (Fig. 17-12). Classic LCIS is not associated with a specific mammographic or palpable abnormality but is

Figure 17-12. Lobular carcinoma in situ (100x). There are small monomorphic cells that distend the terminal duct lobular unit, without necrosis or mitoses. (Used with permission from Dr. Sindhu Menon, Consultant Histopathologist and Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

an incidental finding noted on breast biopsy. There is a variant of LCIS that has been termed *pleomorphic LCIS*. In the case of pleomorphic LCIS, there can be calcifications or other suspicious mammographic changes that dictate the need for biopsy. Classic LCIS is not treated with excision as the patient is at risk for developing invasive breast cancer in either breast and therefore the patient is counseled regarding appropriate risk reduction strategies. Pleomorphic LCIS can be difficult to distinguish from high-grade DCIS and there are some proponents who have suggested that patients with pleomorphic LCIS be managed similar to those with DCIS with attention to margins and consideration for radiation therapy in the setting of breast conserving treatment. The use of immunohistochemical staining for E-cadherin can help to discriminate between LCIS and DCIS. In lobular neoplasias, such as ALH and LCIS, there is a lack of E-cadherin expression, whereas the majority of ductal lesions will demonstrate E-cadherin reactivity.

Treatment of Selected Benign Breast Disorders and Diseases

Cysts. Because needle biopsy of breast masses may produce artifacts that make mammography assessment more difficult, many multidisciplinary teams prefer to image breast masses before performing either fine-needle aspiration or core-needle biopsy.^{36,37} In practice, however, the first investigation of palpable breast masses may be a needle biopsy, which allows for the early diagnosis of cysts. A 21-gauge needle attached to a 10-mL syringe is placed directly into the mass, which is fixed by fingers of the nondominant hand. The volume of a typical cyst is 5 to 10 mL, but it may be 75 mL or more. If the fluid that is aspirated is not bloodstained, then the cyst is aspirated to dryness, the needle is removed, and the fluid is discarded because cytologic examination of such fluid is not cost effective. After aspiration, the breast is carefully palpated to exclude a residual mass. In most cases, however, imaging has been performed prior to a needle being introduced into the breast, and indeed the majority of cysts are now aspirated under ultrasound

guidance. If a mass was noted on initial ultrasound or there is a residual mass post aspiration, then a tissue specimen is obtained, usually by core biopsy. When cystic fluid is bloodstained, fluid can be sent for cytologic examination. A simple cyst is rarely of concern, but a complex cyst may be the result of an underlying malignancy. A pneumocystogram can be obtained by injecting air into the cyst and then obtaining a repeat mammogram. When this technique is used, the wall of the cyst cavity can be more carefully assessed for any irregularities.

Fibroadenomas. Most fibroadenomas are self-limiting and many go undiagnosed, so a more conservative approach is reasonable. Careful ultrasound examination with core-needle biopsy will provide for an accurate diagnosis. Ultrasonography may reveal specific features that are pathognomonic for fibroadenoma, and in a young woman (e.g., under 25 years) where the risk of breast cancer is already very low a core-needle biopsy may not be necessary. In patients where biopsy is performed, the patient is counseled concerning the ultrasound and biopsy results, and surgical excision of the fibroadenoma may be avoided. Cryoablation and ultrasound-guided vacuum-assisted biopsy are approved treatments for fibroadenomas of the breast, especially lesions <3 cm. Larger lesions are often still best treated by excision. With short-term follow-up, a significant percentage of fibroadenomas will decrease in size and will no longer be palpable.³⁸ However, many will remain palpable, especially those larger than 2 cm.³⁹ Therefore, women should be counseled that the options for treatment include surgical removal, cryoablation, vacuum assisted biopsy, or observation.

Sclerosing Disorders. The clinical significance of sclerosing adenosis lies in its imitation of cancer. On physical examination, it may be confused with cancer, by mammography, and at gross pathologic examination. Excisional biopsy and histologic examination are frequently necessary to exclude the diagnosis of cancer. The diagnostic work-up for radial scars and complex sclerosing lesions frequently involves stereotactic biopsy. It usually is not possible to differentiate these lesions with certainty from cancer by mammographic features, so a larger tissue biopsy is recommended either by way of vacuum-assisted biopsy or an open surgical excisional biopsy. The mammographic appearance of a radial scar or sclerosing adenosis (mass density with spiculated margins) will usually lead to an assessment that the results of a core-needle biopsy specimen showing benign disease are discordant with the radiographic findings.

Periductal Mastitis. Painful and tender masses behind the nipple-areola complex are aspirated with a 21-gauge needle attached to a 10-mL syringe. Any fluid obtained is submitted for culture using a transport medium appropriate for the detection of anaerobic organisms. In the absence of pus, women are started on a combination of antibiotics to cover polymicrobial infections while awaiting the results of culture. Antibiotics are then continued based on sensitivity tests. Many cases respond satisfactorily to antibiotics alone, but when considerable purulent material is present, repeated ultrasound guided aspiration is performed, and ultimately in a proportion of cases surgical treatment is required. Unlike puerperal abscesses, a subareolar abscess is usually unilocular and often is associated with a single duct system. Ultrasound will accurately delineate its extent. In those cases that come to surgery, the surgeon may either undertake simple drainage with a view toward formal

Table 17-5

Treatment of recurrent subareolar sepsis

SUITABLE FOR FISTULECTOMY	SUITABLE FOR TOTAL DUCT EXCISION
Small abscess localized to one segment	Large abscess affecting >50% of the areolar circumference
Recurrence involving the same segment	Recurrence involving a different segment
Mild or no nipple inversion	Marked nipple inversion
Patient unconcerned about nipple inversion	Patient requests correction of nipple inversion
Younger patient	Older patient
No discharge from other ducts	Purulent discharge from other ducts
No prior fistulectomy	Recurrence after fistulectomy

surgery, should the problem recur, or proceed with definitive surgery. In a woman of childbearing age, simple drainage is preferred, but if there is an anaerobic infection, recurrent infection frequently develops. Recurrent abscess with fistula is a difficult problem. Treatment of periductal fistula was initially recommended to be opening up of the fistulous track and allowing it to granulate.⁴⁰ This approach may still be used, especially if the fistula is recurrent after previous attempts at fistulectomy. However, nowadays the preferred initial surgical treatment is by fistulectomy and primary closure with antibiotic coverage.⁴¹ Excision of all the major ducts is an alternative option depending on the circumstances (Table 17-5). When a localized periareolar abscess recurs at the previous site and a fistula is present, the preferred operation is fistulectomy, which has minimal complications and a high degree of success. However, when subareolar sepsis is diffused rather than localized to one segment or when more than one fistula is present, total duct excision is the most expeditious approach. The first circumstance is seen in young women with squamous metaplasia of a single duct, whereas the latter circumstance is seen in older women with multiple ectatic ducts. Age is not always a reliable guide, however, and fistula excision is the preferred initial procedure for localized sepsis irrespective of age. Antibiotic therapy is useful for recurrent infection after fistula excision, and a 2- to 4-week course is recommended before total duct excision.

Nipple Inversion. More women request correction of congenital nipple inversion than request correction for the nipple inversion that occurs secondary to duct ectasia. Although the results are usually satisfactory, women seeking correction for cosmetic reasons should always be made aware of the surgical complications of altered nipple sensation, nipple necrosis, and postoperative fibrosis with nipple retraction. Because nipple inversion is a result of shortening of the subareolar ducts, a complete division of these ducts is necessary for permanent correction of the disorder.

RISK FACTORS FOR BREAST CANCER

Hormonal and Nonhormonal Risk Factors

Increased exposure to estrogen is associated with an increased risk for developing breast cancer, whereas reducing exposure is thought to be protective.⁴²⁻⁴⁸ Correspondingly, factors that increase the number of menstrual cycles, such as early menarche, nulliparity, and late menopause, are associated with increased risk. Moderate levels of exercise and a longer lactation period, factors that decrease the total number of menstrual cycles, are protective. The terminal differentiation of breast epithelium associated with a full-term pregnancy is also protective, so older age at first live birth is associated with an increased risk of breast cancer. Finally, there is an association between obesity and increased breast cancer risk. Because the major source of estrogen in postmenopausal women is the conversion of androstenedione to estrone by adipose tissue, obesity is associated with a long-term increase in estrogen exposure.

Nonhormonal risk factors include radiation exposure. Young women who receive mantle radiation therapy for Hodgkin's lymphoma have a breast cancer risk that is 75 times greater than that of age-matched control subjects. Survivors of the atomic bomb blasts in Japan during World War II have a very high incidence of breast cancer, likely because of somatic mutations induced by the radiation exposure. In both circumstances, radiation exposure during adolescence, a period of active breast development, magnifies the deleterious effect. Studies also suggest that the risk of breast cancer increases as the amount of alcohol a woman consumes increases.⁴⁹ Alcohol consumption is known to increase serum levels of estradiol. Finally, evidence suggests that long-term consumption of foods with a high fat content contributes to an increased risk of breast cancer by increasing serum estrogen levels.

Risk Assessment Models

The average lifetime risk of breast cancer for newborn U.S. women is 12%.^{50,51} The longer a woman lives without cancer, the lower her risk of developing breast cancer. Thus, a woman age 50 years has an 11% lifetime risk of developing breast cancer, and a woman age 70 years has a 7% lifetime risk of developing breast cancer. Because risk factors for breast cancer interact, evaluating the risk conferred by combinations of risk factors is difficult. There are several risk assessment models available to predict the risk of breast cancer. From the Breast Cancer Detection Demonstration Project, a mammography screening program conducted in the 1970s, Gail et al developed the model most frequently used in the United States, which incorporates age, age at menarche, age at first live birth, the number of breast biopsy specimens, any history of atypical hyperplasia, and number of first-degree relatives with breast cancer.⁵² It predicts the cumulative risk of breast cancer according to decade of life. To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories (Table 17-6). This risk score is then compared to an adjusted population risk of breast cancer to determine a woman's individual or absolute risk. The output is a 5-year risk and a lifetime risk of developing breast cancer. A software program incorporating the Gail model is available from the National Cancer Institute at <http://bcra.nci.nih.gov/brc>. This model was recently modified to more accurately assess risk in African American women.^{52,53} There have also been modifications that project individualized absolute

Table 17-6

Relative risk estimates for the Gail model

VARIABLE	RELATIVE RISK

invasive breast cancer risk for Asian and Pacific Island American women. The Gail model is the most widely used model in the United States. Gail and colleagues have also described a revised model that includes body weight and mammographic density but excludes age at menarche.⁵⁴

Claus et al, using data from the Cancer and Steroid Hormone Study, a case-control study of breast cancer, developed the other frequently used risk assessment model, which is based on assumptions about the prevalence of high-penetrance breast cancer susceptibility genes.⁵⁵ Compared with the Gail model, the Claus model incorporates more information about family history but excludes other risk factors. The Claus model provides individual estimates of breast cancer risk according to decade of life based on presence of first- and second-degree relatives with

breast cancer and their age at diagnosis. Risk factors that are less consistently associated with breast cancer (diet, use of oral contraceptives, lactation) or are rare in the general population (radiation exposure) are not included in either the Gail or Claus risk assessment model. Other models have been proposed that account for mammographic breast density in assessing breast cancer risk.^{54,56}

Neither the Gail model nor the Claus model accounts for the risk associated with mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* (described in detail in the following section). The BRCAPRO model is a Mendelian model that calculates the probability that an individual is a carrier of a mutation in one of the breast cancer susceptibility genes based on their family history of breast and ovarian cancer.⁵⁷ The probability that an individual will develop breast or ovarian cancer is derived from this mutation probability based on age-specific incidence curves for both mutation carriers and noncarriers.⁵⁸ Use of the BRCAPRO model in the clinic is challenging since it requires input of all family history information regarding breast and ovarian cancer. The Tyrer-Cuzick model attempts to utilize both family history information and individual risk information. It uses the family history to calculate the probability that an individual carries a mutation in one of the breast cancer susceptibility genes, and then the risk is adjusted based on personal risk factors, including age at menarche, parity, age at first live birth, age at menopause, history of atypical hyperplasia or LCIS, height, and body mass index.⁵⁹ Once a risk model has been utilized to assess breast cancer risk, this must be communicated to the individual and put into context with competing risk and medical comorbidities. This information can then be used to discuss options that are available to the individual for managing risk.

Risk Management

Several important medical decisions may be affected by a woman's underlying risk of developing breast cancer.⁶⁰⁻⁶⁸ These decisions include when to use postmenopausal hormone replacement therapy, at what age to begin mammography screening or incorporate magnetic resonance imaging (MRI) screening, when to use tamoxifen to prevent breast cancer, and when to perform prophylactic mastectomy to prevent breast cancer. Postmenopausal hormone replacement therapy was widely prescribed in the 1980s and 1990s because of its effectiveness in controlling the symptoms of estrogen deficiency, namely vasomotor symptoms such as hot flashes, night sweats and their associated sleep deprivation, osteoporosis, and cognitive changes. Furthermore, these hormone supplements were thought to reduce coronary artery disease as well. Use of combined estrogen and progesterone became standard for women who had not undergone hysterectomy because unopposed estrogen increases the risk of uterine cancer. Concerns of prolonging a woman's lifetime exposure to estrogen, coupled with conflicting data regarding the impact of these hormones on cardiovascular health, motivated the implementation of large-scale phase 3 clinical trials to definitively evaluate the risks vs. benefits of postmenopausal hormone replacement therapy. The Women's Health Initiative (WHI) was therefore designed by the National Institutes of Health as a series of clinical trials to study the effects of diet, nutritional supplements, and hormones on the risk of cancer, cardiovascular disease, and bone health in postmenopausal women. Findings from primary studies of postmenopausal hormone replacement therapy were released in 2002, demonstrating conclusively that

breast cancer risk is threefold to fourfold higher after >4 years of use and there is no significant reduction in coronary artery or cerebrovascular risks. The Collaborative Group on Hormonal Factors in Breast Cancer combined and reanalyzed data from a number of studies totaling 52,705 women with breast cancer and 108,411 women without breast cancer. They found an increased risk of breast cancer with every use of estrogen replacement therapy. They also reported increased risk among current users but not past users and risk increased with increasing duration of use of hormone replacement therapy.⁶⁹ Cheblowski et al also reported from the WHI study that estrogen + progesterone increased the incidence of breast cancer.⁷⁰ This was confirmed by the Million Women study, which also showed that the increased risk was substantially greater for the combined estrogen + progesterone replacement therapy than other types of hormone replacement therapy.⁷¹

Breast Cancer Screening. Routine use of screening mammography in women ≥50 years of age has been reported to reduce mortality from breast cancer by 25%.⁷² This reduction comes at an acceptable economic cost. More recently, there has been debate over the potential harms associated with breast screening.⁷³ Controversy over the age to initiate screening mammography is evident in the current recommendations. The U.S. Preventive Services Task Force (USPSTF), the American Cancer Society (ACS), and the National Comprehensive Cancer Network (NCCN) are three organizations with differing recommendations for screening mammography in average risk women. The guidelines, however, similarly define high-risk women as those with personal history of breast cancer, history of chest radiation at young age, and confirmed or suspected genetic mutation known to increase risk for developing breast cancer. The USPSTF recommends biennial screening mammography for women age 50 to 74 years. The USPSTF applies these guidelines to asymptomatic women age >40 years who do not have a preexisting breast cancer or who were not previously diagnosed with a high-risk breast lesion, and who are not at high risk for breast cancer because of a known underlying genetic mutation or history of chest radiation at a young age.⁷⁴⁻⁷⁶ In October 2015, the ACS released updated guidelines stating average-risk women should start annual screening mammography at 45 years of age. Women age 45 to 54 years should be screened annually, and those 55 years and older should transition to biennial screening or have the opportunity to continue annual screening. Women should have the opportunity to begin annual screening between the ages of 40 and 44 years and should continue screening as long as their overall health is good and have a life expectancy of 10 years or longer. The ACS does not recommend clinical breast examination for breast cancer screening among average-risk women at any age.⁷⁷ The NCCN recommends that average-risk women begin annual screening mammograms at ≥40 years of age, along with annual clinical breast exams and breast awareness.⁷⁸

The United Kingdom recently established an independent expert panel to review the published literature and estimate the benefits and harms associated with screening women >50 years of age in its national screening program.⁷⁹ The expert panel estimated that an invitation to breast screening delivers about a 20% reduction in breast cancer mortality. At the same time, however, the panel estimated that in women invited to the screening, about 11% of the cancers diagnosed in their lifetime constitute overdiagnosis. Despite the overdiagnosis, the panel concluded that breast screening confers significant benefit and

should continue. The use of screening mammography in women <50 years of age is more controversial for several reasons: (a) breast density is greater, and screening mammography is less likely to detect early breast cancer (i.e., reduced sensitivity); (b) screening mammography results in more false-positive test findings (i.e., reduced specificity), which results in unnecessary biopsy specimens; and (c) younger women are less likely to have breast cancer (i.e., lower incidence), so fewer young women will benefit from screening.^{80,81} In the United States, on a population basis, however, the benefits of screening mammography in women between the ages of 40 and 49 years is still felt to outweigh the risks; although targeting mammography to women at higher risk of breast cancer improves the balance of risks and benefits and is the approach some health care systems have taken. In one study of women age 40 to 49 years, an abnormal mammography finding was three times more likely to be cancer in a woman with a family history of breast cancer than in a woman without such a history. Furthermore, as noted previously in the section *Risk Assessment Models*, mounting data regarding mammographic breast density demonstrate an independent correlation with breast cancer risk. Incorporation of breast density measurements into breast cancer risk assessment models appears to be a promising strategy for increasing the accuracy of these tools. Unfortunately, widespread application of these modified models is hampered by inconsistencies in the reporting of mammographic density. Ultrasonography can also be used for breast cancer screening in women with dense breasts, but there is no data available that the additional cancers detected with this modality reduce mortality from breast cancer.

Current recommendations by the United States Preventive Services Task Force are that women undergo biennial mammographic screening between the ages of 50 and 74 years.⁷⁷ The use of MRI for breast cancer screening is recommended by the ACS for women with a 20% to 25% or greater lifetime risk using risk assessment tools based mainly on family history, *BRCA* mutation carriers, those individuals who have a family member with a *BRCA* mutation who have not been tested themselves, individuals who received radiation to the chest between the ages of 10 and 30 years, and those individuals with a history of Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or those who have a first-degree relative with one of these syndromes. MRI is an extremely sensitive screening tool that is not limited by the density of the breast tissue as mammography is; however, its specificity is moderate, leading to more false-positive events and the increased need for biopsy.

Chemoprevention. Tamoxifen, a selective estrogen receptor modulator, was the first drug shown to reduce the incidence of breast cancer in healthy women. There have been four prospective studies published evaluating tamoxifen vs. placebo for reducing the incidence of invasive breast cancer for women at increased risk. The largest trial was the Breast Cancer Prevention Trial (NSABP P-01), which randomly assigned >13,000 women with a 5-year Gail relative risk of breast cancer of 1.66% or higher or LCIS to receive tamoxifen or placebo. After a mean follow-up period of 4 years, the incidence of breast cancer was reduced by 49% in the group receiving tamoxifen.⁶⁰ The decrease was evident only in ER-positive breast cancers with no significant change in ER-negative tumors. The Royal Marsden Hospital Tamoxifen Chemoprevention Trial,⁷⁸ the Italian Tamoxifen Prevention Trial,⁸² and the International Breast Cancer Intervention Study I (IBIS-I) trial all⁸³ showed a reduction in

ER-positive breast cancers with the use of tamoxifen compared with placebo. There was no effect on mortality; however, the trials were not powered to assess either breast cancer mortality or all-cause mortality events. The adverse events were similar in all four randomized trials, including an increased risk of endometrial cancer, thromboembolic events, cataract formation, and vasomotor disturbances in individuals receiving tamoxifen.

Tamoxifen therapy currently is recommended only for women who have a Gail relative risk of 1.66% or higher, who are age 35 to 59, women over the age of 60, or women with a diagnosis of LCIS or atypical ductal or lobular hyperplasia. In addition, deep vein thrombosis occurs 1.6 times as often, pulmonary emboli 3.0 times as often, and endometrial cancer 2.5 times as often in women taking tamoxifen. The increased risk for endometrial cancer is restricted to early stage cancers in postmenopausal women. Cataract surgery is required almost twice as often among women taking tamoxifen. Gail et al subsequently developed a model that accounts for underlying risk of breast cancer as well as comorbidities to determine the net risk-benefit ratio of tamoxifen use for chemoprevention.⁸⁴

The NSABP completed a second chemoprevention trial, designed to compare tamoxifen and raloxifene for breast cancer risk reduction in high-risk postmenopausal women. Raloxifene, another selective estrogen receptor modulator, was selected for the experimental arm in this follow-up prevention trial because its use in managing postmenopausal osteoporosis suggested that it might be even more effective at breast cancer risk reduction, but without the adverse effects of tamoxifen on the uterus. The P-2 trial, the Study of Tamoxifen and Raloxifene (known as the *STAR trial*), randomly assigned 19,747 postmenopausal women at high-risk for breast cancer to receive either tamoxifen or raloxifene. The initial report of the P-2 trial showed the two agents were nearly identical in their ability to reduce breast cancer risk, but raloxifene was associated with a more favorable adverse event profile.⁸⁵ An updated analysis revealed that raloxifene maintained 76% of the efficacy of tamoxifen in prevention of invasive breast cancer with a more favorable side effect profile. The risk of developing endometrial cancer was significantly higher with tamoxifen use at longer follow-up.⁸⁶ Although tamoxifen has been shown to reduce the incidence of LCIS and DCIS, raloxifene did not have an effect on the frequency of these diagnoses.

Aromatase inhibitors (AIs) have been shown to be more effective than tamoxifen in reducing the incidence of contralateral breast cancers in postmenopausal women receiving AIs for adjuvant treatment of invasive breast cancer. The MAP.3 trial was the first study to evaluate an AI as a chemopreventive agent in postmenopausal women at high risk for breast cancer. The trial randomized 4560 women to exemestane 25 mg daily vs. placebo for 5 years. After a median follow-up of 35 months, exemestane was shown to reduce invasive breast cancer incidence by 65%. Side effect profiles demonstrated more grade II or higher arthritis and hot flashes in patients taking exemestane.⁸⁷ The IBIS II trial on the other hand, randomized 3864 postmenopausal women to either anastrozole, a nonsteroidal aromatase inhibitor, vs. placebo with a further randomization to bisphosphonate or not based on bone density.^{88,89} After a median follow-up of 5 years, anastrozole reduced the incidence of invasive breast cancer by about 50%. The trial also had an initial sub-study that looked at the effect of the aromatase inhibitor on cognitive function and reported no adverse effects.⁹⁰ The American Society of Clinical Oncology recommends tamoxifen for

chemoprevention in premenopausal or postmenopausal women and consideration for raloxifene or exemestane in postmenopausal women who are noted to be at increased risk of breast cancer.^{91,92} The discussion with an individual patient should include risk assessment and potential risks and benefits with each agent.

Risk-Reducing Surgery. A retrospective study of women at high risk for breast cancer found that prophylactic mastectomy reduced their risk by >90%.⁶² However, the effects of prophylactic mastectomy on the long-term quality of life are poorly quantified. A study involving women who were carriers of a breast cancer susceptibility gene (*BRCA*) mutation found that the benefit of prophylactic mastectomy differed substantially according to the breast cancer risk conferred by the mutations. For women with an estimated lifetime risk of 40%, prophylactic mastectomy added almost 3 years of life, whereas for women with an estimated lifetime risk of 85%, prophylactic mastectomy added >5 years of life.⁶⁶ Domchek et al evaluated a cohort of *BRCA1* and 2 mutation carriers who were followed prospectively and reported on outcomes with risk-reducing surgery.⁹³ They found that risk-reducing mastectomy was highly effective at preventing breast cancer in both *BRCA1* and 2 mutation carriers. Risk-reducing salpingo-oophorectomy was highly effective at reducing the incidence of ovarian cancer and breast cancer in *BRCA* mutation carriers and was associated with a reduction in breast cancer-specific mortality, ovarian cancer-specific mortality, and all-cause mortality. While studies of bilateral prophylactic or risk-reducing mastectomy have reported dramatic reductions in breast cancer incidence among those without known *BRCA* mutations, there is little data to support a survival benefit. Another consideration is that while most patients are satisfied with their decision to pursue risk-reducing surgery, some are dissatisfied with the cosmetic outcomes mostly due to reconstructive issues.

BRCA Mutations

BRCA1. Up to 5% of breast cancers are caused by inheritance of germline mutations such as *BRCA1* and *BRCA2*, which are inherited in an autosomal dominant fashion with varying degrees of penetrance (Table 17-7).⁹⁴⁻¹⁰⁰ *BRCA1* is located on chromosome arm 17q, spans a genomic region of approximately 100 kilobases (kb) of DNA, and contains 22 coding exons for 1863 amino acids. Both *BRCA1* and *BRCA2* function as tumor-suppressor genes, and for each gene, loss of both alleles is required for the initiation of cancer. Data accumulated since the isolation of the *BRCA1* gene suggest a role in transcription, cell-cycle control, and DNA damage repair pathways. More than 500 sequence variations in *BRCA1* have been identified. It now is known that germline mutations in *BRCA1* represent a predisposing genetic factor in as many as 45% of hereditary breast cancers and in at least 80% of hereditary ovarian cancers. Female mutation carriers have been reported to have up to an 85% lifetime risk (for some families) for developing breast cancer and up to a 40% lifetime risk for developing ovarian cancer. The initial families reported had high penetrance and subsequently the average lifetime risk has been reported to lie between 60% and 70%. Breast cancer susceptibility in these families appears as an autosomal dominant trait with high penetrance. Approximately 50% of children of carriers inherit the trait. In general, *BRCA1*-associated breast cancers are invasive ductal carcinomas, are poorly differentiated, are in the majority

Table 17-7

Incidence of sporadic, familial, and hereditary breast cancer

Sporadic breast cancer	65%–75%
Familial breast cancer	20%–30%
Hereditary breast cancer	5%–10%
<i>BRCA1</i> ^a	45%
<i>BRCA2</i>	35%
p53 ^a (Li-Fraumeni syndrome)	1%
STK11/LKB1 ^a (Peutz-Jeghers syndrome)	<1%
PTEN ^a (Cowden disease)	<1%
MSH2/MLH1 ^a (Muir-Torre syndrome)	<1%
ATM ^a (Ataxia-telangiectasia)	<1%
Unknown	20%

^aAffected gene.

Data from Martin AM, Weber BL: *Genetic and hormonal risk factors in breast cancer*, J Natl Cancer Inst. 2000 Jul 19;92(14):1126-1135.

hormone receptor negative, and have a triple receptor negative (immunohistochemical profile: ER-negative, PR-negative, and *HER2*-negative) or basal phenotype (based on gene expression profiling). *BRCA1*-associated breast cancers have a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases; a higher prevalence of bilateral breast cancer; and the presence of associated cancers in some affected individuals, specifically ovarian cancer and possibly colon and prostate cancers.

Several founder mutations have been identified in *BRCA1*. The two most common mutations are 185delAG and 5382insC, which account for 10% of all the mutations seen in *BRCA1*. These two mutations occur at a 10-fold higher frequency in the Ashkenazi Jewish population than in non-Jewish Caucasians. The carrier frequency of the 185delAG mutation in the Ashkenazi Jewish population is 1% and, along with the 5382insC mutation, accounts for almost all *BRCA1* mutations in this population. Analysis of germline mutations in Jewish and non-Jewish women with early-onset breast cancer indicates that 20% of Jewish women who develop breast cancer before age 40 years carry the 185delAG mutation. There are founder *BRCA1* mutations in other populations including, among others, Dutch, Polish, Finnish, and Russian populations.¹⁰¹⁻¹⁰⁵

***BRCA2*.** *BRCA2* is located on chromosome arm 13q and spans a genomic region of approximately 70 kb of DNA. The 11.2-kb coding region contains 26 coding exons.⁹⁴⁻¹⁰⁰ It encodes a protein of 3418 amino acids. The *BRCA2* gene bears no homology to any previously described gene, and the protein contains no previously defined functional domains. The biologic function of *BRCA2* is not well defined, but like *BRCA1*, it is postulated to play a role in DNA damage response pathways. *BRCA2* messenger RNA also is expressed at high levels in the late G₁ and S phases of the cell cycle. The kinetics of *BRCA2* protein regulation in the cell cycle is similar to that of *BRCA1* protein, which suggests that these genes are coregulated. The mutational spectrum of *BRCA2* is not as well established as that of *BRCA1*. To date, >250 mutations have been found. The breast cancer risk for *BRCA2* mutation carriers is close to 85%, and the lifetime ovarian cancer risk, while lower than for *BRCA1*, is still

estimated to be close to 20%. Breast cancer susceptibility in *BRCA2* families is an autosomal dominant trait and has a high penetrance. Approximately 50% of children of carriers inherit the trait. Unlike male carriers of *BRCA1* mutations, men with germline mutations in *BRCA2* have an estimated breast cancer risk of 6%, which represents a 100-fold increase over the risk in the general male population. *BRCA2*-associated breast cancers are invasive ductal carcinomas, which are more likely to be well differentiated and to express hormone receptors than are *BRCA1*-associated breast cancers. *BRCA2*-associated breast cancer has a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases, a higher prevalence of bilateral breast cancer, and the presence of associated cancers in some affected individuals, specifically ovarian, colon, prostate, pancreatic, gallbladder, bile duct, and stomach cancers, as well as melanoma. A number of founder mutations have been identified in *BRCA2*. The 6174delT mutation is found in Ashkenazi Jews with a prevalence of 1.2% and accounts for 60% of ovarian cancer and 30% of early-onset breast cancer patients among Ashkenazi women.¹⁰⁶ Another *BRCA2* founder mutation, 999del5, is observed in Icelandic and Finnish populations, while more recently 3036delACAA has been observed in a number of Spanish families.¹⁰⁷⁻¹⁰⁹

Identification of *BRCA* Mutation Carriers. Identifying hereditary risk for breast cancer is a four-step process that includes: (a) obtaining a complete, multigenerational family history, (b) assessing the appropriateness of genetic testing for a particular patient, (c) counseling the patient, and (d) interpreting the results of testing.¹¹⁰ Genetic testing should not be offered in isolation, but only in conjunction with patient education and counseling, including referral to a genetic counselor. Initial determinations include whether the individual is an appropriate candidate for genetic testing and whether genetic testing will be informative for personal and clinical decision-making. A thorough and accurate family history is essential to this process, and the maternal and paternal sides of the family are both assessed because 50% of the women with a *BRCA* mutation have inherited the mutation from their fathers. To help clinicians advise women about genetic testing, statistically based models that determine the probability that an individual carries a *BRCA* mutation have been developed. A method for calculating carrier probability that has been demonstrated to have acceptable performance (i.e., both in terms of calibration and discrimination) such as the Manchester scoring system and BODICEA should be used to offer referral to a specialist genetic clinic. A hereditary risk of breast cancer is considered if a family includes Ashkenazi Jewish heritage; a first-degree relative with breast cancer before age 50; a history of ovarian cancer at any age in the patient or first- or second-degree relative with ovarian cancer; breast and ovarian cancer in the same individual; two or more first- or second-degree relatives with breast cancer at any age; patient or relative with bilateral breast cancer; and male breast cancer in a relative at any age.¹¹¹ The threshold for genetic testing is lower in individuals who are members of ethnic groups in whom the mutation prevalence is increased.

***BRCA* Mutation Testing.** Appropriate counseling for the individual being tested for a *BRCA* mutation is strongly recommended, and documentation of informed consent is required.^{110,112} The test that is clinically available for analyzing *BRCA* mutations is gene sequence analysis. In a family with a history suggestive of hereditary breast cancer and no previously

tested member, the most informative strategy is first to test an affected family member. This person undergoes complete sequence analysis of both the *BRCA1* and *BRCA2* genes. If a mutation is identified, relatives are usually tested only for that specific mutation. An individual of Ashkenazi Jewish ancestry is tested initially for the three specific mutations that account for hereditary breast and ovarian cancer in that population. If results of that test are negative, it may then be appropriate to fully analyze the *BRCA1* and *BRCA2* genes.

A positive test result is one that discloses the presence of a *BRCA* mutation that interferes with translation or function of the *BRCA* protein. A woman who carries a deleterious mutation has a breast cancer risk of up to 85% (in some families) as well as a greatly increased risk of ovarian cancer. A negative test result is interpreted according to the individual's personal and family history, especially whether a mutation has been previously identified in the family, in which case the woman is generally tested only for that specific mutation. If the mutation is not present, the woman's risk of breast or ovarian cancer may be no greater than that of the general population. In addition, no *BRCA* mutation can be passed on to the woman's children. In the absence of a previously identified mutation, a negative test result in an affected individual generally indicates that a *BRCA* mutation is not responsible for the familial cancer. However, the possibility remains of an unusual abnormality in one of these genes that cannot yet be identified through clinical testing. It also is possible that the familial cancer is indeed caused by an identifiable *BRCA* mutation but that the individual tested had sporadic cancer, a situation known as *phenocopy*. This is especially possible if the individual tested developed breast cancer close to the age of onset of the general population (age 60 years or older) rather than before age 50 years, as is characteristic of *BRCA* mutation carriers. Overall, the false-negative rate for *BRCA* mutation testing is <5%. Some test results, especially when a single base-pair change (missense mutation) is identified, may be difficult to interpret. This is because single base-pair changes do not always result in a nonfunctional protein. Thus, missense mutations not located within critical functional domains, or those that cause only minimal changes in protein structure, may not be disease associated and are usually reported as indeterminate results. In communicating indeterminate results to women, care must be taken to relay the uncertain cancer risk associated with this type of mutation and to emphasize that ongoing research might clarify its meaning. In addition, testing other family members with breast cancer to determine if a genetic variant tracks with their breast cancer may provide clarification as to its significance. Indeterminate genetic variance currently accounts for 12% of the test results.

Concern has been expressed that the identification of hereditary risk for breast cancer may interfere with access to affordable health insurance. This concern refers to discrimination directed against an individual or family based solely on an apparent or perceived genetic variation from the normal human genotype. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) made it illegal in the United States for group health plans to consider genetic information as a preexisting condition or to use it to deny or limit coverage. Most states also have passed laws that prevent genetic discrimination in the provision of health insurance. In addition, individuals applying for health insurance are not required to report whether relatives have undergone genetic testing for cancer risk, only whether those relatives have actually been diagnosed with cancer.

Currently, there is little documented evidence of genetic discrimination resulting from findings of available genetic tests.

Cancer Prevention for *BRCA* Mutation Carriers. Risk management strategies for *BRCA1* and *BRCA2* mutation carriers include the following:

1. Risk-reducing mastectomy and reconstruction
2. Risk-reducing salpingo-oophorectomy
3. Intensive surveillance for breast and ovarian cancer
4. Chemoprevention

Although removal of breast tissue reduces the likelihood that *BRCA1* and *BRCA2* mutation carriers will develop breast cancer, mastectomy does not remove all breast tissue, and women continue to be at risk because a germline mutation is present in any remaining breast tissue. For postmenopausal *BRCA1* and *BRCA2* mutation carriers who have not had a mastectomy, it may be advisable to avoid hormone replacement therapy because no data exist regarding the effect of the therapy on the penetrance of breast cancer susceptibility genes. Because breast cancers in *BRCA* mutation carriers have the same mammographic appearance as breast cancers in noncarriers, a screening mammogram is likely to be effective in *BRCA* mutation carriers, provided it is performed and interpreted by an experienced radiologist with a high level of suspicion. Present screening recommendations for *BRCA* mutation carriers who do not undergo risk-reducing mastectomy include clinical breast examination every 6 months and mammography every 12 months beginning at age 25 years because the risk of breast cancer in *BRCA* mutation carriers increases after age 30 years. Recent attention has been focused on the use of MRI for breast cancer screening in high-risk individuals and known *BRCA* mutation carriers. MRI appears to be more sensitive at detecting breast cancer in younger women with dense breasts.¹¹³ However, as noted previously, MRI does lead to the detection of benign breast lesions that cannot easily be distinguished from malignancy, and these false-positive events can result in more interventions, including biopsy specimens. The current recommendations from the American Cancer Society are for annual MRI in women with a 20% to 25% or greater lifetime risk of developing breast cancer (mainly based on family history), women with a known *BRCA1* or *BRCA2* mutation, those who have a first-degree relative with a *BRCA1* or *BRCA2* mutation and have not had genetic testing themselves, women who were treated with radiation therapy to the chest between the ages of 10 and 30 years, and those who have Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome, or a first-degree relative with one of these syndromes.^{75,114} Despite a 49% reduction in the overall incidence of breast cancer and a 69% reduction in the incidence of estrogen receptor positive tumors in high-risk women taking tamoxifen reported in the NSABP P1 trial, there is insufficient evidence to recommend the use of tamoxifen uniformly for *BRCA1* mutation carriers.⁶⁰ Cancers arising in *BRCA1* mutation carriers are usually high grade and are most often hormone receptor negative. Approximately 66% of *BRCA1*-associated DCIS lesions are estrogen receptor negative, which suggests early acquisition of the hormone-independent phenotype. In the NSABP P1 trial there was a 62% reduction in the incidence of breast cancer in *BRCA2* carriers, similar to the overall reduction seen in the P1 trial. In contrast, there was no reduction seen in breast cancer incidence in *BRCA1* carriers who started tamoxifen in P1 age 35 years or

older.¹¹⁵ Tamoxifen appears to be more effective at preventing estrogen receptor-positive breast cancers.

The risk of ovarian cancer in *BRCA1* and *BRCA2* mutation carriers ranges from 20% to 40%, which is 10 times higher than that in the general population. Risk-reducing salpingo-oophorectomy is a reasonable prevention option in mutation carriers. In women with a documented *BRCA1* or *BRCA2* mutation, consideration for bilateral risk-reducing salpingo-oophorectomy should be between the ages of 35 and 40 years at the completion of childbearing. Removing the ovaries reduces the risk of ovarian cancer and breast cancer when performed in premenopausal *BRCA* mutation carriers. Hormone replacement therapy is discussed with the patient at the time of oophorectomy. The Cancer Genetics Studies Consortium recommends yearly transvaginal ultrasound timed to avoid ovulation and annual measurement of serum cancer antigen 125 levels beginning at age 25 years as the best screening modalities for ovarian carcinoma in *BRCA* mutation carriers who have opted to defer risk-reducing surgery.

PALB2 (partner and localizer of *BRCA2*) has recently been characterized as a potential high-risk gene for breast cancer. *PALB2* allows nuclear localization of *BRCA2* and provides a scaffold for the *BRCA1*–*PALB2*–*BRCA2* complex. Analysis by Antoniou et al has suggested that the risk of breast cancer for *PALB2* mutation carriers is as high as that of *BRCA2* mutation carriers.¹¹⁶ The absolute risk of breast cancer for *PALB2* female mutation carriers by 70 years of age ranged from 33% (95% CI, 25–44) for those with no family history of breast cancer to 58% (95% CI, 50–66) for those with two or more first-degree relatives with breast cancer at 50 years of age. The risk of breast cancer for female *PALB2* mutation carriers, depending on the age, was about five to nine times as high compared with the general population. While screening with mammogram along with MRI has been suggested for *PALB2* mutation carriers starting at age 30 with consideration of risk-reducing mastectomy, there is currently insufficient evidence regarding the risk of ovarian cancer and its management.

Other hereditary syndromes associated with an increased risk of breast cancer include Cowden disease (*PTEN* mutations, in which cancers of the thyroid, GI tract, and benign skin and subcutaneous nodules are also seen), Li-Fraumeni syndrome (*TP53* mutations, also associated with sarcomas, lymphomas, and adrenocortical tumors), hereditary diffuse gastric cancer syndrome (*CDH1* mutations, associated with diffuse gastric cancer and lobular breast cancers), and syndromes of breast and melanoma. With the discovery of additional genes related to breast cancer susceptibility, panel testing is available for a number of genes in addition to *BRCA1* and *BRCA2*. The interpretation of results is complex and is best done with a genetic counselor.

EPIDEMIOLOGY AND NATURAL HISTORY OF BREAST CANCER

Epidemiology

Breast cancer is the most common site-specific cancer in women and is the leading cause of death from cancer for women age 20 to 59 years. Based on Surveillance, Epidemiology, and End Results registries (SEER) data, 266,120 new cases were estimated in 2018 with 40,920 estimated deaths attributed to breast cancers.¹¹⁷ It accounts for 30% of all newly diagnosed cancers in

women and is responsible for 14% of the cancer-related deaths in women.

Breast cancer was the leading cause of cancer-related mortality in women until 1987, when it was surpassed by lung cancer. In the 1970s, the probability that a woman in the United States would develop breast cancer at some point in her lifetime was estimated at 1 in 13; in 1980 it was 1 in 11; and in 2004 it was 1 in 8. Cancer registries in Connecticut and upper New York State document that the age-adjusted incidence of new breast cancer cases had steadily increased since the mid-1940s. The incidence in the United States, based on data from nine SEER registries, has been decreasing by 23% per year since 2000. The increase had been approximately 1% per year from 1973 to 1980, and there was an additional increase in incidence of 4% between 1980 and 1987, which was characterized by frequent detection of small primary cancers. The increase in breast cancer incidence occurred primarily in women age ≥ 55 years and paralleled a marked increase in the percentage of older women who had mammograms taken. At the same time, incidence rates for regional metastatic disease dropped and breast cancer mortality declined. From 1960 to 1963, 5-year overall survival rates for breast cancer were 63% and 46% in white and African American women, respectively, whereas the rates for 1981 to 1983 were 78% and 64%, respectively. For 2002 to 2008 rates were 92% and 78%, respectively.

There is a 10-fold variation in breast cancer incidence among different countries worldwide. Cyprus and Malta have the highest age-adjusted mortality for breast cancer (29.6 per 100,000 population), whereas Haiti has the lowest (2.0 deaths per 100,000 population). The United States has an age-adjusted mortality for breast cancer of 19.0 cases per 100,000 population. Women living in less industrialized nations tend to have a lower incidence of breast cancer than women living in industrialized countries, although Japan is an exception. In the United States, Mormons, Seventh Day Adventists, American Indians, Alaska natives, Hispanic/Latina Americans, and Japanese and Filipino women living in Hawaii have a below-average incidence of breast cancer, whereas nuns (due to nulliparity) and Ashkenazi Jewish women have an above-average incidence.

The incidence rates of breast cancer increased in most countries through the 1990s. Since the estimates for 1990, there was an overall increase in incidence rates of approximately 0.5% annually. It was predicted that there would be approximately 1.4 million new cases in 2010. The cancer registries in China have noted annual increases in incidence of up to 3% to 4%, and in eastern Asia, increases are similar.

Data from the SEER program reveal declines in breast cancer incidence over the past decade, and this is widely attributed to decreased use of hormone replacement therapy as a consequence of the Women's Health Initiative reports.¹¹⁸

Breast cancer burden has well-defined variations by geography, regional lifestyle, and racial or ethnic background.¹¹⁹ In general, both breast cancer incidence and mortality are relatively lower among the female populations of Asia and Africa, relatively underdeveloped nations, and nations that have not adopted Westernized reproductive and dietary patterns. In contrast, European and North American women and women from heavily industrialized or Westernized countries have a substantially higher breast cancer burden. These international patterns are mirrored in breast cancer incidence and mortality rates observed for the racially, ethnically, and culturally diverse population of the United States.¹²⁰

Although often related, the factors that influence breast cancer incidence may differ from those that affect mortality. Incidence rates are lower among populations that are heavily weighted with women who begin childbearing at young ages and who have multiple full-term pregnancies followed by prolonged lactation. These are features that characterize many underdeveloped nations and also many eastern nations. Breast cancer mortality rates should be lower in populations that have a lower incidence, but the mortality burden will simultaneously be adversely affected by the absence of effective mammographic screening programs for early detection and diminished access to multidisciplinary cancer treatment programs. These features are likely to account for much of the disproportionate mortality risks that are seen in underdeveloped nations. Similar factors probably account for differences in breast cancer burden observed among the various racial and ethnic groups within the United States. Interestingly, breast cancer incidence and mortality rates rise among second- and third-generation Asian Americans as they adopt Western lifestyles.

Disparities in breast cancer survival among subsets of the American population are generating increased publicity because they are closely linked to disparities in socioeconomic status. Poverty rates and proportions of the population that lack health care insurance are two to three times higher among minority racial and ethnic groups such as African Americans and Hispanic/Latino Americans. These socioeconomic disadvantages create barriers to effective breast cancer screening and result in delayed breast cancer diagnosis, advanced stage distribution, inadequacies in comprehensive treatment, and, ultimately, increased mortality rates. Furthermore, the rapid growth in the Hispanic population is accompanied by increasing problems in health education because of linguistic barriers between physicians and recently immigrated, non-English-speaking patients. Recent studies also are documenting inequities in the treatments delivered to minority breast cancer patients, such as increased rates of failure to provide systemic therapy, use of sentinel lymph node dissection, and breast reconstruction. Some of the treatment delivery disparities are related to inadequately controlled comorbidities (such as hypertension and diabetes), which are more prevalent in minority populations. However, some studies that adjust for these factors report persistent and unexplained unevenness in treatment recommendations. It is clear that breast cancer disparities associated with racial or ethnic background have a multifactorial cause, and improvements in outcome will require correction of many public health problems at both the patient and provider levels.

Advances in the ability to characterize breast cancer subtypes and the genetics of the disease are now provoking speculation regarding possible hereditary influences on breast cancer risk that are related to racial or ethnic ancestry.¹²¹ These questions become particularly compelling when one looks at disparities in breast cancer burden between African Americans and Caucasians. Lifetime risk of breast cancer is lower for African Americans, yet a paradoxically increased breast cancer mortality risk also is seen. African Americans also have a younger age distribution for breast cancer; among women <45 years of age, breast cancer incidence is highest among African Americans compared to other subsets of the American population. Lastly and most provocatively, African American women of all ages have notably higher incidence rates for estrogen receptor-negative tumors. These same patterns of disease are seen in contemporary female populations of western, sub-Saharan Africa,

Figure 17-13. Survival of women with untreated breast cancer compared with natural survival. (Reproduced with permission from Bloom HJG, Richardson WW, Harries EJ: *Natural history of untreated breast cancer (1805-1933)*. Comparison of untreated and treated cases according to histological grade of malignancy, *Br Med J.* 1962 Jul 28;2(5299):213-221.)

who are likely to share ancestry with African American women as a consequence of the Colonial-era slave trade. Interestingly, male breast cancer also is seen with increased frequency among both African Americans and Africans.

Natural History

Bloom and colleagues described the natural history of breast cancer based on the records of 250 women with untreated breast cancers who were cared for on charity wards in the Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis (Fig. 17-13).¹²² The 5- and 10-year survival rates for these women were 18.0% and 3.6%, respectively. Only 0.8% survived for 15 years or longer. Autopsy data confirmed that 95% of these women died of breast cancer, whereas the remaining 5% died of other causes. Almost 75% of the women developed ulceration of the breast during the course of the disease. The longest surviving patient died in the 19th year after diagnosis.

Primary Breast Cancer. More than 80% of breast cancers show productive fibrosis that involves the epithelial and stromal tissues. With growth of the cancer and invasion of the surrounding breast tissues, the accompanying desmoplastic response entraps and shortens Cooper's suspensory ligaments to produce a characteristic skin retraction. Localized edema (peau d'orange) develops when drainage of lymph fluid from the skin is disrupted. With continued growth, cancer cells invade the skin, and eventually ulceration occurs. As new areas of skin are invaded, small satellite nodules appear near the primary ulceration. The size of the primary breast cancer correlates with disease-free and overall survival, but there is a close association between cancer size and axillary lymph node involvement (Fig. 17-14). In general, up to 20% of breast cancer recurrences are local-regional, >60% are distant, and 20% are both local-regional and distant.

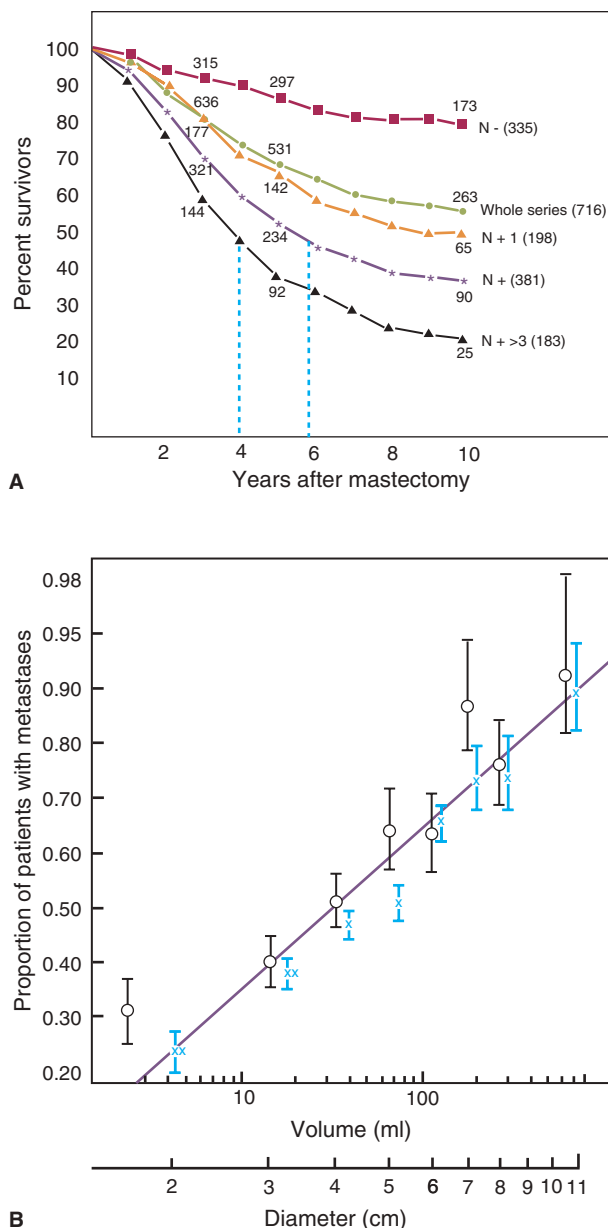

Figure 17-14. **A.** Overall survival for women with breast cancer according to axillary lymph node status. The time periods are years after radical mastectomy. (Reproduced with permission from Valagussa P, Bonadonna G, Veronesi U, et al: Patterns of relapse and survival following radical mastectomy. Analysis of 716 consecutive patients, *Cancer*. 1978 Mar;41(3):1170-1178.) **B.** Risk of metastases according to breast cancer volume and diameter. (Reproduced with permission from Koscielny S, Tubiana M, Lê MG, et al: Breast cancer: Relationship between the size of the primary tumour and the probability of metastatic dissemination, *Br J Cancer*. 1984 Jun;49(6):709-715.)

Axillary Lymph Node Metastases. As the size of the primary breast cancer increases, some cancer cells are shed into cellular spaces and transported via the lymphatic network of the breast to the regional lymph nodes, especially the axillary lymph nodes. Lymph nodes that contain metastatic cancer are at first ill-defined and soft but become firm or hard with continued growth of the metastatic cancer. Eventually the lymph

nodes adhere to each other and form a conglomerate mass. Cancer cells may grow through the lymph node capsule and fix to contiguous structures in the axilla, including the chest wall. Typically, axillary lymph nodes are involved sequentially from the low (level I) to the central (level II) to the apical (level III) lymph node groups. Approximately 95% of the women who die of breast cancer have distant metastases, and traditionally the most important prognostic correlate of disease-free and overall survival was axillary lymph node status (see Fig. 17-14A). Women with node-negative disease had less than a 30% risk of recurrence, compared with as much as a 75% risk for women with node-positive disease.

Distant Metastases. At approximately the 20th cell doubling, breast cancers acquire their own blood supply (neovascularization). Thereafter, cancer cells may be shed directly into the systemic venous blood to seed the pulmonary circulation via the axillary and intercostal veins or the vertebral column via Batson's plexus of veins, which courses the length of the vertebral column. These cells are scavenged by natural killer lymphocytes and macrophages. Successful implantation of metastatic foci from breast cancer predictably occurs after the primary cancer exceeds 0.5 cm in diameter, which corresponds to the 27th cell doubling. For 10 years after initial treatment, distant metastases are the most common cause of death in breast cancer patients. For this reason, conclusive results cannot be derived from breast cancer trials until at least 5 to 10 years have elapsed. Although 60% of the women who develop distant metastases will do so within 60 months of treatment, metastases may become evident as late as 20 to 30 years after treatment of the primary cancer.¹²³ Patients with estrogen receptor negative breast cancers are proportionately more likely to develop recurrence in the first 3 to 5 years, whereas those with estrogen receptor positive tumors have a risk of developing recurrence, which drops off more slowly beyond 5 years than is seen with ER-negative tumors.¹²⁴ Recently, a report showed that tumor size and nodal status remain powerful predictors of late recurrences compared to more recently developed tools such as the immunohistochemical score (IHC4) and two gene expression profile tests (Recurrence Score and PAM50).¹²⁵ Common sites of involvement, in order of frequency, are bone, lung, pleura, soft tissues, and liver. Brain metastases are less frequent overall, although with the advent of adjuvant systemic therapies it has been reported that CNS disease may be seen earlier.^{126,127} There are also reports of factors that are associated with the risk of developing brain metastases.¹²⁸ For example, they are more likely to be seen in patients with triple receptor negative breast cancer (ER-negative, PR-negative, and HER2-negative) or patients with HER2-positive breast cancer who have received chemotherapy and HER2-directed therapies.

HISTOPATHOLOGY OF BREAST CANCER

Carcinoma In Situ

Cancer cells are in situ or invasive depending on whether or not they invade through the basement membrane.^{129,130} Broders's original description of in situ breast cancer stressed the absence of invasion of cells into the surrounding stroma and their confinement within natural ductal and alveolar boundaries.¹²⁹ Because areas of invasion may be minute, the accurate diagnosis of in situ cancer necessitates the analysis of multiple microscopic sections to exclude invasion. In 1941, Foote and Stewart published

a landmark description of LCIS, which distinguished it from DCIS.¹³⁰ In the late 1960s, Gallagher and Martin published their study of whole-breast sections and described a stepwise progression from benign breast tissue to in situ cancer and subsequently to invasive cancer. Before the widespread use of mammography, diagnosis of breast cancer was by physical examination. At that time, in situ cancers constituted <6% of all breast cancers, and LCIS was more frequently diagnosed than DCIS by a ratio of >2:1. However, when screening mammography became popular, a 14-fold increase in the incidence of in situ cancer (45%) was demonstrated, and DCIS was more frequently diagnosed than LCIS by a ratio of >2:1. Table 17-8 lists the clinical and pathologic characteristics of DCIS and LCIS. *Multicentricity* refers to the occurrence of a second breast cancer outside the breast quadrant of the primary cancer (or at least 4 cm away), whereas *multifocality* refers to the occurrence of a second cancer within the same breast quadrant as the primary cancer (or within 4 cm of it). Multicentricity occurs in 60% to 90% of women with LCIS, whereas the rate of multicentricity for DCIS is reported to be 40% to 80%. LCIS occurs bilaterally in 50% to 70% of cases, whereas DCIS occurs bilaterally in 10% to 20% of cases.

Lobular Carcinoma In Situ. LCIS originates from the terminal duct lobular units and develops only in the female breast. It is characterized by distention and distortion of the terminal duct lobular units by cells that are large but maintain a normal nuclear to cytoplasmic ratio. Cytoplasmic mucoid globules are a distinctive cellular feature. LCIS may be observed in breast tissues that contain microcalcifications, but the calcifications associated with LCIS typically occur in adjacent tissues. This neighborhood calcification is a feature that is unique to LCIS

Table 17-8

Salient characteristics of in situ ductal (DCIS) and lobular (LCIS) carcinoma of the breast

	LCIS	DCIS
Age (years)	44–47	54–58
Incidence ^a	2%–5%	5%–10%
Clinical signs	None	Mass, pain, nipple discharge
Mammographic signs	None	Microcalcifications
Premenopausal	2/3	1/3
Incidence of synchronous invasive carcinoma	5%	2%–46%
Multicentricity	60%–90%	40%–80%
Bilaterality	50%–70%	10%–20%
Axillary metastasis	1%	1%–2%
Subsequent carcinomas:		
Incidence	25%–35%	25%–70%
Laterality	Bilateral	Ipsilateral
Interval to diagnosis	15–20 y	5–10 y
Histologic type	Ductal	Ductal

and contributes to its diagnosis. The frequency of LCIS in the general population cannot be reliably determined because it usually presents as an incidental finding. The average age at diagnosis is 45 years, which is approximately 15 to 25 years younger than the age at diagnosis for invasive breast cancer. LCIS has a distinct racial predilection, occurring 12 times more frequently in white women than in African-American women. Invasive breast cancer develops in 25% to 35% of women with LCIS. Invasive cancer may develop in either breast, regardless of which breast harbored the initial focus of LCIS, and is detected synchronously with LCIS in 5% of cases. In women with a history of LCIS, up to 65% of subsequent invasive cancers are ductal, not lobular, in origin. For these reasons, LCIS is regarded as a marker of increased risk for invasive breast cancer rather than as an anatomic precursor. Individuals should be counseled regarding their risk of developing breast cancer and appropriate risk reduction strategies, including observation with screening, chemoprevention, and risk-reducing bilateral mastectomy.

Ductal Carcinoma In Situ. Although DCIS is predominantly seen in the female breast, it accounts for 5% of male breast cancers. Published series suggest a detection frequency of 7% in all biopsy tissue specimens. The term *intraductal carcinoma* is frequently applied to DCIS, which carries a high risk for progression to an invasive cancer. Histologically, DCIS is characterized by a proliferation of the epithelium that lines the minor ducts, resulting in papillary growths within the duct lumina. Early in their development, the cancer cells do not show pleomorphism, mitoses, or atypia, which leads to difficulty in distinguishing early DCIS from benign hyperplasia. The papillary growths (papillary growth pattern) eventually coalesce and fill the duct lumina so that only scattered, rounded spaces remain between the clumps of atypical cancer cells, which show hyperchromasia and loss of polarity (cribriform growth pattern). Eventually pleomorphic cancer cells with frequent mitotic figures obliterate the lumina and distend the ducts (solid growth pattern). With continued growth, these cells outstrip their blood supply and become necrotic (comedo growth pattern). Calcium deposition occurs in the areas of necrosis and is a common feature seen on mammography. DCIS is now frequently classified based on nuclear grade and the presence of necrosis (Table 17-9). Based

Table 17-9

Classification of breast ductal carcinoma in situ (DCIS)

HISTOLOGIC SUBTYPE	DETERMINING CHARACTERISTICS		DCIS GRADE
	NUCLEAR GRADE	NECROSIS	
Comedo	High	Extensive	High
Intermediate ^a	Intermediate	Focal or absent	Intermediate
Noncomedo ^b	Low	Absent	Low

^aOften a mixture of noncomedo patterns.

^bSolid, cribriform, papillary, or focal micropapillary.

Adapted with permission from Koo JS, Kim MJ, Kim EK, et al: *Comparison of immunohistochemical staining in breast papillary neoplasms of cytokeratin 5/6 and p63 in core needle biopsies and surgical excisions*. Appl Immunohistochem Mol Morphol. 2012 Mar;20(2):108-115.

on multiple consensus meetings, grading of DCIS has been recommended. Although there is no universal agreement on classification, most systems endorse the use of cytologic grade and presence or absence of necrosis.¹³¹

The risk for invasive breast cancer is increased nearly fivefold in women with DCIS.¹³² The invasive cancers are observed in the ipsilateral breast, usually in the same quadrant as the DCIS that was originally detected, which suggests that DCIS is an anatomic precursor of invasive ductal carcinoma (Fig. 17-15A and B).

Invasive Breast Carcinoma

Invasive breast cancers have been described as lobular or ductal in origin.¹²⁸⁻¹³¹ Early classifications used the term *lobular* to describe invasive cancers that were associated with LCIS, whereas all other invasive cancers were referred to as *ductal*.

Current histologic classifications recognize special types of breast cancers (10% of total cases), which are defined by specific histologic features. To qualify as a special-type cancer, at least 90% of the cancer must contain the defining histologic features. About 80% of invasive breast cancers are described as invasive ductal carcinoma of no special type (NST). These cancers generally have a worse prognosis than special-type cancers. Foote and Stewart originally proposed the following classification for invasive breast cancer¹³⁰:

1. Paget's disease of the nipple
2. Invasive ductal carcinoma—Adenocarcinoma with productive fibrosis (scirrhous, simplex, NST), 80%
3. Medullary carcinoma, 4%
4. Mucinous (colloid) carcinoma, 2%
5. Papillary carcinoma, 2%
6. Tubular carcinoma, 2%
7. Invasive lobular carcinoma, 10%
8. Rare cancers (adenoid cystic, squamous cell, apocrine)

Paget's disease of the nipple was described in 1874. It frequently presents as a chronic, eczematous eruption of the nipple, which may be subtle but may progress to an ulcerated, weeping lesion. Paget's disease usually is associated with extensive DCIS and may be associated with an invasive cancer. A palpable mass may or may not be present. A nipple biopsy specimen will show a population of cells that are identical to the underlying DCIS cells (pagetoid features or pagetoid change). Pathognomonic of this cancer is the presence of large, pale, vacuolated cells (Paget cells) in the rete pegs of the epithelium. Paget's disease may be confused with superficial spreading melanoma. Differentiation from pagetoid intraepithelial melanoma is based on the presence of S-100 antigen immunostaining in melanoma and carcinoembryonic antigen immunostaining in Paget's disease. Surgical therapy for Paget's disease may involve lumpectomy or mastectomy, depending on the extent of involvement of the nipple-areolar complex and the presence of DCIS or invasive cancer in the underlying breast parenchyma.

Invasive ductal carcinoma of the breast with productive fibrosis (scirrhous, simplex, NST) accounts for 80% of breast cancers and presents with macroscopic or microscopic axillary lymph node metastases in up to 25% of screen-detected cases and up to 60% of symptomatic cases. This cancer occurs most frequently in perimenopausal or postmenopausal women in the fifth to sixth decades of life as a solitary, firm mass. It has poorly defined margins, and its cut surfaces show a central stellate configuration with chalky white or yellow streaks extending into surrounding breast tissues. The cancer cells often are arranged in small clusters, and there is a broad spectrum of histologic types with variable cellular and nuclear grades (Fig. 17-16A and B). In a large patient series from the SEER database, 75% of ductal cancers showed estrogen receptor expression.¹³³

Medullary carcinoma is a special-type breast cancer; it accounts for 4% of all invasive breast cancers and is a frequent phenotype of *BRCA1* hereditary breast cancer. Grossly, the cancer is soft and hemorrhagic. A rapid increase in size may occur secondary to necrosis and hemorrhage. On physical examination, it is bulky and often positioned deep within the breast. Bilaterality is reported in 20% of cases. Medullary carcinoma is characterized microscopically by: (a) a dense lymphoreticular infiltrate composed predominantly of lymphocytes and plasma cells; (b) large pleomorphic nuclei that are poorly

A

B

Figure 17-16. Invasive ductal carcinoma with productive fibrosis (scirrhous, simplex, no special type) **A.** 100x. **B.** 200x. differentiated and show active mitosis; and (c) a sheet-like growth pattern with minimal or absent ductal or alveolar differentiation. Approximately 50% of these cancers are associated with DCIS, which characteristically is present at the periphery of the cancer, and <10% demonstrate hormone receptors. In rare circumstances, mesenchymal metaplasia or anaplasia is noted. Because of the intense lymphocyte response associated with the cancer, benign or hyperplastic enlargement of the lymph nodes of the axilla may contribute to erroneous clinical staging. Women with this cancer have a better 5-year survival rate than those with NST or invasive lobular carcinoma.

Mucinous carcinoma (colloid carcinoma), another special-type breast cancer, accounts for 2% of all invasive breast cancers and typically presents in the older population as a bulky tumor. This cancer is defined by extracellular pools of mucin, which surround aggregates of low-grade cancer cells. The cut surface of this cancer is glistening and gelatinous in quality. Fibrosis is variable, and when abundant it imparts a firm consistency to the cancer. Over 90% of mucinous carcinomas display hormone receptors.¹³³ Lymph node metastases occur in 33% of cases, and 5- and 10-year survival rates are 73% and 59%, respectively. Because of the mucinous component, cancer cells may not be evident in all microscopic sections, and analysis of multiple sections is essential to confirm the diagnosis of a mucinous carcinoma.

Papillary carcinoma is a special-type cancer of the breast that accounts for 2% of all invasive breast cancers. It generally presents in the seventh decade of life and occurs in a disproportionate number of nonwhite women. Typically, papillary carcinomas are small and rarely attain a size of 3 cm in diameter. These cancers are defined by papillae with fibrovascular stalks and multilayered epithelium. In a large series from the SEER database 87% of papillary cancers have been reported to express estrogen receptor.¹³³ McDivitt and colleagues noted that these tumors showed a low frequency of axillary lymph node metastases and had 5- and 10-year survival rates similar to those for mucinous and tubular carcinoma.¹³⁴

Tubular carcinoma is another special-type breast cancer and accounts for 2% of all invasive breast cancers. It is reported in as many as 20% of women whose cancers are diagnosed

by mammographic screening and usually is diagnosed in the perimenopausal or early menopausal periods. Under low-power magnification, a haphazard array of small, randomly arranged tubular elements is seen. In a large SEER database 94% of tubular cancers were reported to express estrogen receptor.¹³³ Approximately 10% of women with tubular carcinoma or with invasive cribriform carcinoma, a special-type cancer closely related to tubular carcinoma, will develop axillary lymph node metastases. However, the presence of metastatic disease in one or two axillary lymph nodes does not adversely affect survival. Distant metastases are rare in tubular carcinoma and invasive cribriform carcinoma. Long-term survival approaches 100%.

Invasive lobular carcinoma accounts for 10% of breast cancers. The histopathologic features of this cancer include small cells with rounded nuclei, inconspicuous nucleoli, and scant cytoplasm (Fig. 17-17). Special stains may confirm the

Figure 17-17. Lobular carcinoma (100x). Uniform, relatively small lobular carcinoma cells are seen arranged in a single-file orientation (“Indian file”). (Used with permission from Dr. Sindhu Menon, Consultant Histopathologist and Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

presence of intracytoplasmic mucin, which may displace the nucleus (signet-ring cell carcinoma). At presentation, invasive lobular carcinoma varies from clinically inapparent carcinomas to those that replace the entire breast with a poorly defined mass. It is frequently multifocal, multicentric, and bilateral. Because of its insidious growth pattern and subtle mammographic features, invasive lobular carcinoma may be difficult to detect. Over 90% of lobular cancers express estrogen receptor.¹³³

DIAGNOSIS OF BREAST CANCER

In ~30% of cases, the woman discovers a lump in her breast. Other less frequent presenting signs and symptoms of breast cancer include: (a) breast enlargement or asymmetry; (b) nipple changes, retraction, or discharge; (c) ulceration or erythema of the skin of the breast; (d) an axillary mass; and (e) musculoskeletal discomfort. However, up to 50% of women presenting with breast complaints have no physical signs of breast pathology. Breast pain usually is associated with benign disease.

Misdiagnosed breast cancer accounts for the greatest number of malpractice claims for errors in diagnosis and for the largest number of paid claims. Litigation often involves younger women, whose physical examination and mammogram may be misleading. If a young woman (≤ 45 years) presents with a palpable breast mass and equivocal mammographic findings, ultrasound examination and biopsy are used to avoid a delay in diagnosis.

Examination

Inspection. The clinician inspects the woman's breast with her arms by her side (Fig. 17-18A), with her arms straight up in the air (Fig. 17-18B), and with her hands on her hips (with and without pectoral muscle contraction).^{135,136} Symmetry, size, and shape of the breast are recorded, as well as any evidence of edema (peau d'orange), nipple or skin retraction, or erythema. With the arms extended forward and in a sitting position, the woman leans forward to accentuate any skin retraction.

Figure 17-18. Examination of the breast. **A.** Inspection of the breast with arms at sides. **B.** Inspection of the breast with arms raised. **C.** Palpation of the breast with the patient supine. **D.** Palpation of the axilla.

Figure 17-19. A breast examination record.

Palpation. As part of the physical examination, the breast is carefully palpated. With the patient in the supine position (see Fig. 17-18C) the clinician gently palpates the breasts, making certain to examine all quadrants of the breast from the sternum laterally to the latissimus dorsi muscle and from the clavicle inferiorly to the upper rectus sheath. The examination is performed with the palmar aspects of the fingers, avoiding a grasping or pinching motion. The breast may be cupped or molded in the examiner's hands to check for retraction. A systematic search for lymphadenopathy then is performed. Figure 17-18D shows the position of the patient for examination of the axilla. By supporting the upper arm and elbow, the examiner stabilizes the shoulder girdle. Using gentle palpation, the clinician assesses all three levels of possible axillary lymphadenopathy. Careful palpation of supraclavicular and parasternal sites also is performed. A diagram of the chest and contiguous lymph node sites is useful for recording location, size, consistency, shape, mobility, fixation, and other characteristics of any palpable breast mass or lymphadenopathy (Fig. 17-19).

Imaging Techniques

Mammography. Mammography has been used in North America since the 1960s, and the techniques used continue to be modified and improved to enhance image quality.¹³⁷⁻¹⁴⁰ Conventional mammography delivers a radiation dose of 0.1 cGy per study. By comparison, chest radiography delivers 25% of this dose. However, there is no increased breast cancer risk associated with the radiation dose delivered with screening mammography. Screening mammography is used to detect unexpected breast cancer in asymptomatic women. In this regard, it supplements history taking and physical examination. With screening mammography, two views of the breast are obtained: the craniocaudal (CC) view (Fig. 17-20A,B) and the mediolateral oblique (MLO) view (Fig. 17-20C,D). The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. Diagnostic mammography is used to evaluate women with abnormal

findings such as a breast mass or nipple discharge. In addition to the MLO and CC views, a diagnostic examination may use views that better define the nature of any abnormalities, such as the 90° lateral and spot compression views. The 90° lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammographic abnormality that is obscured by

overlying tissues (Fig. 17-21C). The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques ($\times 1.5$) often are combined with spot compression to better resolve calcifications and the margins of masses. Mammography also is used to guide interventional procedures, including needle localization and needle biopsy.

Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50% of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammographic abnormality. The clinical impetus for screening mammography came from the Health Insurance Plan study and the Breast Cancer Detection Demonstration Project, which demonstrated a 33% reduction in mortality for women after⁷² screening mammography. Mammography was more accurate than clinical examination for the detection of early breast cancers, providing a true-positive rate of 90%. Only 20% of women with nonpalpable cancers had axillary lymph node metastases, compared with 50% of women with palpable cancers.¹⁴¹ Current guidelines of the National Comprehensive Cancer Network suggest that normal-risk women ≥ 20 years of age should have a breast examination at least every 3 years. Starting at age 40 years, breast examinations should be performed yearly, and a yearly mammogram should be taken.¹⁴² Screening mammography in women ≥ 50 years of age has been noted to reduce breast cancer mortality by 20% to 25%.^{72,79} With the increased discussion about the potential harms associated with breast screening, the United Kingdom recently established an independent expert panel to review the published literature and estimate the benefits and harms associated with its national screening program for women age >50 years. The panel estimated that in women invited to screening, about 11% of the cancers diagnosed in their lifetime constitute overdiagnosis. Despite this overdiagnosis, the panel concluded that breast screening programs confer significant benefit and should continue. The use of screening

mammography in women <50 years of age is more controversial for previously noted reasons: (a) reduced sensitivity, (b) reduced specificity, and (c) lower incidence of breast cancer. Because of the combination of these three reasons, targeting mammography screening to women <50 years of age, who are at higher risk of breast cancer, improves the balance of risks and benefits and is the approach some health care systems have taken. There are now a number of risk assessment models—as described earlier in this chapter—that can be used to estimate a younger woman's risk of developing breast cancer and that help assess the risks and benefits of regular screening.

Screen film mammography has replaced xeromammography because it requires a lower dose of radiation and provides similar image quality. Digital mammography was developed to allow the observer to manipulate the degree of contrast in the image. This is especially useful in women with dense breasts and women <50 years of age. Recently, investigators directly compared digital vs. screen film mammography in a prospective (DMIST) trial that enrolled over 42,000 women.¹⁴³ The investigators found that digital and screen film mammography had similar accuracy; however, digital mammography was more accurate in women <50 years of age, women with mammographically dense breasts, and premenopausal or perimenopausal women. The use of digital breast tomosynthesis with 3D images has been introduced as an alternative to standard 2D mammography imaging that is limited by superimposition of breast parenchyma and breast density.^{144,145} The STORM trial reported that in 7,292 women screened, 3D mammography had a higher cancer detection rate and fewer false-positive recalls than the standard 2D imaging.^{146,147} Randomized controlled trials are planned to further study tomosynthesis and its role in breast cancer screening. Standard two-dimensional mammography has limitations,

such as the parenchymal density or superimposition of breast tissue, which obscures cancers or causes normal structures to appear suspicious reducing the sensitivity of mammography and increasing the false-positive rates. Digital breast tomosynthesis is a technology developed to assist with overcoming these limitations. In digital breast tomosynthesis, multiple projection images are reconstructed to allow visual review of thin breast sections, each reconstructed slice as thin as 0.5 mm, which provides better characterization of noncalcified lesions. These multiple projection exposures are obtained by a digital detector from a mammography X-ray source that moves through a limited arc angle while the breast is compressed. Then these projection image data sets are reconstructed using specific algorithms, which provide the clinical reader a series of images through the entire breast.¹⁴⁸

In 2011, tomosynthesis was approved by the U.S. Food and Drug Administration (FDA) to be used in combination with standard digital mammography for breast cancer screening. The total radiation dose when tomosynthesis is added is about twice the current dose of digital mammography alone but remains below the limits set by the FDA.¹⁴⁹

The STORM-2 trial reported that synthetic 2D-3D mammography yields similar breast cancer detection as dual-acquisition 2D-3D mammography with the advantage of reducing radiation exposure.¹⁵⁰

Contrast-enhanced digital mammography (CEDM) was also approved by the FDA in 2001, which utilizes an iodinated contrast material and modified digital mammography units for imaging.¹⁴⁸ CEDM has been shown to be feasible and detects breast cancers at a rate similar to MRI, which has potential to offer an alternative to MRI.¹⁵¹ The advantages of CEDM over MRI are that the use of compression limits motion, there is decrease in cost, decrease in exam time, and there is an option for patients who are unable to tolerate MRI or who due to various reasons cannot have MRI due to incompatibility, such as the presence of a pacemaker or tissue expanders.^{148,152}

Ductography. The primary indication for ductography is nipple discharge, particularly when the fluid contains blood. Radiopaque contrast media is injected into one or more of the major ducts, and mammography is performed. A duct is gently enlarged with a dilator, and then a small, blunt cannula is inserted under sterile conditions into the nipple ampulla. With the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected, and CC and MLO mammographic views are obtained without compression. Intraductal papillomas are seen as small filling defects surrounded by contrast media (Fig. 17-22). Cancers may appear as irregular masses or as multiple intraluminal filling defects.

Ultrasonography. Second only to mammography in frequency of use for breast imaging, ultrasonography is an important method of resolving equivocal mammographic findings, defining cystic masses, and demonstrating the echogenic qualities of specific solid abnormalities. On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center (Fig. 17-23). Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well-defined anterior and posterior margins (Fig. 17-24). Breast cancer characteristically has irregular walls (Fig. 17-25) but may have smooth margins with acoustic enhancement. Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization

A

of breast lesions. Its findings are highly reproducible, and it has a high patient acceptance rate, but it does not reliably detect lesions that are ≤ 1 cm in diameter. Ultrasonography can also be utilized to image the regional lymph nodes in patients with breast cancer (Fig. 17-26). The sensitivity of examination for the status of axillary nodes ranges from 35% to 82% and specificity ranges from 73% to 97%. The features of a lymph node involved with cancer include cortical thickening, change in shape of the node to more circular appearance, size larger

than 10 mm, absence of a fatty hilum and hypoechoic internal echoes.¹⁵³

Magnetic Resonance Imaging. In the process of evaluating magnetic resonance imaging (MRI) as a means of characterizing mammographic abnormalities, additional breast lesions have been detected. However, in the circumstance of negative findings on both mammography and physical examination, the probability of a breast cancer being diagnosed by MRI is extremely low. There is current interest in the use of MRI to screen the breasts of high-risk women and of women with a newly diagnosed breast cancer. In the first case, women who have a strong family history of breast cancer or who carry known genetic mutations require screening at an early age because mammographic evaluation is limited due to the increased breast density in younger women. In the second case, an MRI study of the contralateral breast in women with a known breast cancer has shown a contralateral breast cancer in 5.7% of these women (Fig. 17-27). MRI can also detect additional tumors in the index breast (multifocal or multicentric disease) that may be missed on routine breast imaging and this may alter surgical decision making (Fig. 17-28). In fact, MRI has been advocated by some for routine use in surgical treatment planning based on the fact that additional disease can be identified with this advanced imaging modality and the

Figure 17-25. Ultrasonography images of malignant breast lesions. **A.** 25 mm irregular mass. **B.** Ultrasound 30 mm mass anterior to an implant. **C.** Ultrasound breast cancer with calcification. **D.** Ultrasound shows a 9 mm spiculated mass (see arrow) with attenuation. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

extent of disease may be more accurately assessed. A randomized trial performed in the United Kingdom (COMICE trial) that enrolled 1623 women did not show a decrease in rates of reoperation in those women randomized to undergo MRI in addition to mammography and ultrasonography (19%) compared to those undergoing standard breast imaging without MRI (19%).¹⁵⁴ Houssami and colleagues performed a meta-analysis including two randomized trials and seven comparative cohort studies to examine the effect of preoperative MRI compared to standard preoperative evaluation on surgical outcomes.¹⁵⁵ They reported that the use of MRI was associated with increased mastectomy rates. This is problematic because there is no evidence that the additional disease detected by MRI is of clinical or biologic significance, particularly in light of the low local-regional failure rates currently reported in patients undergoing breast conserving surgery who receive

whole breast irradiation and systemic therapies. There is an ongoing trial in the Alliance for Clinical Trials in Oncology that is randomizing patients to preoperative MRI vs. standard imaging to assess the impact of MRI on local regional recurrence rates in patients with triple receptor negative and HER2 positive breast cancers.

The use of dedicated breast coils is mandatory in the MRI imaging of the breast. A BIRADS lexicon is assigned to each examination and an abnormality noted on MRI that is not seen on mammography requires a focused ultrasound examination for further assessment. If the abnormality is not seen on corresponding mammogram or ultrasound, then MRI-guided biopsy is necessary. Some clinical scenarios where MRI may be useful include the evaluation of a patient who presents with nodal metastasis from breast cancer without an identifiable primary tumor; to assess response to therapy in the setting of neoadjuvant

systemic treatment; to select patients for partial breast irradiation techniques; and evaluation of the treated breast for tumor recurrence.

Breast Biopsy

Nonpalpable Lesions. Image-guided breast biopsy specimens are frequently required to diagnose nonpalpable lesions.¹⁵⁶ Ultrasound localization techniques are used when a mass is present, whereas stereotactic techniques are used when no mass is present (microcalcifications or architectural distortion only). The combination of diagnostic mammography, ultrasound or stereotactic localization, and fine-needle aspiration (FNA) biopsy achieves almost 100% accuracy in the preoperative diagnosis of breast cancer. However, although FNA biopsy permits

cytologic evaluation, core-needle permits the analysis of breast tissue architecture and allows the pathologist to determine whether invasive cancer is present. This permits the surgeon and patient to discuss the specific management of a breast cancer before therapy begins. Core-needle biopsy is preferred over open biopsy for nonpalpable breast lesions because a single surgical procedure can be planned based on the results of the core biopsy. The advantages of core-needle biopsy include a

low complication rate, minimal scarring, and a lower cost compared with excisional breast biopsy.

Palpable Lesions. FNA or core biopsy of a palpable breast mass can usually be performed in an outpatient setting.¹⁵⁷ A 1.5-in, 22-gauge needle attached to a 10-mL syringe or a 14-gauge core biopsy needle is used. For FNA, use of a syringe holder

Figure 17-27. MRI examination revealing contralateral breast cancer (see arrows) in a patient diagnosed with unilateral breast cancer on mammography (two arrows). (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

Figure 17-28. MRI imaging of the breast revealing multifocal tumors not detected with standard breast imaging. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

enables the surgeon performing the FNA biopsy to control the syringe and needle with one hand while positioning the breast mass with the opposite hand. After the needle is placed in the mass, suction is applied while the needle is moved back and forth within the mass. Once cellular material is seen at the hub of the needle, the suction is released and the needle is withdrawn. The cellular material is then expressed onto microscope slides. Both air-dried and 95% ethanol-fixed microscopic sections are prepared for analysis. When a breast mass is clinically and mammographically suspicious, the sensitivity and specificity of FNA biopsy approaches 100%. Core-needle biopsy of palpable breast masses is performed using a 14-gauge needle, such as the Tru-Cut needle. Automated devices also are available. Vacuum-assisted core biopsy devices (with 8–10 gauge needles) are commonly utilized with image guidance where between 4 and 12 samples can be acquired at different positions within a mass, area of architectural distortion or microcalcifications. If the target lesion was microcalcifications, the specimen should be radiographed to confirm appropriate sampling. A radiopaque marker should be placed at the site of the biopsy to mark the area for future intervention. In some cases the entire lesion is removed with the biopsy technique and clip placement allows for accurate targeting of the site for surgical resection. Tissue specimens are placed in formalin and then processed to paraffin blocks. Although the false-negative rate for core-needle biopsy specimens is very low, a tissue specimen that does not show breast cancer cannot conclusively rule out that diagnosis because a sampling error may have occurred. The clinical, radiographic, and pathologic findings should be in concordance. If the biopsy findings do not concur with the clinical and radiographic findings, the multidisciplinary team (including clinician, radiologist, and pathologist) should review the findings and decide whether or not to recommend an image-guided or open biopsy to be certain that the target lesion has been adequately sampled for diagnosis.

BREAST CANCER STAGING AND BIOMARKERS

Breast Cancer Staging

The clinical stage of breast cancer is determined primarily through physical examination of the skin, breast tissue, and regional lymph nodes (axillary, supraclavicular, and internal mammary).¹⁵⁸ However, clinical determination of axillary lymph node metastases has an accuracy of only 33%. Ultrasound (US) is more sensitive than physical examination alone in determining axillary lymph node involvement during preliminary staging of breast carcinoma. FNA or core biopsy of sonographically indeterminate or suspicious lymph nodes can provide a more definitive diagnosis than US alone.^{153,159} Pathologic stage combines

the findings from pathologic examination of the resected primary breast cancer and axillary or other regional lymph nodes. Fisher and colleagues found that accurate predictions regarding the occurrence of distant metastases were possible after resection and pathologic analysis of 10 or more levels I and II axillary lymph nodes.¹⁶⁰ A frequently used staging system is the TNM (tumor, nodes, and metastasis) system. The American Joint Committee on Cancer (AJCC) has recently modified the TNM system for breast cancer to include both anatomic and biologic factors¹⁶¹ (Tables 17-10 and 17-11). Koscielny and colleagues demonstrated that tumor size correlates with the presence of axillary lymph node metastases (see Fig. 17-14B). Others have shown an association between tumor size, axillary lymph node metastases, and disease-free survival. One of the most important predictors of 10- and 20-year survival rates in breast cancer is the number of axillary lymph nodes involved with metastatic disease. Routine biopsy of internal mammary lymph nodes is not generally performed; however, it has been reported that in the context of a “triple node” biopsy approach either the internal mammary node or a low axillary node when positive alone carried the same prognostic weight. When both nodes were positive, the prognosis declined to the level associated with apical node positivity. A double node biopsy of the low axillary node and either the apical or the internal mammary node gave the same maximum prognostic information as a triple node biopsy.¹⁶² With the advent of sentinel lymph node dissection and the use of preoperative lymphoscintigraphy for localization of the sentinel nodes, surgeons have again begun to biopsy the internal mammary nodes but in a more targeted manner. The 8th edition of the AJCC staging system does allow for staging based on findings from the internal mammary sentinel nodes.¹⁶³ Drainage to the internal mammary nodes is more frequent with central and medial quadrant cancers. Clinical or pathologic evidence of metastatic spread to supraclavicular lymph nodes is no longer considered stage IV disease, but routine scalene or supraclavicular lymph node biopsy is not indicated.

Biomarkers

Breast cancer biomarkers are of several types. Risk factor biomarkers are those associated with increased cancer risk.¹⁶⁴⁻¹⁶⁸ These include familial clustering and inherited germline abnormalities, proliferative breast disease with atypia, and mammographic density. Exposure biomarkers are a subset of risk factors that include measures of carcinogen exposure such as DNA adducts. Surrogate endpoint biomarkers are biologic alterations in tissue that occur between cancer initiation and development. These biomarkers are used as endpoints in short-term chemoprevention trials and include histologic changes, indices of proliferation, and genetic alterations leading to cancer. Prognostic biomarkers provide information regarding

Table 17-10

TNM staging system for breast cancer

Primary tumor (T)

The T classification of the primary tumor is the same regardless of whether it is based on clinical or pathologic criteria, or both. Size should be measured to the nearest millimeter. If the tumor size is slightly less than or greater than a cutoff for a given T classification, it is recommended that the size be rounded to the millimeter reading that is closest to the cutoff. For example, a reported size of 1.1 mm is reported as 1 mm, or a size of 2.01 cm is reported as 2.0 cm. Designation should be made with the subscript “c” or “p” modifier to indicate whether the T classification was determined by clinical (physical examination or radiologic) or pathologic measurements, respectively. In general, pathologic determination should take precedence over clinical determination of T size.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis (DCIS)*	Ductal carcinoma <i>in situ</i>
Tis (Paget)	Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma <i>in situ</i> (DCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted.
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension (round any measurement >1.0–1.9 mm to 2 mm).
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or macroscopic nodules); invasion of the dermis alone does not qualify as T4
T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures does not qualify as T4
T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or edema (including peau d’orange) of the skin that does not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b are present
T4d	Inflammatory carcinoma (see section “Rules for Classification”)

*Note: Lobular carcinoma *in situ* (LCIS) is a benign entity and is removed from TNM staging in the *AJCC Cancer Staging Manual, 8th edition*.

Regional lymph nodes—Clinical (N)

cNX*	Regional lymph nodes cannot be assessed (e.g., previously removed)
cN0	No regional lymph node metastases (by imaging or clinical examination)
cN1	Metastases to movable ipsilateral Level I, II axillary lymph node(s)
cN1mi**	Micrometastases (approximately 200 cells, larger than 0.2 mm, but none larger than 2.0 mm)
cN2	Metastases in ipsilateral Level I, II axillary lymph nodes that are clinically fixed or matted; <i>or</i> in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN2a	Metastases in ipsilateral Level I, II axillary lymph nodes fixed to one another (matted) or to other structures
cN2b	Metastases only in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN3	Metastases in ipsilateral infraclavicular (Level III axillary) lymph node(s) with or without Level I, II axillary lymph node involvement; <i>or</i> in ipsilateral internal mammary lymph node(s) with Level I, II axillary lymph node metastases; <i>or</i> metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
cN3a	node involvement
cN3b	Metastases in ipsilateral infraclavicular lymph node(s)
cN3c	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s) Metastases in ipsilateral supraclavicular lymph node(s)

Note: (sn) and (f) suffixes should be added to the N category to denote confirmation of metastasis by sentinel node biopsy or fine needle aspiration/core needle biopsy respectively.

*the cNX category is used sparingly in cases where regional lymph nodes have previously been surgically removed or where there is no documentation of physical examination of the axilla.

**cN1mi is rarely used but may be appropriate in cases where sentinel node biopsy is performed before tumor resection, most likely to occur in cases treated with neoadjuvant therapy.

(Continued)

Table 17-10

TNM staging system for breast cancer (*Continued*)

Regional lymph nodes—Pathologic (pN)	
pNX	Regional lymph nodes cannot be assessed (e.g., not removed for pathological study or previously removed)
pN0	No regional lymph node metastasis identified or ITCs only
pN0(i+)	ITCs only (malignant cell clusters no larger than 0.2 mm) in regional lymph node(s)
pN0(mol+)	Positive molecular findings by reverse transcriptase polymerase chain reaction (RT-PCR); no ITCs detected
pN1	Micrometastases; or metastases in 1–3 axillary lymph nodes; and/or clinically negative internal mammary nodes with micrometastases or macrometastases by sentinel lymph node biopsy
pN1mi	Micrometastases (approximately 200 cells, larger than 0.2 mm, but none larger than 2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis larger than 2.0 mm
pN1b	Metastases in ipsilateral internal mammary sentinel nodes, excluding ITCs
pN1c	pN1a and pN1b combined
pN2	Metastases in 4–9 axillary lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the absence of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least one tumor deposit larger than 2.0 mm)
pN2b	Metastases in clinically detected internal mammary lymph nodes with or without microscopic confirmation; with pathologically negative axillary nodes
pN3	Metastases in 10 or more axillary lymph nodes; or in infraclavicular (Level III axillary) lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the presence of one or more positive Level I, II axillary lymph nodes; or in more than three axillary lymph nodes and micrometastases or macrometastases by sentinel lymph node biopsy in clinically negative ipsilateral internal mammary lymph nodes;
pN3a	or in ipsilateral supraclavicular lymph nodes
pN3b	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit larger than 2.0 mm); or metastases to the infraclavicular (Level III axillary lymph) nodes
pN3c	pN1a or pN2a in the presence of cN2b (positive internal mammary nodes by imaging); or pN2a in the presence of pN1b Metastases in ipsilateral supraclavicular lymph nodes
<i>Note:</i> (sn) and (f) suffixes should be added to the N category to denote confirmation of metastasis by sentinel node biopsy or FNA/core needle biopsy respectively, with NO further resection of nodes.	
Distant metastasis (M)	
M0	No clinical or radiographic evidence of distant metastases*
cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumor cells or deposits no larger than 0.2 mm detected microscopically or by molecular techniques in circulating blood, bone marrow, or other nonregional nodal tissue in a patient without symptoms or signs of metastases
cM1	Distant metastases detected by clinical and radiographic means
pM1	Any histologically proven metastases in distant organs; or if in non-regional nodes, metastases greater than 0.2 mm

Used with the permission of the American College of Surgeons. Amin MB, Edge SB, Greene FL, et al. (Eds.) *AJCC Cancer Staging Manual*, 8th Ed. Springer New York, 2017.

cancer outcome irrespective of therapy, whereas predictive biomarkers provide information regarding response to therapy.¹⁶⁹ Candidate prognostic and predictive biomarkers and biologic targets for breast cancer include (a) the steroid hormone receptor pathway; (b) growth factors and growth factor receptors such as human epidermal growth factor receptor 2 (HER2)/neu, epidermal growth factor receptor (EGFR), transforming growth factor, platelet-derived growth factor, and the insulin-like growth factor family; (c) indices of proliferation such as proliferating cell nuclear antigen (PCNA) and Ki-67; (d) indices of angiogenesis such as vascular endothelial growth factor (VEGF) and the angiogenesis index; (e) the mammalian target of rapamycin (mTOR) signaling pathway; (f) tumor-suppressor genes such as p53; (g) the cell cycle, cyclins, and cyclin-dependent kinases; (h) the proteasome; (i) the COX-2 enzyme; (j) the peroxisome proliferator-activated receptors (PPARs); and (k)

indices of apoptosis and apoptosis modulators such as bcl-2 and the bax:bcl-2 ratio.

Steroid Hormone Receptor Pathway. Hormones play an important role in the development and progression of breast cancer. Estrogens, estrogen metabolites, and other steroid hormones such as progesterone all have been shown to have an effect. Breast cancer risk is related to estrogen exposure over time. In postmenopausal women, hormone replacement therapy consisting of estrogen plus progesterone increases the risk of breast cancer by 26% compared to placebo.⁷⁰ Patients with hormone receptor-positive tumors survive two to three times longer after a diagnosis of metastatic disease than do patients with hormone receptor-negative tumors. Patients with tumors negative for both estrogen receptors and progesterone receptors are not considered candidates for hormonal therapy. Tumors positive

Table 17-11

TNM stage groupings

When T is...	And N is...	And M is...	Then the stage group is...
Tis	N0	M0	0
T1	N0	M0	IA
T0	N1mi	M0	IB
T1	N1mi	M0	IB
T0	N1	M0	IIA
T1	N1	M0	IIA
T2	N0	M0	IIA
T2	N1	M0	IIB
T3	N0	M0	IIB
T0	N2	M0	IIIA
T1	N2	M0	IIIA
T2	N2	M0	IIIA
T3	N1	M0	IIIA
T3	N2	M0	IIIA
T4	N0	M0	IIIB
T4	N1	M0	IIIB
T4	N2	M0	IIIB
Any T	N3	M0	IIIC
Any T	Any N	M1	IV

Notes:

1. T1 includes T1 mi.
2. T0 and T1 tumors with nodal micrometastases (N1mi) are staged as Stage IB.
3. T2, T3, and T4 tumors with nodal micrometastases (N1mi) are staged using the N1 category.
4. M0 includes M0(i+).
5. The designation pM0 is not valid; any M0 is clinical.
6. If a patient presents with M1 disease prior to neoadjuvant systemic therapy, the stage is Stage IV and remains Stage IV regardless of response to neoadjuvant therapy.
7. Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided the studies are performed within 4 months of diagnosis in the absence of disease progression, and provided the patient has not received neoadjuvant therapy.
8. Staging following neoadjuvant therapy is denoted with a “ye” or “yp” prefix to the T and N classification. There is no anatomic stage group assigned if there is a complete pathological response (pCR) to neoadjuvant therapy, for example, ypT0ypN0cM0.

Used with the permission of the American College of Surgeons. Amin MB, Edge SB, Greene FL, et al. (Eds.) *AJCC Cancer Staging Manual*, 8th Ed. Springer New York, 2017.

for estrogen or progesterone receptors have a higher response rate to endocrine therapy than tumors that do not express estrogen or progesterone receptors. The determination of estrogen and progesterone receptor status used to require biochemical evaluation of fresh tumor tissue. Today, however, estrogen and progesterone receptor status can be measured in archived tissue using immunohistochemical techniques. Hormone receptor status also can be measured in specimens obtained with fine-needle aspiration biopsy or core-needle biopsy, and this can help guide treatment planning. Testing for estrogen and progesterone receptors should be performed on all primary invasive breast

cancer specimens. The tumor hormone receptor status should be ascertained for both premenopausal and postmenopausal patients to identify patients who are most likely to benefit from endocrine therapy.

Growth Factor Receptors and Growth Factors. Overexpression of EGFR in breast cancer correlates with estrogen receptor–negative status and with p53 overexpression.¹⁷⁰⁻¹⁷² Similarly, increased immunohistochemical membrane staining for the HER2 growth factor receptor in breast cancer is associated with mutated *TP53*, Ki67 overexpression, and estrogen receptor–negative status. HER2 is a member of the ErbB family of growth factor receptors in which ligand binding results in receptor homodimerization and tyrosine phosphorylation by tyrosine kinase domains within the receptor. Tyrosine phosphorylation is followed by signal transduction, which results in changes in cell behavior. An important property of this family of receptors is that ligand binding to one receptor type also may result in heterodimerization between two different receptor types that are coexpressed; this leads to transphosphorylation and transactivation of both receptors in the complex (transmodulation). In this context, the lack of a specific ligand for the HER2/neu receptor suggests that HER2/neu may function solely as a co-receptor, modulating signaling by other EGFR family members. HER2/neu is both an important prognostic factor and a predictive factor in breast cancer.¹⁷³ When overexpressed in breast cancer, HER2/neu promotes enhanced growth and proliferation, and increases invasive and metastatic capabilities. Clinical studies have shown that patients with HER2/neu–overexpressing breast cancer have poorly differentiated tumors with high proliferation rates, positive lymph nodes, decreased hormone receptor expression, and an increased risk of recurrence and death due to breast cancer.¹⁷³⁻¹⁷⁷ Routine testing of the primary tumor specimen for HER2/neu expression should be performed on all invasive breast cancers. This can be done with immunohistochemical analysis to evaluate for overexpression of the cell-surface receptor at the protein level or by using fluorescence in situ hybridization to evaluate for gene amplification. While HER2/ERBB2 activation can also be assessed based on mRNA expression and reverse transcription polymerase chain reaction (RT-PCR) (Oncotype Dx, Genomic Health), this approach is not recommended for clinical decision-making because of the high false negative rate.¹⁷⁸ Patients whose tumors show *HER2* amplification or HER2/neu protein overexpression are candidates for anti-HER2/neu therapy. Trastuzumab (Herceptin) is a recombinant humanized monoclonal antibody directed against HER2. Randomized clinical trials have demonstrated that single-agent trastuzumab therapy is well tolerated and active in the treatment of women with HER2/neu–overexpressing metastatic breast cancer.¹⁷⁹ Subsequent adjuvant trials demonstrated that trastuzumab also was highly effective in the treatment of women with early-stage breast cancer when used in combination with chemotherapy.¹⁸⁰⁻¹⁸² Patients who received trastuzumab in combination with chemotherapy had between a 40% and 50% reduction in the risk of breast cancer recurrence and approximately a one-third reduction in breast cancer mortality compared with those who received chemotherapy alone.^{181,183-185}

Indices of Proliferation. PCNA is a nuclear protein associated with a DNA polymerase whose expression increases in phase G₁ of the cell cycle, reaches its maximum at the G₁/S interface, and then decreases through G₂.¹⁸⁶⁻¹⁸⁹ Immunohistochemical staining for PCNA outlines the proliferating compartments in

breast tissue. Good correlation is noted between PCNA expression and (a) cell-cycle distributions seen on flow cytometry based on DNA content, and (b) uptake of bromodeoxyuridine and the proliferation-associated Ki67 antigen. Individual proliferation markers are associated with slightly different phases of the cell cycle and are not equivalent. PCNA and Ki67 expression are positively correlated with p53 overexpression, high S-phase fraction, aneuploidy, high mitotic index, and high histologic grade in human breast cancer specimens, and are negatively correlated with estrogen receptor content. Ki67 was included with three other widely measured breast cancer markers (ER, PR, and HER2) into a panel of four immunohistochemical makers (IHC4), which together provided similar prognostic information to that in the 21 Gene Recurrence Score (Oncotype DX, Genomic Health).¹⁹⁰ While there has been significant interest in using Ki67 as a biomarker, and while the IHC4 panel would be much less expensive than the 21 Gene Recurrence Score, there remain issues regarding reproducibility across laboratories.

Indices of Angiogenesis. Angiogenesis is necessary for the growth and invasiveness of breast cancer and promotes cancer progression through several different mechanisms, including delivery of oxygen and nutrients and the secretion of growth-promoting cytokines by endothelial cells.^{191,192} VEGF induces its effect by binding to transmembrane tyrosine kinase receptors. Overexpression of VEGF in invasive breast cancer is correlated with increased microvessel density and recurrence in node-negative breast cancer. An angiogenesis index has been developed in which microvessel density (CD31 expression) is combined with expression of thrombospondin (a negative modulator of angiogenesis) and p53 expression. Both VEGF expression and the angiogenesis index may have prognostic and predictive significance in breast cancer.¹⁹³ Bevacizumab (a monoclonal antibody to VEGF) was approved by the FDA for use in metastatic breast cancer in combination with paclitaxel chemotherapy. This approval was based on results from a phase 3 trial by the Eastern Cooperative Oncology Group. The group's E2100 trial showed that when bevacizumab was added to paclitaxel chemotherapy, median progression-free survival increased to 11.3 months from the 5.8 months seen in patients who received paclitaxel alone.¹⁹⁴ The results were not reproduced in other trials, and the indication for the drug was revoked by the FDA in 2011.

Indices of Apoptosis. Alterations in programmed cell death (apoptosis), which may be triggered by p53-dependent or p53-independent factors, may be important prognostic and predictive biomarkers in breast cancer.¹⁹⁵⁻¹⁹⁷ Bcl-2 family proteins appear to regulate a step in the evolutionarily conserved pathway for apoptosis, with some members functioning as inhibitors of apoptosis and others as promoters of apoptosis. *Bcl-2* is the only oncogene that acts by inhibiting apoptosis rather than by directly increasing cellular proliferation. The death-signal protein bax is induced by genotoxic stress and growth factor deprivation in the presence of wild-type (normal) p53 and/or AP-1/fos. The bax to bcl-2 ratio and the resulting formation of either bax-bax homodimers, which stimulate apoptosis, or bax-bcl-2 heterodimers, which inhibit apoptosis, represent an intracellular regulatory mechanism with prognostic and predictive implications. In breast cancer, overexpression of bcl-2 and a decrease in the bax to bcl-2 ratio correlate with high histologic grade, the presence of axillary lymph node metastases, and reduced disease-free and overall survival rates. Similarly, decreased bax

expression correlates with axillary lymph node metastases, a poor response to chemotherapy, and decreased overall survival.

The remaining biomarkers and biologic targets listed earlier are still in preclinical testing, and clinical trials are evaluating their importance in breast cancer for both prognostic and predictive purposes.

Coexpression of Biomarkers. Selection of optimal therapy for breast cancer requires both an accurate assessment of prognosis and an accurate prediction of response to therapy. The breast cancer markers that are most important in determining therapy are estrogen receptor, progesterone receptor, and HER2/neu. Clinicians evaluate clinical and pathologic staging and the expression of estrogen receptor, progesterone receptor, and HER2/neu in the primary tumor to assess prognosis and assign therapy. Adjuvant! Online (<http://www.adjuvantonline.com>) is one of a number of programs available to clinicians that incorporates clinical and pathologic factors for an individual patient and calculates risk of recurrence and death due to breast cancer and then provides an assessment of the reduction in risk of recurrence that would be expected with the use of combination chemotherapy, endocrine therapy, or both of these. Adjuvant! Online was developed using information from the SEER database, the EBCTCG overview analyses, and results from other individual published trials.¹⁹⁸ The website is updated and modified as new information becomes available. Clinicopathologic factors are used to separate breast cancer patients into broad prognostic groups, and treatment decisions are made on this basis (Table 17-12). Other indices and programs that are validated and used include the Nottingham Prognostic Index, and PREDICT.¹⁹⁹⁻²⁰¹ When an approach, which combines prognostic factors is used, up to 70% of early breast cancer patients receive adjuvant chemotherapy that is either unnecessary or ineffective. As described earlier, a wide variety of biomarkers have been shown to individually predict prognosis and response to therapy, but they do not improve the accuracy of either the assessment of prognosis or the prediction of response to therapy.

As knowledge regarding cellular, biochemical, and molecular biomarkers for breast cancer have improved, prognostic indices have been developed that combine the predictive power

Table 17-12

Traditional prognostic and predictive factors for invasive breast cancer

TUMOR FACTORS	HOST FACTORS
Nodal status	Age
Tumor size	Menopausal status
Histologic/nuclear grade	Family history
Lymphatic/vascular invasion	Previous breast cancer
Pathologic stage	Immunosuppression
Hormone receptor status	Nutrition
DNA content (ploidy, S-phase fraction)	Prior chemotherapy
Extent of intraductal component	Prior radiation therapy
HER2/neu expression

of several individual biomarkers with the relevant clinicopathologic factors.

Recent technological advances have enabled implementation of high throughput gene expression assays in clinical practice.²⁰² These assays enable detailed stratification of breast cancer patients for assessment of prognosis and for prediction of response to therapy. The *Oncotype DX* is a 21-gene RT-PCR-based assay that has been approved for use in newly diagnosed patients with node-negative, ER-positive breast cancer.²⁰³ A recurrence score is generated, and those patients with high recurrence scores are likely to benefit from chemotherapy, whereas those with low recurrence scores benefit most from endocrine therapy and may not require chemotherapy. Results from the Trial Assessing Individualized Options for Treatment for breast cancer (TAILORx), designed to prospectively validate the use of 21-gene expression assay, have shown that patients with low recurrence score (0 to 10) have a low rate of local-regional and distant recurrence (98.7%) and very good overall survival at 5 years (98%) with endocrine therapy alone without chemotherapy.²⁰⁴ This study has randomly assigned patients with an intermediate recurrence score (11 to 25) to endocrine therapy alone or to chemotherapy followed by endocrine therapy.

Additionally, retrospective analysis has shown that the 21-gene recurrence score can be used in postmenopausal patients with ER-positive tumors and 1 to 3 involved axillary lymph nodes to predict the benefit of chemotherapy in addition to endocrine therapy.²⁰⁵ Knowledge of the recurrence score has been shown to alter treatment recommendations by oncologists, and patients likewise change their decision to undergo treatment based on the risk of recurrence.²⁰⁶ The MammaPrint assay uses a 70-gene expression profile to assess the risk of distant metastasis. MammaPrint is FDA approved for use in stage-1 or stage-2, node negative, ER-positive or ER-negative breast cancers to identify patients with high or low risk of recurrence. Although fresh tissue was initially required to perform the assay, it has since been adapted for use in paraffin-embedded tissue samples. The prospective RASTER study reported that patients classified as low risk based on MammaPrint had a 97% distant recurrence-free interval at five years.²⁰⁷ Results of the prospective MINDACT (MicroarrayInNode negative and 1–3 positive lymph node Disease may Avoid ChemoTherapy) trial were recently reported.²⁰⁸ The study was designed to assess whether the 70-gene expression assay would help avoid chemotherapy in patients who are considered clinically high risk but categorized as low genomic risk based on the assay. A 5-year rate of distant metastasis-free survival of more than 92% was identified as the cutoff for the benefit of chemotherapy. At 5 years, the rate of survival without distant metastasis in patients with high clinical risk and low genomic risk was 94.7%, meeting the criteria for noninferiority. However, the rate of disease-free survival and overall survival was higher with chemotherapy in the intention to treat population.

OVERVIEW OF BREAST CANCER THERAPY

Before diagnostic biopsy, the surgeon must consider the possibility that a suspicious mass or mammographic finding may be a breast cancer. Once a diagnosis of breast cancer is made, the type of therapy offered to a breast cancer patient is determined by the stage of the disease, the biologic subtype, and the general health status of the individual. Laboratory tests and imaging

Table 17-13

Diagnostic studies for breast cancer patients

	CANCER STAGE				
	0	I	II	III	IV
History & physical	X	X	X	X	X
Complete blood count, platelet count			X	X	X
Liver function tests and alkaline phosphatase level			X	X	X
Chest radiograph			X	X	X
Bilateral diagnostic mammograms, ultrasound as indicated	X	X	X	X	X
Hormone receptor status	X	X	X	X	X
HER2/neu expression		X	X	X	X
Bone scan				X	X
Abdominal (without or without pelvis) computed tomographic scan or ultrasound or magnetic resonance imaging				X	X

Abdominal imaging and bone scanning are indicated for evaluation of symptoms or abnormal laboratory test results at any presenting stage. Data from NCCN Practice Guidelines in Oncology. Fort Washington, PA: National Comprehensive Cancer Network, 2006.

studies are performed based on the initial stage as presented in Table 17-13. Before therapy is initiated, the patient and the surgeon must share a clear perspective on the planned course of treatment. Before initiating local therapy, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels.

In Situ Breast Cancer (Stage 0)

Both LCIS and DCIS may be difficult to distinguish from atypical hyperplasia or from cancers with early invasion.^{60,209-214} Expert pathologic review is required in all cases. Bilateral mammography is performed to determine the extent of the in situ cancer and to exclude a second cancer. Because LCIS is considered a marker for increased risk rather than an inevitable precursor of invasive disease, the current treatment options for LCIS include observation, chemoprevention, and bilateral total mastectomy. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently develops in 25% to 35% of these women. There is no benefit to excising LCIS because the disease diffusely involves both breasts in many cases and the risk of developing invasive cancer is equal for both breasts. The use of tamoxifen as a risk-reduction strategy should be considered in women with a diagnosis of LCIS.

Women with DCIS and evidence of extensive disease (>4 cm of disease or disease in more than one quadrant) usually require mastectomy (Fig. 17-29). For women with limited disease, lumpectomy and radiation therapy are generally recommended. For nonpalpable DCIS, needle localization or other image-guided techniques are used to guide the surgical resection. Specimen mammography is performed to ensure that all visible evidence of cancer is excised. Adjuvant tamoxifen therapy is considered for DCIS patients with ER-positive

A

B

Figure 17-29. Extensive DCIS seen on mammography. **A.** Extensive calcifications are seen throughout the breast on this cranial caudal view. **B.** Magnification view of calcifications. Due to the extent of the disease the patient is not a good candidate for breast conserving surgery. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

disease. The gold standard against which breast conservation therapy for DCIS is evaluated is mastectomy. Women treated with mastectomy have local recurrence and mortality rates of <2%. There is no randomized trial comparing mastectomy vs. breast conserving surgery, and none of the randomized trials of breast-conserving surgery with or without radiotherapy for DCIS were powered to show a difference in mortality. Women treated with lumpectomy and adjuvant radiation therapy in the initial clinical trials were noted to have a local recurrence rate that is increased compared to mastectomy. About 45% of these recurrences will be invasive cancer when radiation therapy is not used. The B-17 trial was conducted by the NSABP to assess the need for radiation in patients treated with breast conserving surgery for DCIS.²¹⁵ Patients were randomly assigned to lumpectomy with radiation or lumpectomy alone, and after a mean follow-up time of 90 months rates of both ipsilateral noninvasive and invasive recurrences were significantly lower in patients who received radiation. However, in the B-17 trial the margins were not prospectively assessed, and it is estimated that up to half of the patients may have had tumor at the margin of resection. The benefit of the addition of radiation over breast-conserving surgery alone for DCIS has also been demonstrated in several other randomized trials where margins were prospectively assessed including the European Organization for Research and Treatment of Cancer (EORTC) protocol 10853; the United Kingdom, Australia, New Zealand DCIS Trial; and the Swedish Trial.^{209,216-218} In 2016, the Society of Surgical Oncology (SSO), American Society for Radiation Oncology (ASTRO), and the American Society of Clinical Oncology (ASCO) established consensus guidelines on margins for patients with DCIS undergoing breast-conserving surgery.²¹⁹ Based on a multidisciplinary consensus panel using a meta-analysis of margin width and ipsilateral breast tumor recurrence, a 2-mm margin was determined as adequate width for DCIS for patients undergoing breast-conserving surgery with whole-breast radiation therapy.²¹⁹

Despite the data from randomized trials showing a benefit in all patient subgroups with the addition of radiation in DCIS, there has been an interest in trying to define a subset where radiation could be avoided in order to minimize the cost and inconvenience associated with radiation. In addition, there have been several studies published where patients were treated with excision alone and never developed invasive breast cancer even at 25 years of follow-up. Silverstein and colleagues were proponents of avoiding radiation therapy in selected patients with DCIS who have widely negative margins after surgery.²¹³ They reported that when greater than 10-mm margins were achieved, there was no additional benefit from radiation therapy. When margins were between 1 and 10 mm, there was a relative risk of local recurrence of 1.49, compared to 2.54 for those with margins less than 1 mm. These data suggested that appropriately selected patients with DCIS might not require postoperative radiation therapy.

The Eastern Cooperative Oncology Group (ECOG) initiated a prospective registry trial (ECOG 5194) to identify those patients who could safely undergo breast-conserving surgery without radiation.²²² Eligible patients were those with low or intermediate grade DCIS measuring 2.5 cm or less who had negative margins of at least 3 mm and those with high-grade DCIS who had tumors measuring 1 cm or less with a negative margin of at least 3 mm. At a median follow-up of 6.2 years, patients with low or intermediate grade DCIS had an in-breast

recurrence rate of 6.1% while those with high-grade DCIS had a recurrence rate of 15.3%. Approximately 4% of patients developed a contralateral breast cancer during follow-up in both the low/intermediate and high-grade groups. This study identified an acceptable recurrence rate for those patients with low or intermediate grade DCIS treated with excision alone with a margin of at least 3 mm. In contrast, patients with high-grade DCIS had an unacceptably high local recurrence rate.

The Radiation Therapy Oncology Group (RTOG) initiated the 9804 trial for patients with “good risk” DCIS and randomized them to lumpectomy vs. lumpectomy with whole breast irradiation. Eligible patients were those with unicentric, low or intermediate grade DCIS measuring 2.5 cm or less with a margin of 3 mm or greater. The trial was closed early due to slow accrual; however, the results for 585 patients were recently reported with a median follow-up of 6.46 years.^{223,224} The local recurrence rate at 5 years was 0.4% for patients randomized to receive radiation and 3.2% for those who did not receive radiation.

Solin et al utilized samples from the ECOG 5194 trial to develop a quantitative multigene RT-PCR assay for predicting recurrence risk in patients with DCIS treated with surgery alone.²⁰¹ They were able to define low, intermediate, and high risk groups using a DCIS Score. The DCIS Score was able to quantify the risk of recurrence in the breast for both DCIS and invasive events. This tool has recently been evaluated in another dataset and appears to be a promising tool for clinical use.²²⁵ When selecting therapy for patients with DCIS, one must consider clinical and pathologic factors, including tumor size, grade, mammographic appearance, and patient preference. There is no single correct surgical treatment, and many patients will require extensive counseling in order to make a decision regarding surgical therapy. The role of axillary staging in patients with DCIS is limited. One consideration is for patients undergoing mastectomy. Since most lesions are currently diagnosed with needle core biopsy, there is about a 20% incidence of invasive breast cancer on final pathologic assessment of the primary tumor. Since it is not feasible to perform sentinel node dissection after mastectomy, most surgeons will recommend the use of sentinel node dissection at the time of mastectomy for DCIS.

Results from the NSABP B-24 trial reported a significant reduction in local recurrence after 5 years of tamoxifen in women with ER-positive DCIS. Based on this finding, some guidelines have advocated that all patients (women with ER-positive DCIS without contraindications to tamoxifen therapy) should be offered tamoxifen following surgery and radiation therapy for a duration of 5 years. The B-24 trial revealed a significant reduction in recurrence with adjuvant tamoxifen therapy for patients with DCIS; however, the results were not initially assessed based on ER status.²²⁶ There were 1804 women with DCIS randomized to lumpectomy and radiation with or without tamoxifen. The rate of breast cancer events was significantly lower in those who received tamoxifen at a median follow-up of 74 months (8.2% vs. 13.4%, $P = 0.0009$). Subsequently, Allred and colleagues evaluated 41% of patients with DCIS in the NSABP B-24 trial to determine the effect of tamoxifen based on ER status measured in the primary tumor.²⁰³ They found that 76% of women had DCIS that was ER-positive and these women had a greater reduction in ipsilateral breast tumor recurrence with tamoxifen than did patients with ER-negative DCIS (11% vs. 5.2%, $P < 0.001$). However, it should be noted that 15% of patients in B-24 had tumor at the resection margins. For

these patients, tamoxifen could be viewed as treating what, by the current standard, would be viewed as inadequate local excision of the primary tumor.

Early Invasive Breast Cancer (Stage I, IIA, or IIB)

There have been six prospective randomized trials comparing breast-conserving surgery to mastectomy in early stage breast cancer, and all have shown equivalent survival rates regardless of the surgical treatment type. One caveat, however, is that the majority of studies had a restriction of tumor size; most were either 2 cm or 2.5 cm, while the NSABP B-06 trial was 4 cm, and the NCI trial was up to 5 cm. NSABP B-06, which is the largest of all the breast conservation trials, compared total mastectomy to lumpectomy with or without radiation therapy in the treatment of women with stages I and II breast cancer.²²⁷⁻²³³ After 5- and 8-year follow-up periods, the disease-free (DFS), distant disease-free, and overall survival (OS) rates for lumpectomy with or without radiation therapy were similar to those observed after total mastectomy. However, the incidence of ipsilateral breast cancer recurrence was higher in the group not receiving radiation therapy. These findings supported the use of lumpectomy and radiation therapy in the treatment of stages I and II breast cancer and this has since become the preferred method of treatment for women with early stage breast cancer who have unifocal disease and who are not known *BRCA* mutation carriers. Reanalysis of the B-06 study results was undertaken after 20 years of follow-up and confirmed that there was no difference in disease-free survival rates after total mastectomy or after lumpectomy with or without adjuvant radiation therapy. The in-breast recurrence rate was substantially higher in the lumpectomy alone group (39.2%) compared with the lumpectomy plus adjuvant radiation therapy group (14.3%), confirming the importance of radiation therapy in the management of patients with invasive disease. However, it should be noted that there were several criteria in the B-06 study. There was a specific lymphadenopathy exclusion criteria. Secondly, all patients randomized to breast-conserving surgery had a frozen section, and if the margins were involved, they were converted to mastectomy but were included in the analysis as having had a breast-conserving operation (on the basis of intention to treat). Finally, in the breast-conserving group recurrences in the treated breast were considered as a “nonevent.”

Data from all of the randomized trials where breast conservation was performed with or without radiation therapy have been examined by the EBCTCG.¹² At 15 years of follow-up, the absolute reduction in mortality with the use of radiation therapy after lumpectomy was 5.1% in node-negative patients and 7.1% in node-positive patients. These data support the concept that the addition of radiation not only improves local control but also has an impact on survival. Similar to DCIS, clinicians have sought to identify subgroups of patients who may not benefit from the addition of radiation therapy, particularly older patients who may have a shorter life expectancy due to medical comorbidities. Randomized trials have shown that in selected patients with small, ER-positive, low-grade tumors, lumpectomy alone without radiation therapy may be appropriate.^{211,212} The Cancer and Leukemia Group B (CALGB) C9343 trial enrolled women over the age of 70 with T1N0 breast cancer and randomized them to lumpectomy with or without radiation therapy. All patients received adjuvant tamoxifen.^{233a} At 5 years, although

there were fewer local recurrences with radiation (1% vs. 4%, $P < 0.001$), there were no differences in DFS and OS. While long-term follow-up at 10 years showed fewer local recurrences with radiation (2% vs. 10%), there were no significant differences in time to distant metastasis, breast cancer–specific survival, or OS between the two groups. A trial similar to CALGB C9343 was conducted in Canada where they enrolled women age 50 years and older and randomized them to lumpectomy with or without radiation. Mean age was 68 years, and 80% of women had ER-positive tumors. Again, local recurrence rates were lower in women who received radiation (0.6% vs. 7.7%, $P < 0.001$); however, at a median follow-up of 5.6 years, there were no differences in DFS or OS. The PRIME-2 study enrolled women age 65 years or older with ER-positive, node-negative, up to 3 cm breast cancers, who had undergone breast-conserving surgery and were candidates for adjuvant endocrine treatment. They were assigned to receive whole-breast irradiation or no treatment. After a median follow-up of 5 years, ipsilateral breast tumor recurrence was 1.3% with radiation vs. 41% in those assigned to no radiotherapy. However, no differences in distant metastases, contralateral breast cancers, or overall survival were noted between the groups.²³⁴ These studies suggest that radiation can be avoided in select older patients with ER-positive, early-stage breast cancer.

Accelerated partial breast irradiation (APBI) is also an option for carefully selected patients with DCIS and early-stage breast cancer. Since the majority of recurrences after breast conservation occur in or adjacent to the tumor bed, there has been interest in limiting the radiation to the area of the primary tumor bed with a margin of normal tissue. APBI is delivered in an abbreviated fashion (twice daily for 5 days) and at a lower total dose compared with the standard course of 5 to 6 weeks of radiation (50 Gy with or without a boost) in the case of whole breast irradiation. Proponents have suggested that this shortened course of treatment may increase the feasibility of breast conservation for some women and may improve radiation therapy compliance. The RTOG 04-13/NSABP B-39 trial is a randomized comparison of whole breast irradiation to APBI in women with early stage breast cancer. The trial has completed accrual, and it will likely be several years before data are mature to report outcomes between the two radiation treatment strategies. TARGIT is another study that randomized 3451 patients in 33 centers in over 10 countries to intraoperative breast irradiation (IORT) or external beam radiotherapy (EBRT). The preliminary results were reported in 2012: with a median follow-up of 2.4 years, use of IORT had a recurrence rate of 3.3% vs. 1.3% with EBRT, a 2% increased recurrence risk.^{235,236} ASTRO developed guidelines for the use of APBI outside of clinical trials based on data reported from published studies.^{237,238} The ASTRO guidelines describe patients “suitable” for APBI to include women age 60 years or older with a unifocal, T1, ER-positive tumor with no lymphovascular invasion and margins of at least 2 mm. They describe a group where there is uncertainty about the appropriateness of APBI (“cautionary” group) to include patients with invasive lobular histology, a tumor size of 2.1 cm to 3 cm, ER-negative disease, focal lymphovascular invasion, or margins less than 2 mm. Finally, a group felt to be “unsuitable” for APBI includes those with T3 or T4 disease, ER-negative disease, multifocality, multicentricity, extensive LVI, or positive margins.

Currently, mastectomy with axillary staging and breast conserving surgery with axillary staging and radiation therapy

are considered equivalent treatments for patients with stages I and II breast cancer. Breast conservation is considered for all patients because of the important cosmetic advantages and equivalent survival outcomes; however, this approach is not advised in women who are known *BRCA* mutation carriers due to the high lifetime risk for development of additional breast cancers. Relative contraindications to breast conservation therapy include (a) prior radiation therapy to the breast or chest wall, (b) persistently positive surgical margins after reexcision, (c) multicentric disease, and (d) scleroderma or lupus erythematosus.

For most patients with early-stage disease, reconstruction can be performed immediately at the time of mastectomy. Immediate reconstruction allows for skin-sparing, thus optimizing cosmetic outcomes. Skin-sparing mastectomy with immediate reconstruction has been popularized over the past decade as reports of low local-regional failure rates have been reported and reconstructive techniques have advanced. There is a growing interest in the use of nipple-areolar sparing mastectomy with reports suggesting the oncologic safety of this approach in early stage breast cancer. Patients who are planned for postmastectomy radiation therapy may not be ideal candidates for nipple-sparing mastectomy because of the effects of radiation on the preserved nipple. In addition to providing optimal cosmesis from preservation of the skin and/or the nipple-areolar complex, immediate reconstruction allows patients to wake up with a breast mound, which provides some psychological benefit for the patient. Immediate reconstruction is also more economical as both the extirpative and reconstructive surgery are combined in one operation.

Immediate reconstruction can be performed using implants or autologous tissue; tissue flaps commonly used include the transverse rectus abdominis myocutaneous flap, deep inferior epigastric perforator flap, and latissimus dorsi flap (with or without an implant). If postmastectomy radiation therapy is needed, a tissue expander can be placed at the time of mastectomy to save the shape of the breast and reduce the amount of skin replacement needed at the time of definitive reconstruction. The expander can be deflated at the initiation of radiation therapy to allow for irradiation of the chest wall and regional nodal basins. Removal of the tissue expander and definitive reconstruction, usually with autologous tissue, can proceed 6 months to 1 year after completion of radiation therapy.

Axillary lymph node status has traditionally been an important determinant in staging and prognosis for women with early stage breast cancer. Historically, axillary lymph node dissection (ALND) was utilized for axillary staging and regional control by removing involved lymph nodes. Randomized trials evaluating immediate ALND over ALND performed in a delayed fashion once clinically palpable axillary disease became evident have not shown any detriment in survival.^{9,239} With increased mammographic screening and detection of smaller, node-negative breast cancers, it became clear that routine use of ALND for axillary staging was not necessary in up to 75% percent of women with operable breast cancer presenting with a negative axilla at the time of screening. Lymphatic mapping and sentinel lymph node (SLN) dissection were initially developed for assessment of patients with clinically node-negative melanoma. Given the changing landscape of newly diagnosed breast cancer patients with a clinically node-negative axilla, surgeons quickly began to explore the utility of SLN dissection as a replacement for ALND in axillary staging.

In the early 1990s, David Krag at the University of Vermont began performing SLN dissection with injection of a radioisotope in the primary tumor site and localizing the SLN node with a handheld gamma probe.²⁴⁰ He was able to identify a SLN in 18 of 22 patients examined, and the SLN was positive in all 7 patients with positive lymph nodes. Giuliano and colleagues initiated a pilot study in 1991 to examine the use of SLN dissection using blue dye in patients with clinically negative nodes. They reported successful identification of a SLN in 114 (65.5%) of 174 patients, and in 109 (95.6%), the SLN accurately predicted the status of the axillary nodes.^{241,242} These studies along with initial work by Doug Reintgen and Charles Cox at the Moffitt Cancer Center and Umberto Veronesi and his colleagues at the European Institute of Oncology in Milan led the way toward validation of the technique in large single institution and multicenter studies.

Following validation of the technique of SLN dissection for staging of the axilla by multiple centers, randomized trials were initiated in order to determine if SLN dissection could replace ALND in the contemporary management of breast cancer patients. The ALMANAC trial randomized 1031 patients with primary operable breast cancer to SLN dissection vs. standard axillary surgery. The incidence of lymphedema and sensory loss for the SLN group was significantly lower than with the standard axillary treatment. At 12 months, drain usage, length of hospital stay, and time to resumption of normal day-to-day activities after surgery were also statistically significantly lower in the SLN group.²²¹

The NSABP B-32 trial compared clinically node-negative patients undergoing SLN dissection followed by ALND with patients undergoing SLN dissection with ALND only if a SLN was positive for metastatic disease.²⁴³ A total of 5611 patients were randomized with a SLN identification rate of 97% and a false-negative rate of 9.7%. A total of 26% of these clinically node-negative patients had a positive SLN. Over 60% of patients with positive SLNs had no additional positive lymph nodes within the ALND specimen. The B-32 trial and other randomized trials demonstrated no difference in DFS, OS, and local-regional recurrence rates between patients with negative SLNs who had SLN dissection alone compared with those who underwent ALND.^{244,245} Most important, patients who had SLN dissection alone were found to have decreased morbidity (arm swelling and range of motion) and improved quality of life vs. patients who underwent ALND.^{245,246}

The American College of Surgeons Oncology Group (ACOSOG) initiated the Z0010 and Z0011 trials in order to evaluate the incidence and prognostic significance of occult metastases identified in the bone marrow and SLNs (Z0010) of early-stage clinically node-negative patients and to evaluate the utility of ALND in patients with clinical T1-2, N0 breast cancer with 1 or 2 positive SLNs for patients treated with breast-conserving surgery and whole breast irradiation (WBI) (Z0011).^{247,248}

The Z0010 study enrolled 5539 patients with clinical T1-2 breast cancer planned for breast conserving surgery and WBI.²⁴⁷ Of these patients, 24% proved to have positive SLNs based on standard pathologic assessment, and of the negative SLNs subjected to immunohistochemical staining for cytokeratin, 10.5% proved to have occult metastasis. Of the patients who had bone marrow aspiration, 3.0% had immunohistochemically detected tumor cells in the bone marrow. Although the presence of disease in the bone marrow identified a population at high risk for

recurrence, neither immunohistochemical detection of disease in the SLNs or the bone marrow was statistically significant on multivariable analysis with clinicopathologic and treatment factors included. The investigators concluded that routine use of immunohistochemistry to detect occult disease in SLNs is not warranted.

The Z0011 trial was a companion study to Z0010 and was designed to study the role of completion ALND on survival in women with positive SLNs. Patients were not eligible if they received neoadjuvant chemotherapy or neoadjuvant hormonal therapy or if their treatment plan included mastectomy, lumpectomy without radiation, or lumpectomy with APBI. WBI was to be administered using standard tangential fields without specific treatment of the axilla or additional fields targeting other nodal basins. Patients with 1 or 2 positive SLNs were randomized to completion ALND or no further surgery. Adjuvant systemic therapy recommendations were left to the treating clinicians. After median follow-up of 6.3 years, there was no difference between patients randomized to ALND and those randomized to no further surgery (SLN only) in terms of OS (91.9% and 92.5%, respectively; $P = 0.25$) or DFS (82.2% and 83.8%, respectively; $P = 0.14$). The low local regional failure rates and similar survival outcomes were recently reported with 10-year follow-up.^{249,250}

The morbidity of SLN dissection alone vs. SLN dissection with completion ALND has been reported by the ACOSOG investigators.^{251,252} Immediate effects of SLN dissection in the Z0010 trial included wound infection in 1%, axillary seroma in 7.1%, and axillary hematoma in 1.4%.²⁵¹ At 6 months following surgery, axillary paresthesias were noted in 8.6% of patients, decreased range of motion in the upper extremity was reported in 3.8%, and 6.9% of patients had a change in the arm circumference of >2 cm on the ipsilateral side, which was reported as lymphedema. Younger patients were more likely to report paresthesias, whereas increasing age and body mass index were more predictive of lymphedema. When adverse surgical effects were examined in the Z0011 trial, patients undergoing SLN dissection with ALND had more wound infections, seromas, and paresthesias than those women undergoing SLN dissection alone. Lymphedema at 1 year after surgery was reported by 13% in the SLN plus ALND group but only 2% in the SLN dissection alone group. Arm circumference measurements were greater at 1 year in patients undergoing SLN dissection plus ALND, but the difference between study groups was not statistically significant.²⁵² This supports the results published from the ALMANAC trial.

Prior to the publication of ACOSOG Z0011, completion ALND was standard of care for patients with positive SLNs. Since the reporting of ACOSOG Z0011, the National Comprehensive Cancer Network (NCCN) guidelines now state that there was no OS difference for patients with 1 or 2 positive SLNs treated with breast-conserving surgery who underwent completion ALND vs. those who had no further axillary surgery. In addition, the American Society of Breast Surgeons issued a consensus statement supporting omission of ALND for patients who meet Z0011 criteria.²⁵³ The results of ACOSOG Z0011 have revolutionized management of the axilla and changed practice such that selected patients with axillary metastasis can now avoid ALND if they have clinical and pathologic features similar to those patients enrolled on Z0011. However, there have been some concerns raised about the Z0011 study that include the fact that the study only recruited about half of

the intended patients and that there was no standardization of whether or not patients received irradiation to the low axilla when the radiation oncologist irradiated the breast. These issues have thus far limited the uptake of the results of Z0011 by some centers.

The International Breast Cancer Study Group (IBCSG) 23-01 trial was similar in design to Z0011 but enrolled only patients with micrometastases in the SLNs. Patients with SLN micrometastases were randomized to ALND vs. no further surgery. Unlike Z0011, the 23-01 trial did not exclude patients treated with mastectomy. Approximately 9% of patients randomized to each study arm underwent mastectomy. The investigators published the primary and secondary endpoints of the trial showing no differences in OS or local-regional recurrence between the study arms.²⁵⁴ However, as with the Z0011 trial, some concerns have been raised regarding the 23-01 study. For example, in the statistics on the primary endpoint, local recurrence included contralateral breast cancer and other tumor types as events. No hypothesis was presented as to why the difference in axillary surgery should impact on either of these events. Including these events therefore reduced the power of the study to show a statistical difference between treatment arms. There is also concern that the study appears underpowered to show a meaningful difference in overall survival.

Most pathology laboratories perform a more detailed analysis of the SLN than is routinely done for axillary nodes recovered from a levels I and II dissection. This can include examining thin sections of the node with step sectioning at multiple levels through the paraffin blocks or performing immunohistochemical staining of the SLN for cytokeratin or a combination of these techniques. The results of ACOSOG Z0010 and NSABP B-32 showed no clinically meaningful difference in survival based on detection of occult metastases in the SLNs using immunohistochemical staining and do not support the routine use in SLN processing. The type of intraoperative assessment of SLNs also varies for different clinicians and pathology laboratories. Some centers prefer to use touch preparation cytologic analysis of the SLNs, whereas others use frozen-section analysis, and the sensitivity and specificity of these assays vary considerably. The GeneSearch Breast Lymph Node Assay is a real-time reverse-transcriptase polymerase chain reaction assay that detects breast tumor cell metastasis in lymph nodes through the identification of the gene expression markers mammaglobin and cytokeratin 19. These markers are present in higher levels in breast tissue and not in nodal tissue (cell type-specific messenger RNA). The GeneSearch breast lymph node assay generates expression data for genes of interest, which are then evaluated against predetermined criteria to provide a qualitative (positive/negative) result. The assay is designed to detect foci that correspond to metastases that are seen with examination by standard hematoxylin and eosin staining and measure >0.2 mm. The GeneSearch assay results have been compared with permanent-section histologic analysis and frozen-section analysis of sentinel nodes in a prospective trial, and the assay was approved by the FDA for the intraoperative assessment of sentinel nodes.²⁵⁵ When a positive node is identified intraoperatively by touch preparation, frozen-section analysis, or GeneSearch assay, the surgeon can proceed with immediate ALND. With the findings of ACOSOG Z0011 that there is not a survival benefit to the use of ALND in selected patients, many surgeons have abandoned the intraoperative evaluation of SLNs. There are a number of nomograms and predictive models designed to

determine which patients with a positive SLN are at risk for harboring additional positive non-SLNs in the axilla. These tools can be helpful in determining the likelihood of additional disease in the axilla and may be used clinically to counsel patients.²⁵⁶

In patients who present with axillary lymphadenopathy that is confirmed to be metastatic disease on FNA or core biopsy, SLN dissection is not necessary, and patients can proceed directly to ALND or be considered for preoperative systemic therapy (see “Neoadjuvant [Preoperative] Chemotherapy” under “Nonsurgical Breast Cancer Therapies”). Initially there was controversy about the suitability of SLN dissection in women with larger primary tumors (T3) and those treated with neoadjuvant chemotherapy. The American Society of Clinical Oncology has included SLN dissection in its guidelines as appropriate for axillary staging in these patients.^{257,258} If an SLN cannot be identified, then ALND is generally performed for appropriate staging. However, this is not universally accepted, and there are as yet no randomized studies that have assessed how a patient with a locally advanced cancer at presentation should be treated if SLN dissection reveals no metastases or micrometastases after neoadjuvant therapy.

The ASCO guidelines suggest that adjuvant chemotherapy should be considered for patients with positive lymph nodes, ER-negative disease, HER2-positive disease, Adjuvant! Online mortality greater than 10%, grade 3 node-negative tumors >5 mm, triple-negative tumors, lymphovascular invasion, or estimated distant relapse risk of greater than 15% at 10 years based on the 21 gene recurrence score assay.²⁵⁹ Adjuvant endocrine therapy is considered for women with hormone receptor-positive cancers, and an aromatase inhibitor is recommended if the patient is postmenopausal. HER2/neu status is determined for all patients with newly diagnosed invasive breast cancer and when positive, should be used to guide systemic therapy recommendations. The FDA approved trastuzumab in November 2006 for use as part of a treatment regimen containing doxorubicin, cyclophosphamide, and paclitaxel for treatment of HER2/neu-positive, node-positive breast cancer.^{181,183} Subsequently, the BCIRG 006 study reported that giving trastuzumab concurrently with docetaxel and carboplatin appeared as effective as giving trastuzumab following an anthracycline containing regimen.^{182,185} In addition to trastuzumab, pertuzumab has also recently been FDA approved for adjuvant use in patients with HER2 amplified breast cancers with high risk of recurrence.

Advanced Local-Regional Breast Cancer (Stage IIIA or IIIB)

Women with stage IIIA and IIIB breast cancer have advanced local-regional breast cancer but have no clinically detected distant metastases (Fig. 17-30).²⁶⁰ In an effort to provide optimal local-regional disease-free survival as well as distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy (Fig. 17-31). However, it should be noted that these patients have an increased risk of distant metastasis that is often highlighted by radiological evidence when staging PET or CT and bone scans are performed. Thus, the paradigm for small screen detected cancers where cure can be expected in >90% of patients, often by local treatment alone, is not appropriate for patients with locally advanced disease.

Preoperative (also known as neoadjuvant) chemotherapy should be considered in the initial management of patients with

Figure 17-30. Locally advanced breast cancer. **A.** Mammography of the right breast reveals a large tumor with enlarged axillary lymph nodes. **B.** Imaging of the left breast is normal. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

locally advanced stage III breast cancer, especially those with estrogen receptor negative tumors. Chemotherapy is used to maximize distant disease-free survival, whereas radiation therapy is used to maximize local-regional control and disease-free survival.

In selected patients with stage IIIA cancer, preoperative chemotherapy can reduce the size of the primary cancer and permit breast-conserving surgery. Investigators from the MD Anderson Cancer Center reported that low local-regional failure rates could be achieved in selected patients with stage III disease treated with preoperative chemotherapy followed by breast-conserving surgery and radiation.²⁶¹ The 5-year actuarial

ipsilateral breast tumor recurrence-free survival rates in this study were 95%. They noted that the ipsilateral breast tumor recurrence rates increased when patients had clinical N2 or N3 disease, >2 cm of residual disease in the breast at surgery, a pattern of multifocal residual disease in the breast at surgery, and lymphovascular space invasion in the primary tumor. This study demonstrated that breast-conserving surgery can be used for appropriately selected patients with locally advanced breast cancer who achieve a good response with preoperative chemotherapy. However, the Oxford overview of all randomized studies of neoadjuvant therapy (vs. adjuvant therapy) reported a hazard ratio of 1.5 (i.e., 50% increase) in local recurrence rates.

Figure 17-31. Treatment pathways for stage IIIA and stage IIIB breast cancer.

A meta-analysis reported a hazard ratio of 1.3.²⁶² These studies included some patients treated with radiation therapy alone without resection of the primary tumor bed, which results in higher local failure rates. These findings are important in view of the previous findings that the avoidance of recurrence in a conserved breast avoids about one breast cancer death over the next 15 years for every four such recurrences avoided.¹² The German Breast Cancer Group recently reported their local recurrence rate in 5535 patients in seven studies. With a median of 46 months (range 1–127) follow-up the local recurrence rates ranged from 7.6% to 19.5% for T1-T4 tumors and from 6.4% to 17.9% for N0-N3 tumors treated with neoadjuvant therapy.²³⁸ For patients with stage IIIA disease who experience minimal response to chemotherapy and for patients with stage IIIB breast cancer, preoperative chemotherapy can decrease the local-regional cancer burden enough to permit subsequent modified radical mastectomy to establish local-regional control. In both stages IIIA and IIIB disease, surgery is followed by adjuvant radiation therapy. However there is a small percentage of patients who experience progression of disease during neoadjuvant therapy, and therefore the surgeon should review patients with the oncologist at regular points during the neoadjuvant regimen.

For selected clinically indolent, ER-positive, locally advanced tumors, primary endocrine therapy may be considered, especially if the patient has other comorbid conditions. A series of 195 patients with ER-positive, locally advanced breast cancer treated by endocrine therapy—median age 69 years, median tumor size 6 cm, median follow-up 61 months—reported a 5-year overall survival of 76%, a breast cancer–specific survival of 86%, and a metastasis-free survival of 77%. The median time to an alternative treatment was 48 months.²⁶³ Given that this was a 20-year series, the number of such patients is small but should be considered when the clinician is discussing treatment options. Results from the ACOSOG Z1031 trial suggest that neoadjuvant endocrine therapy is a good option for tumor downstaging in patients with strongly ER-positive tumors. The preoperative endocrine prognostic index (PEPI score) can be calculated based on pathologic findings from surgery following neoadjuvant endocrine therapy. This can help guide decision-making regarding the need for systemic chemotherapy in this patient population.^{264,265}

Internal Mammary Lymph Nodes

Metastatic disease to internal mammary lymph nodes may be occult, may be evident on chest radiograph or CT scan, or may present as a painless parasternal mass with or without skin involvement. There is no consensus regarding the need for internal mammary lymph node radiation therapy in women who are at increased risk for occult involvement (cancers involving the medial aspect of the breast, axillary lymph node involvement) but who show no signs of internal mammary lymph node involvement. Systemic chemotherapy and radiation therapy are indicated in the treatment of grossly involved internal mammary lymph nodes.

Distant Metastases (Stage IV)

Treatment for stage IV breast cancer is not curative but may prolong survival and enhance a woman's quality of life.²⁶⁶ Endocrine therapies that are associated with minimal toxicity are preferred to cytotoxic chemotherapy in ER-positive disease. Appropriate candidates for initial endocrine therapy include women with hormone receptor-positive cancers who do not have

immediately life threatening disease (or “visceral crisis”). This includes not only women with bone or soft tissue metastases but also women with limited visceral metastases. Symptoms per se (e.g., breathlessness) are not in themselves an indication for chemotherapy. For example, breathlessness due to a pleural effusion can be treated with percutaneous drainage, and if the breathlessness is relieved, the patient should be commenced on endocrine therapy; if the breathlessness is due to lymphangitic spread, then chemotherapy would be the treatment of choice. The same approach should be taken to other symptoms such as pain. Systemic chemotherapy is indicated for women with hormone receptor-negative cancers, “visceral crisis,” and hormone-refractory metastases. Women with stage IV breast cancer may develop anatomically localized problems that will benefit from individualized surgical or radiation treatment, such as brain metastases, pleural effusion, pericardial effusion, biliary obstruction, ureteral obstruction, impending or existing pathologic fracture of a long bone, spinal cord compression, and painful bone or soft tissue metastases. Bisphosphonates or anti-RANKL (receptor activator of nuclear factor kappa-B ligand) agent, denosumab, which may be given in addition to chemotherapy or endocrine therapy, should be considered in women with bone metastases. Whether to perform surgical resection of the local-regional disease in women with stage IV breast cancer has been debated after several reports have suggested that women who undergo resection of the primary tumor have improved survival over those who do not. Khan and associates used the National Cancer Data Base to identify patterns of treatment in women with metastatic breast cancer and found that those who had surgical resection with negative margins had a better prognosis than those women who did not have surgical therapy.²⁶⁷ Gnerlich et al reported similar findings using the SEER database, and there have been several reports subsequent to this study from single institutions that have confirmed these findings.²⁶⁸ Some have suggested that the finding of improved survival is due to selection bias and that local therapy should be reserved for palliation of symptoms. A randomized trial through ECOG (E2108) was designed to address this question.²⁶⁹ The surgical management of patients with stage IV disease should be addressed by obtaining multidisciplinary input and by considering the treatment goals of each individual patient and the patient's treating physicians.

Local-Regional Recurrence

Women with local-regional recurrence of breast cancer may be separated into two groups: those who have had mastectomy and those who have had lumpectomy. Women treated previously with mastectomy undergo surgical resection of the local-regional recurrence and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered, and adjuvant radiation therapy is given if the chest wall has not previously received radiation therapy or if the radiation oncologist feels that given the time from previous treatment there is scope for further radiation therapy, particularly if this is palliative. Women treated previously with a breast-conservation procedure undergo a mastectomy and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered depending of the hormone receptor status and HER2 status of the tumor.

Breast Cancer Prognosis

Survival rates for women diagnosed with breast cancer in the United States can be obtained from the SEER Program of the

National Cancer Institute. Data have been collected since 1973 and are updated at regular intervals. The overall 5-year relative survival for breast cancer patients from the time period of 2003 to 2009 from 18 SEER geographic areas was 89.2%.²⁷⁰ The 5-year relative survival by race was reported to be 90.4% for white women and 78.7% for black women. The 5-year survival rate for patients with localized disease (61% of patients) is 98.6%; for patients with regional disease (32% of patients), 84.4%; and for patients with distant metastatic disease (5% of patients), 24.3%. Breast cancer survival has significantly increased over the past two decades due to improvements in screening and local and systemic therapies. Data from the American College of Surgeons National Cancer Data Base can also be accessed; this data reports survival based on stage of disease at presentation using the AJCC staging system.

SURGICAL TECHNIQUES IN BREAST CANCER THERAPY

Excisional Biopsy With Needle Localization

Excisional biopsy implies complete removal of a breast lesion with a margin of normal-appearing breast tissue. In the past, surgeons would obtain prior consent from the patient, allowing mastectomy if the initial biopsy results confirmed cancer. Today it is important to consider the options for local therapy (lumpectomy vs. mastectomy with or without reconstruction) and the need for nodal assessment with SLN dissection. Needle-core biopsy is the preferred diagnostic method, and excisional biopsy should be reserved for those cases in which the needle biopsy results are discordant with the imaging findings or clinical examination (Fig. 17-32). In general, circumareolar incisions can be used to access lesions that are subareolar or within a short distance of the nipple-areolar complex. Elsewhere in the breast, incisions can be placed along the lines of tension in the skin that are generally concentric with the nipple-areola complex. In the lower half of the breast, the use of radial incisions typically

provides the best outcome. When the tumor is quite distant from the central breast, the biopsy incision can be excised separately from the primary mastectomy incision, should a mastectomy be required. Radial incisions in the upper half of the breast are not recommended because of possible scar contracture resulting in displacement of the ipsilateral nipple-areola complex. Similarly, curvilinear incisions in the lower half of the breast may displace the nipple-areolar complex downward.

After excision of a suspicious breast lesion, the specimen should be X-rayed to confirm that the lesion has been excised with appropriate margins. The biopsy tissue specimen is orientated for the pathologist using sutures, clips, or dyes. Additional margins (superior, inferior, medial, lateral, superficial, and deep) may be taken from the surgical bed if the specimen X-ray shows the lesion is close to one or more margins. Some surgeons also take additional shavings from the margins as one approach to confirm complete excision of the suspicious lesion. Electrocautery or absorbable ligatures are used to achieve wound hemostasis. Cosmesis may be facilitated by approximation of the surgical defect using 3-0 absorbable sutures. A running subcuticular closure of the skin using 4-0 or 5-0 absorbable monofilament sutures is performed. Wound drainage is usually not required.

Excisional biopsy with needle or seed localization requires a preoperative visit to the mammography suite for placement of a localization wire or a radioactive or magnetic seed that can be detected intraoperatively with a handheld probe. The lesion can also be targeted by sonography in the imaging suite or in the operating room. The lesion to be excised is accurately localized by mammography, and the tip of a thin wire hook or a seed is positioned close to the lesion (Fig. 17-33). Using the wire hook as a guide, or detection of the seed with a handheld probe, the surgeon subsequently excises the suspicious breast lesion while removing a margin of normal-appearing breast tissue. Before the patient leaves the operating room, specimen radiography is performed to confirm complete excision of the suspicious lesion (Fig. 17-34).

Sentinel Lymph Node Dissection

Sentinel lymph node (SLN) dissection is primarily used to assess the regional lymph nodes in women with early breast cancers who are clinically node-negative by physical examination and imaging studies.²⁷¹⁻²⁷⁹ This method also is accurate in

9► women with larger tumors (T3 N0), but nearly 75% of these women will prove to have axillary lymph node metastases on histologic examination, and wherever possible it is better to identify them preoperatively as this will allow a definitive procedure for known axillary disease. SLN dissection has also been reported to be accurate for staging of the axilla after chemotherapy in women with clinically node-negative disease at initial presentation.^{280,281} Tan et al in a review and meta-analysis of 449 cases of SLN biopsy in clinically lymph node-negative disease reported a sensitivity of 93%, giving a false negative rate of 7% with a negative predictive value of 94% and an overall accuracy of 95%.²⁸² Clinical situations where SLN dissection is not recommended include patients with inflammatory breast cancers, those with biopsy proven metastasis, DCIS without mastectomy, or prior axillary surgery. Although limited data are available, SLN dissection appears to be safe in pregnancy when performed with radioisotope alone.

Evidence from large prospective studies suggests that the combination of intraoperative gamma probe detection of radioactive colloid and intraoperative visualization of blue dye (isosulfan blue dye or methylene blue) is more accurate for identification of SLNs than the use of either agent alone. Some surgeons use preoperative lymphoscintigraphy, although it is not required for identification of the SLNs. On the day before surgery, or the day of surgery, the radioactive colloid is injected either in the breast parenchyma around the primary tumor or prior biopsy site, into the subareolar region, or subdermally in proximity to the primary tumor site. With a 25-gauge needle, 0.5 mCi of 0.2- μ m technetium 99m-labeled sulfur colloid is injected for same-day surgery, or a higher dose of 2.5 mCi of technetium-labeled sulfur colloid is administered when the isotope is to be injected on the day before surgery. Subdermal injections are given in proximity to the cancer site or in the subareolar location. Later, in the operating room, 3 to 5 mL of blue dye is injected either in the breast parenchyma or in the subareolar location. It is not recommended that the blue dye be used in a subdermal injection because this can result in tattooing of the skin (isosulfan blue dye) or skin necrosis (methylene blue). For nonpalpable cancers, the injection of the technetium-labeled sulfur colloid solution can be guided by ultrasound or by mammographic guidance. In women who have undergone previous excisional biopsy, the injections are made in the breast parenchyma around the biopsy cavity but not into the cavity itself. Women are told preoperatively that the isosulfan blue dye injection will cause a change in the color of their urine and that there is a very small risk of allergic reaction to the dye (1 in 10,000). Anaphylactic reactions have been documented, and some groups administer a regimen of antihistamine, steroids, and a histamine H-2 receptor antagonist preoperatively as a prophylactic regimen to prevent allergic reactions. The use of radioactive colloid is safe, and radiation exposure is very low. Sentinel node dissection can be performed in pregnancy with the radioactive colloid without the use of blue dye.

A hand-held gamma counter is used to transcutaneously identify the location of the SLN. This can help to guide placement of the incision. A 3- to 4-cm incision is made in line with that used for an axillary dissection, which is a curved transverse

incision in the lower axilla just below the hairline. After dissecting through the subcutaneous tissue, the surgeon dissects through the axillary fascia, being mindful to identify blue lymphatic channels. Following these channels can lead directly to the SLN and limit the amount of dissection through the axillary tissues. The gamma probe is used to facilitate the dissection and to pinpoint the location of the SLN. As the dissection continues, the signal from the probe increases in intensity as the SLN is approached. The SLN also is identified by visualization of blue dye in the afferent lymph vessel and in the lymph node itself. Before the SLN is removed, a 10-second *in vivo* radioactivity count is obtained. After removal of the SLN, a 10-second *ex vivo* radioactive count is obtained, and the node is then sent to the pathology laboratory for either permanent- or frozen-section analysis. The lowest false-negative rates for SLN dissection have been obtained when all blue lymph nodes and all lymph nodes with counts >10% of the 10-second *ex vivo* count of the SLN are harvested ("10% rule"). Based on this, the gamma counter is used before closing the axillary wound to measure residual radioactivity in the surgical bed. A search is made for additional SLNs if the counts remain high. This procedure is repeated until residual radioactivity in the surgical bed is less than 10% of the 10-second *ex vivo* count of the most radioactive SLN and all blue nodes have been removed. Studies have demonstrated that 98% of all positive SLNs will be recovered with the removal of four SLNs; therefore, it is not necessary to remove greater than four SLNs for accurate staging of the axilla.

Results from the NSABP B-32 trial showed that the false-negative rate for SLN dissection is influenced by tumor location, type of diagnostic biopsy, and number of SLNs removed at surgery.²⁴³ The authors reported that tumors located in the lateral breast were more likely to have a false-negative SLN. This may be explained by difficulty in discriminating the hot spot in the axilla when the radioisotope has been injected at the primary tumor site in the lateral breast. Those patients who had undergone an excisional biopsy before the SLN procedure were significantly more likely to have a false-negative SLN. This report further confirms that surgeons should use needle biopsy for diagnosis whenever possible and reserve excisional biopsy for the rare situations in which needle biopsy findings are non-diagnostic or discordant. Finally, removal of a larger number of SLNs at surgery appears to reduce the false-negative rate. In B-32, the false-negative rate was reduced from 17.7% to 10% when two SLNs were recovered and to 6.9% when three SLNs were removed. Yi and associates reported that the number of SLNs that need to be removed for accurate staging is influenced by individual patient and primary tumor factors.²⁸³

In the B-32 trial, SLNs were identified outside the levels I and II axillary nodes in 1.4% of cases. This was significantly influenced by the site of radioisotope injection. When a subareolar or periareolar injection site was used, there were no instances of SLNs identified outside the level I or II axilla, compared with a rate of 20% when a peritumoral injection was used. This supports the overall concept that the SLN is the first site of drainage from the lymphatic vessels of the primary tumor. Although many patients will have similar drainage patterns from injections given at the primary tumor site and at the subareolar plexus, some patients will have extra-axillary drainage, either alone or in combination with axillary node drainage, and this is best assessed with a peritumoral injection of the radioisotope. Kong et al reported that internal mammary node drainage on preoperative lymphoscintigraphy was associated with

worse distant disease-free survival in early-stage breast cancer patients.²⁸⁴

Breast Conservation

Breast conservation involves resection of the primary breast cancer with a margin of normal-appearing breast tissue, adjuvant radiation therapy, and assessment of regional lymph node status.^{285,286} Resection of the primary breast cancer is alternatively called *segmental mastectomy*, *lumpectomy*, *partial mastectomy*, *wide local excision*, and *tylectomy*. For many women with stage I or II breast cancer, breast-conserving therapy (BCT) is preferable to total mastectomy because BCT produces survival rates equivalent to those after total mastectomy while preserving the breast.²⁸⁷ Six prospective randomized trials have shown that overall and disease-free survival rates are similar with BCT and mastectomy; however, three of the studies showed higher local-regional failure rates in patients undergoing BCT. In two of these studies, there were no clear criteria for histologically negative margins.²⁸⁵⁻²⁸⁷ Data from the EBCTCG meta-analysis revealed that the addition of radiation reduces recurrence by half and improves survival at year 15 by about a sixth.²⁸⁸ When all of this information is taken together, BCT is considered to be oncologically equivalent to mastectomy.

In addition to being equivalent to mastectomy in terms of oncologic safety, BCT appears to offer advantages over mastectomy with regard to quality of life and aesthetic outcomes. BCT allows for preservation of breast shape and skin as well as preservation of sensation, and it provides an overall psychological advantage associated with breast preservation.

Breast conservation surgery is currently the standard treatment for women with stage 0, I, or II invasive breast cancer. Women with DCIS require only resection of the primary cancer and adjuvant radiation therapy without assessment of regional lymph nodes. When a lumpectomy is performed, a curvilinear incision lying concentric to the nipple-areola complex is made in the skin overlying the breast cancer when the tumor is in the upper aspect of the breast. Radial incisions are preferred when the tumor is in the lower aspect of the breast. Skin excision is not necessary unless there is direct involvement of the overlying skin by the primary tumor. The breast cancer is removed with an envelope of normal-appearing breast tissue that is adequate to achieve a cancer-free margin. Significant controversy has existed on the appropriate margin width for BCT.²⁶⁰ However, recently the SSO and ASTRO developed a consensus statement, supported by data from a systematic review data, encouraging “no tumor on ink” to be the standard definition of a negative margin for invasive stages I and II breast cancer in patients who undergo breast conserving surgery with whole-breast irradiation. The meta-analysis found that increasing the margin width does not affect local recurrence rates as long as the inked or transected margin is microscopically negative.²⁸⁹⁻²⁹² Specimen X-ray should routinely be performed to confirm the lesion has been excised. Specimen orientation is performed by the surgeon. Additional margins from the surgical bed are taken as needed to provide a histologically negative margin. Requests for determination of ER, PR, and HER2 status are conveyed to the pathologist.

It is the surgeon’s responsibility to ensure complete removal of cancer in the breast. Ensuring surgical margins that are free of breast cancer will minimize the chances of local recurrence and will enhance cure rates. If negative margins are not obtainable with reexcision, mastectomy is required. SLN is performed before removal of the primary breast tumor. When

indicated, intraoperative assessment of the sentinel node can proceed while the segmental mastectomy is being performed.

The use of oncoplastic surgery can be entertained at the time of segmental mastectomy or at a later time to improve the overall aesthetic outcome. The use of oncoplastic techniques range from a simple reshaping of breast tissue to local tissue rearrangement to the use of pedicled flaps or breast reduction techniques. The overall goal is to achieve the best possible aesthetic result. In determining which patients are candidates for oncoplastic breast surgery, several factors should be considered, including the extent of the resection of breast tissue necessary to achieve negative margins, the location of the primary tumor within the breast, and the size of the patient’s breast and body habitus. Oncoplastic techniques are of prime consideration when (a) a significant area of breast skin will need to be resected with the specimen to achieve negative margins; (b) a large volume of breast parenchyma will be resected resulting in a significant defect; (c) the tumor is located between the nipple and the inframammary fold, an area often associated with unfavorable cosmetic outcomes; or (d) excision of the tumor and closure of the breast may result in malpositioning of the nipple.

Mastectomy and Axillary Dissection

A skin-sparing mastectomy removes all breast tissue, the nipple-areola complex, and scars from any prior biopsy procedures.^{293,294} There is a recurrence rate of less than 6% to 8%, comparable to the long-term recurrence rates reported with standard mastectomy, when skin-sparing mastectomy is used for patients with Tis to T3 cancers. A total (simple) mastectomy without skin sparing removes all breast tissue, the nipple-areola complex, and skin. An extended simple mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I axillary lymph nodes. A modified radical (“Patey”) mastectomy removes all breast tissue, the nipple-areola complex, skin, and the levels I, II, and III axillary lymph nodes; the pectoralis minor that was divided and removed by Patey may be simply divided, giving improved access to level III nodes, and then left in situ, or occasionally the axillary clearance can be performed without dividing pectoralis minor. The Halsted radical mastectomy removes all breast tissue and skin, the nipple-areola complex, the pectoralis major and pectoralis minor muscles, and the levels I, II, and III axillary lymph nodes. The use of systemic chemotherapy and hormonal therapy as well as adjuvant radiation therapy for breast cancer have nearly eliminated the need for the radical mastectomy.

Nipple-areolar sparing mastectomy has been popularized over the last decade especially for risk-reducing mastectomy in high risk women. For those patients with a cancer diagnosis, many consider the following factors for eligibility: tumor located more than 2 to 3 cm from the border of the areola, smaller breast size, minimal ptosis, no prior breast surgeries with periareolar incisions, body mass index less than 40 kg/m², no active tobacco use, no prior breast irradiation, and no evidence of collagen vascular disease.

For a variety of biologic, economic, and psychosocial reasons, some women desire mastectomy rather than breast conservation. Women who are less concerned about cosmesis may view mastectomy as the most expeditious and desirable therapeutic option because it avoids the cost and inconvenience of radiation therapy. Some women whose primary breast cancers cannot be excised with a reasonable cosmetic result or those who have extensive microcalcifications are best treated with

Figure 17-35. Modified radical mastectomy: elevation of skin flaps. Skin flaps are 7 to 8 mm in thickness, inclusive of the skin and tela subcutanea. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)

mastectomy. Similarly, women with large cancers that occupy the subareolar and central portions of the breast and women with multicentric primary cancers also undergo mastectomy.

Modified Radical Mastectomy

A modified radical mastectomy preserves the pectoralis major muscle with removal of levels I, II, and III (apical) axillary lymph nodes.²⁹³ The operation was first described by David Patey, a surgeon at St Bartholomew's Hospital London, who reported a series of cases where he had removed the pectoralis minor muscle allowing complete dissection of the level III axillary lymph nodes while preserving the pectoralis major and the lateral pectoral nerve. A modified radical mastectomy permits preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and usually penetrates the pectoralis minor to supply the lateral border of the pectoralis major. Anatomic boundaries of the modified radical mastectomy are the anterior margin of the latissimus dorsi muscle laterally, the midline of the sternum medially, the subclavius muscle superiorly, and the caudal extension of the breast 2 to 3 cm inferior to the inframammary fold inferiorly. Skin-flap thickness varies with body habitus but ideally is 7 to 8 mm inclusive of skin and tela subcutanea (Fig. 17-35). Once the skin flaps are fully developed, the fascia of the pectoralis major muscle and the overlying breast tissue are elevated off the underlying musculature, which allows for the complete removal of the breast (Fig. 17-36).

Subsequently, an axillary lymph node dissection is performed. The most lateral extent of the axillary vein is identified, and the areolar tissue of the lateral axillary space is elevated as the vein is cleared on its anterior and inferior surfaces. The areolar tissues at the junction of the axillary vein and the anterior edge of the latissimus dorsi muscle, which include the lateral and subscapular lymph node groups (level I), are cleared. Care is taken to preserve the thoracodorsal neurovascular bundle. The dissection then continues medially with clearance of the central axillary lymph node group (level II). The long thoracic nerve of Bell is identified and preserved as it travels in the investing fascia of the serratus anterior muscle. Every effort is made to preserve this nerve because permanent disability with a winged scapula and shoulder weakness will follow denervation of the serratus anterior muscle. Patey divided the pectoralis minor and removed it to allow access right up to the apex of the axilla. The pectoralis minor muscle is usually divided at the tendinous portion near its insertion onto the coracoid process (Fig. 17-37 inset), which allows dissection of the axillary vein medially to the costoclavicular (Halsted's) ligament. Finally, the breast and axillary contents are removed from the surgical bed and are sent for pathologic assessment. In his modified radical mastectomy, Patey removed the pectoralis minor muscle. Many surgeons now divide only the tendon of the pectoralis minor muscle at its insertion onto the coracoid process while leaving the rest of the muscle intact, which still provides good access to the apex of the axilla.

Figure 17-36. Modified radical mastectomy after resection of breast tissue. The pectoralis major muscle is cleared of its fascia as the overlying breast is elevated. The latissimus dorsi muscle is the lateral boundary of the dissection. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)

Figure 17-37. Modified radical mastectomy (Patey): axillary lymph node dissection. The dissection proceeds from lateral to medial, with complete visualization of the anterior and inferior aspects of the axillary vein. Loose areolar tissue at the junction of the axillary vein and the anterior margin of the latissimus dorsi muscle is swept inferomedially inclusive of the lateral (axillary) lymph node group (level I). Care is taken to preserve the thoracodorsal artery, vein, and nerve in the deep axillary space. The lateral lymph node group is resected in continuity with the subscapular lymph node group (level I) and the external mammary lymph node group (level I). Dissection anterior to the axillary vein allows removal of the central lymph node group (level II) and the apical (subclavicular) lymph node group (level III). The superomedial limit of this dissection is the clavpectoral fascia (Halsted's ligament). *Inset* depicts division of the insertion of the pectoralis minor muscle at the coracoid process. The surgeon's finger shields the underlying brachial plexus. (Reproduced with permission from Bland KI, Copeland EMI: *The Breast: Comprehensive Management of Benign and Malignant Diseases*, 4th ed. Philadelphia, PA: Elsevier/Saunders; 2009.)

Seromas beneath the skin flaps or in the axilla represent the most frequent complication of mastectomy and axillary lymph node dissection, reportedly occurring in as many as 30% of cases. The use of closed-system suction drainage reduces the incidence of this complication. Catheters are retained in the wound until drainage diminishes to <30 mL per day. Wound infections occur infrequently after a mastectomy, and the majority are a result of skin-flap necrosis. Cultures of specimens taken from the infected wound for aerobic and anaerobic organisms, debridement, and antibiotic therapy are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed with early wound exploration for control of hemorrhage and reestablishment of closed-system suction drainage. The incidence of functionally significant lymphedema after a modified radical mastectomy is approximately 20% but can be as high as 50% to 60% when postoperative radiation is employed. Extensive axillary lymph node dissection, the delivery of radiation therapy, the presence of pathologic lymph nodes, and obesity are predisposing factors. Patients should be referred to physical therapy at the earliest signs of lymphedema to prevent progression to the later stages. The use of individually fitted compressive sleeves and complex decongestive therapy may be necessary.

Reconstruction of the Breast and Chest Wall

The goals of reconstructive surgery after a mastectomy for breast cancer are wound closure and breast reconstruction, which is either immediate or delayed.²⁹⁵ In most cases, wound closure after mastectomy is accomplished with simple approximation

of the wound edges. However, if a more radical removal of skin and subcutaneous tissue is necessary, a pedicled myocutaneous flap from the latissimus dorsi muscle is generally the best approach for wound coverage. A skin graft provides functional coverage that will tolerate adjuvant radiation therapy; however, this is not preferred because poor graft adherence may delay delivery of radiation therapy. Breast reconstruction after risk-reducing mastectomy or after mastectomy for early-stage breast cancer may be performed at the same time as the mastectomy. This allows for a skin-sparing mastectomy to be performed, which offers the best overall cosmetic outcomes. Reconstruction can proceed with an expander/implant reconstruction or with autologous tissue such as a pedicled myocutaneous flap or a free flap using microvascular techniques. In patients with locally advanced breast cancer, reconstruction is often delayed until after completion of adjuvant radiation therapy to ensure that local-regional control of disease is obtained. The expected use of postmastectomy radiotherapy should also be considered as a reason for delayed reconstruction as radiotherapy to a reconstructed breast has been reported to result in inferior cosmetic outcomes. Consideration can be made for placement of a tissue expander to allow for skin-sparing, but this should be discussed with the radiation oncologist and other members of the treatment team. If chest wall coverage is needed to replace a large skin or soft tissue defect, many different types of myocutaneous flaps are employed, but the latissimus dorsi and the rectus abdominis myocutaneous flaps are most frequently used. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which

is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. A transverse rectus abdominis myocutaneous (TRAM) flap consists of a skin paddle based on the underlying rectus abdominis muscle, which is supplied by vessels from the deep inferior epigastric artery. The free TRAM flap uses microvascular anastomoses to establish blood supply to the flap. When the bony chest wall is involved with cancer, resection of a portion of the bony chest wall is indicated. If only one or two ribs are resected and soft tissue coverage is provided, reconstruction of the bony defect is usually not necessary because scar tissue will stabilize the chest wall. If more than two ribs are sacrificed, it is advisable to stabilize the chest wall with prosthetic material, which is then covered with soft tissue by using a latissimus dorsi or TRAM flap.

NONSURGICAL BREAST CANCER THERAPIES

Radiation Therapy

Radiation therapy is used for all stages of breast cancer depending on whether the patient is undergoing BCT or mastectomy.²⁹⁶⁻³⁰² Adjuvant radiation for patients with DCIS and early-stage breast cancer have been described previously in this chapter. Those women treated with mastectomy who have cancer at the surgical margins are at sufficiently high risk for local recurrence to warrant the use of adjuvant radiation therapy to the chest wall postoperatively. Women with metastatic disease involving four or more axillary lymph nodes and premenopausal women with metastatic disease involving one to three lymph nodes also are at increased risk for recurrence and are candidates for the use of chest wall and supraclavicular lymph node radiation therapy. In advanced local-regional breast cancer (stage IIIA or IIIB), women are at high risk for recurrent disease after surgical therapy, and adjuvant radiation therapy is used to reduce the risk of recurrence. Current recommendations for stages IIIA and IIIB breast cancer are (a) adjuvant radiation therapy to the breast and supraclavicular lymph nodes after neoadjuvant chemotherapy and segmental mastectomy with or without axillary lymph node dissection, (b) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after neoadjuvant chemotherapy and mastectomy with or without axillary lymph node dissection, and (c) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after segmental mastectomy or mastectomy with axillary lymph node dissection and adjuvant chemotherapy. Data from the EBCTCG has shown improvements in local-regional control and survival in patients treated with mastectomy and post-mastectomy radiation therapy for one to three positive axillary lymph nodes.³⁰³ This data is based on clinical trials from the era of axillary lymph node dissection for staging prior to the routine use of sentinel lymph node dissection. It is likely that the volume of disease in the earlier trials was greater overall than what is currently seen in patients who have small volume metastases detected at sentinel node dissection. It is important to include all multidisciplinary team members (medical oncology, plastic surgery, radiation oncology, and surgical oncology) regarding the risks and benefits of postmastectomy radiation therapy in patients with one to three positive nodes.

The use of partial breast irradiation (APBI) for patients treated with breast-conserving surgery has also been previously described. APBI can be delivered via brachytherapy, external beam radiation therapy using 3D conformal radiation, or intensity-modulated radiation therapy. Although initial results are

promising in highly selected low-risk populations, use of APBI should be based on current guidelines or offered in the setting of a prospective trial.³⁰⁴

Chemotherapy Adjuvant

Chemotherapy. The Early Breast Cancer Trialists' Collaborative Group overview analysis of adjuvant chemotherapy demonstrated reductions in the odds of recurrence and death in women ≤ 70 years of age with stage I, IIA, or IIB breast cancer.^{123,305-309} For those ≥ 70 years of age, the lack of definitive clinical trial data regarding adjuvant chemotherapy prevented definitive recommendations. Adjuvant chemotherapy is of minimal benefit to women with negative nodes and cancers ≤ 0.5 cm in size and is not recommended. Women with negative nodes and cancers 0.6 to 1.0 cm are divided into those with a low risk of recurrence and those with unfavorable prognostic features that portend a higher risk of recurrence and a need for adjuvant chemotherapy. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, HER2/neu overexpression, and negative hormone receptor status. American Society of Clinical Oncology guidelines suggest that adjuvant chemotherapy should be considered for patients with positive lymph nodes, HER2-positive disease, Adjuvant! Online mortality greater than 10%, grade 3 lymph node negative tumors > 5 mm, triple-negative tumors, lympho-vascular invasion, or estimated distant relapse risk of greater than 15% at 10 years based on 21 gene recurrence score.²⁵⁹ Adjuvant chemotherapy is recommended by the NCCN guidelines for women with these unfavorable prognostic features. Table 17-14 lists the frequently used chemotherapy regimens for breast cancer.

For women with hormone receptor-negative cancers that are > 1 cm in size, adjuvant chemotherapy is appropriate.

Table 17-14

Adjuvant chemotherapy regimens for breast cancer

Data from NCCN Practice Guidelines in Oncology. Fort Washington, PA: National Comprehensive Cancer Network, 2006.

However, women with node-negative hormone receptor-positive cancers and T1 tumors are candidates for antiestrogen therapy with or without chemotherapy. Assessment of overall risk using known prognostic factors or additional testing such as the 21-gene recurrence score assay can help to guide decision making regarding chemotherapy in patients with node-negative, ER-positive breast cancer. For special-type cancers (tubular, mucinous, medullary, etc), which are usually strongly estrogen receptor positive, adjuvant antiestrogen therapy should be advised for cancers >1 cm. For women with node-positive tumors or with a special-type cancer that is >3 cm, the use of chemotherapy is appropriate; those with hormone receptor-positive tumors should receive antiestrogen therapy.

For stage IIIA breast cancer, preoperative chemotherapy with an anthracycline and taxane-containing regimen followed by either a modified radical mastectomy or segmental mastectomy with axillary dissection followed by adjuvant radiation therapy should be considered, especially for estrogen receptor negative disease. While the same regimen may be considered for estrogen receptor positive disease, it is known that these tumors respond less well to chemotherapy with <10% pCR rate overall and <3% pCR rate for lobular cancers. Other options such as neoadjuvant endocrine therapy followed by local-regional treatment or in some cases primary endocrine therapy may be considered depending on other tumor characteristics and the patient's comorbid conditions and preference.

Neoadjuvant (Preoperative) Chemotherapy. In the early 1970s, the National Cancer Institute in Milan, Italy, initiated two prospective randomized multimodality clinical trials for women with T3 or T4 breast cancer.³¹⁰ The best results were achieved when surgery was interposed between chemotherapy courses, with 82% local-regional control and 25% having a 5-year disease-free survival. The NSABP B-18 trial evaluated the role of neoadjuvant chemotherapy in women with operable stages II and III breast cancer.²⁰⁶ Women entered into this study were randomly assigned to receive either surgery followed by chemotherapy or neoadjuvant chemotherapy followed by surgery. There was no difference in the 5-year disease-free survival rates for the two groups, but after neoadjuvant chemotherapy there was an increase in the number of lumpectomies performed and a decreased incidence of node positivity. It was suggested that neoadjuvant chemotherapy be considered for the initial management of breast cancers judged too large for initial lumpectomy.

Several prospective clinical trials have evaluated the neoadjuvant approach, and two meta-analyses have been performed, each showing that neoadjuvant vs. adjuvant chemotherapy are equivalent in terms of OS.^{262,311} These analyses also evaluated local-regional recurrence (LRR) and found that there was an increase in LRR rates for patients receiving neoadjuvant chemotherapy when radiation therapy was used alone without surgery after completion of chemotherapy. Mittendorf and colleagues evaluated a contemporary series of almost 3000 patients treated with breast conserving surgery and radiation therapy who received either neoadjuvant or adjuvant chemotherapy for breast cancer.³¹² They found that the risk of LRR was driven by biologic factors and disease stage and was not impacted by

10▶ the timing of chemotherapy delivery. These data highlight the importance of the multidisciplinary management of patients with breast cancer in achieving the best outcomes.

The use of neoadjuvant chemotherapy offers the opportunity to observe the response of the intact primary tumor

and any regional nodal metastases to a specific chemotherapy regimen.²⁷⁹ For patients whose tumors remain stable in size or even progress with the initial neoadjuvant chemotherapy regimen, a new regimen may be considered that uses another class of agents, although there is no randomized data confirming this will improve outcome.

After treatment with neoadjuvant chemotherapy, patients are assessed for clinical and pathologic response to the regimen. Patients whose tumors achieve a pathologic complete response to neoadjuvant chemotherapy have been shown to have statistically improved survival outcomes to those of patients whose tumors demonstrate only a partial response, remain stable, or progress on treatment. Researchers at MD Anderson Cancer Center have shown that residual cancer burden (RCB)—categorized into four classes, RCB-0 or pathologic complete response, RCB-1, RCB-2, and RCB-3—is predictive of 10-year relapse-free survival with neoadjuvant chemotherapy in triple negative, ER-positive, and HER2-positive tumors.³¹³ Patients who experience progression of disease during neoadjuvant chemotherapy have the poorest survival.^{314,315} This means that while patients who achieve a pCR will have a better prognosis based on their response to neoadjuvant chemotherapy. Equally other patients will have a poorer prognosis compared to when they started neoadjuvant therapy based on the nonresponse to treatment. Consequently, the FDA has supported the use of the neoadjuvant platform and pathologic response rates as an endpoint for mechanism of accelerated approval for new agents in high risk early stage breast cancer, though the short-term endpoints (i.e., pCR) have not been shown to correlate with long-term outcomes (i.e., disease free survival and overall survival).

Current NCCN recommendations for treatment of operable advanced local-regional breast cancer are neoadjuvant chemotherapy with an anthracycline-containing or taxane-containing regimen or both, followed by mastectomy or lumpectomy with axillary lymph node dissection if necessary, followed by adjuvant radiation therapy. For patients with HER2-positive breast cancer, trastuzumab and pertuzumab can be combined with chemotherapy in the preoperative setting to increase pathologic complete response rates. For inoperable stage IIIA and for stage IIIB breast cancer, neoadjuvant chemotherapy is used to decrease the local-regional cancer burden. This may then permit subsequent modified radical or radical mastectomy, which is followed by adjuvant radiation therapy.

Nodal Evaluation in Patients Receiving Neoadjuvant Chemotherapy.

The management of the axilla after neoadjuvant chemotherapy has not been specifically addressed in randomized trials. Standard practice has been to perform an axillary lymph node dissection after chemotherapy or to perform a sentinel lymph node dissection before chemotherapy for nodal staging before chemotherapy is initiated. A number of small single-institution studies, one multicenter study, and a recent meta-analysis have explored the use of SLN dissection at the completion of chemotherapy. The published results from these studies have demonstrated the feasibility of SLN dissection in breast cancer patients after neoadjuvant chemotherapy. A review of 14 studies with 818 patients showed a false negative rate of 11% with an overall accuracy of 94%.^{280,281,316} While SLN dissection has been accepted for assessment of the axilla in the clinically node-negative axilla after neoadjuvant chemotherapy, clinicians have been slower to adopt this approach for axillary staging after chemotherapy in patients who started with initial node-positive disease. Several clinical

trials have been performed to evaluate the accuracy of SLN dissection in patients with documented axillary metastases at initial presentation, including ACOSOG Z1071, SENTINA, and SN FNAC. ACOSOG Z1071 (Alliance) analyzed women with clinical T0-T4, N1-N2, M0 breast cancer who underwent both SLN surgery and axillary lymph node dissection (ALND).³¹⁷ The primary endpoint was the false-negative rate (FNR) of SLN surgery after chemotherapy with clinically node-positive disease with a prespecified endpoint of 10% considered to be an acceptable rate. However, the FNR was found to be 12.6%, though it was lower when dual-agent mapping technique was used and at least three or more SLNs removed.³¹⁷ The SENTINA and SN FNAC trials had findings similar to Z1071. The results from Z1071 were further analyzed to determine if a clip was placed in the positive node at initial diagnosis and if the clipped node location at surgery (SLN or ALND) was evaluated. Indeed, this showed that identification of the clipped node during the surgical procedure further decreased the FNR.³¹⁸ The results from the ACOSOG Z1071 (Alliance) trial, in cases presenting with cN1 disease and at least two SLN resections and clipped node was within the SLN specimen, showed that the FNR was 6.8%.³¹⁸ Caudle et al at MD Anderson Cancer Center performed a prospective study of patients with biopsy-confirmed nodal metastases with a clip placed in the biopsy-proven lymph node, who were treated with neoadjuvant chemotherapy; at the time of surgery these patients underwent SLN dissection with targeting and removal of the clipped node (targeted axillary dissection [TAD]).³¹⁹ TAD includes SLN surgery and selective localization and removal of the clipped node, with the goal to determine if pathologic changes in the clipped node accurately reflect the status of the nodal basin, and proposing that TAD improves the FNR compared to SLN surgery alone.³¹⁹ In patients undergoing SLN surgery and ALND ($n = 118$), the FNR was 10.1% (95% CI, 4.2–19.8), and adding evaluation of the clipped node reduced the FNR to 1.4% (95% CI, 0.03–7.3; $P = .03$). TAD followed by ALND was performed in 85 patients, with an FNR of 2.0% (1 of 50; 95% CI, 0.05–10.7).³¹⁹ Although the use of dual tracer technique, retrieval of three or more SLNs, and TAD improve axillary staging after neoadjuvant chemotherapy, there is no long-term data about the oncologic safety of omitting ALND in patients who convert from cN1 to cN0 disease at this time.

Neoadjuvant Endocrine Therapy. While initially used in elderly women who were deemed poor candidates for surgery or cytotoxic chemotherapy, neoadjuvant endocrine therapy is being increasingly evaluated in clinical trials. As clinicians have gained experience with neoadjuvant treatment strategies, it is now clear from examination of predictors of complete pathologic response that ER-positive tumors do not shrink in response to chemotherapy as readily as ER-negative tumors.³²⁰ Indeed, the pCR rate in ER-negative tumors is approximately three times that of ER-positive tumors. Fisher et al examined the results of the NSABP B-14 and B-20 trials and found that, as age increased, women obtained less benefit from chemotherapy. They recommended that factors²¹⁴ including tumor estrogen receptor concentration, nuclear grade, histologic grade, tumor type, and markers of proliferation should be considered in these patients before choosing between the use of chemotherapy and hormonal therapy. If in fact the tumor is estrogen-receptor rich, these patients may benefit more from endocrine therapy in the neoadjuvant setting than they might if they received standard chemotherapy. Neoadjuvant endocrine therapy has been shown to shrink tumors, enabling breast-conserving surgery in

women with hormone receptor-positive disease who otherwise would have to be treated with mastectomy, although long-term recurrence rates have not been reported.²⁶⁵ The IMPACT trial evaluated neoadjuvant use of tamoxifen or anastrozole or both in combination in postmenopausal women with ER-positive operable or locally advanced breast cancer.³²¹ While there were no significant differences in objective tumor response among tamoxifen, anastrozole, or a combination of the two, in patients who were initially deemed as mastectomy candidates, only 31% had breast-conserving surgery with tamoxifen, whereas 44% underwent breast-conserving surgery with anastrozole. Invasive lobular cancers in particular have been shown to respond poorly to neoadjuvant chemotherapy and may have better response to neoadjuvant endocrine therapy.³²²⁻³²⁴ A meta-analysis evaluating the response rate and rate of breast conservation surgery with the use of neoadjuvant endocrine therapy compared to combination chemotherapy was recently reported. This meta-analysis included nearly 3500 patients across 20 studies.³²⁵ Interestingly, aromatase inhibitors had a similar response, and breast conservation rates in comparison with combination chemotherapy albeit with lower toxicity suggest that neoadjuvant endocrine therapy is an appropriate alternative in ER-positive breast cancers. However, the incidence of complete pathological response was low (<10%) with both approaches. Also, aromatase inhibitors were associated with significantly higher response and breast conservation rates compared with tamoxifen. The ALTERNATE (Alternate Approaches for Clinical Stage II or III Estrogen Receptor Positive Breast Cancer Neoadjuvant Treatment in Postmenopausal Women) trial is currently evaluating neoadjuvant endocrine therapy with fulvestrant or anastrozole or in combination.

Increasing knowledge of secondary resistance mechanisms to endocrine therapy and cross talk between ER and the PI3K/Akt/mTOR pathway have led to the evaluation of PI3K pathway inhibitors in combination with endocrine therapy. Postmenopausal women with ER-positive early breast cancers were treated with letrozole or letrozole in combination with everolimus, a mTOR inhibitor, in a randomized, phase 2 clinical trial. Clinical response and antiproliferative response, characterized by reduction in Ki67, was superior in the combination arm, suggesting that everolimus can increase efficacy of neoadjuvant letrozole.³²⁶ The LORLEI study is evaluating the use of taselelisib, a PI3K inhibitor in combination with letrozole compared with letrozole alone. With the approval of CDK 4/6 inhibitors in the metastatic setting, clinical trials are evaluating the use of CDK inhibitors in combination with neoadjuvant endocrine therapy. Neoadjuvant anastrozole in combination with palbociclib, a CDK4/6 inhibitor, has been shown to significantly reduce Ki67, suggesting that CDK4/6 inhibition can increase the efficacy of neoadjuvant endocrine therapy.

With the use of neoadjuvant chemotherapy or endocrine therapy, observation of the response of the intact tumor and/or nodal metastases to a specific regimen could ultimately help to define which patients will benefit from specific therapies in the adjuvant setting. In adjuvant trials the primary endpoint is typically survival, whereas in neoadjuvant trials the endpoints have more often been clinical or pathologic response rates. There are a number of clinical trials underway comparing neoadjuvant chemotherapy and endocrine therapy regimens with pretreatment and posttreatment biopsy samples obtained from the primary tumors in all of the participants. These samples are being subjected to intensive genomic and proteomic analyses that may

help to define a more personalized or individualized approach to breast cancer treatment in the future.

Antiestrogen Therapy

Tamoxifen. Within the cytosol of breast cancer cells are specific proteins (receptors) that bind and transfer steroid moieties into the cell nucleus to exert specific hormonal effects.^{308,327-331} The most widely studied hormone receptors are the estrogen receptor and progesterone receptor. Hormone receptors are detectable in >90% of well-differentiated ductal and lobular invasive cancers. Although the receptor status may remain the same between the primary cancer and metastatic disease in the same patient in the majority of cases, there are instances where the status is changed in the metastatic focus; therefore, biopsy of newly diagnosed metastatic disease should be considered for assessment of hormone receptor and HER2 status.

After binding to estrogen receptors in the cytosol, tamoxifen blocks the uptake of estrogen by breast tissue. Clinical responses to antiestrogen are evident in >60% of women with hormone receptor-positive breast cancers but in <10% of women with hormone receptor-negative breast cancers. A meta-analysis by the Early Breast Cancer Trialists' Collaborative Group showed that adjuvant therapy with tamoxifen for 5 years reduced breast cancer mortality by about a third through the first 15 years of follow-up.¹⁴ This mortality benefit continues to be statistically significant in the second and third 5-year periods (i.e., years 5–9 and 10–15) when the patients are no longer receiving endocrine treatment—the so-called carry-over effect. The analysis also showed a 39% reduction in the risk of cancer in the contralateral breast. The antiestrogens do have defined toxicity, including bone pain, hot flashes, nausea, vomiting, and fluid retention. Thrombotic events occur in <3% of treated women. Cataract surgery is more frequently performed in patients receiving tamoxifen. The Stockholm trial showed that 5 years of tamoxifen was associated with a significant reduction in locoregional recurrences and distant metastasis in postmenopausal women with ER-positive breast cancer.³³² However, an increase in endometrial cancers was observed with long-term tamoxifen use. The NSABP B14 trial evaluated 10 years of tamoxifen compared to 5 years.³³³ However, the study was terminated based on interim analyses indicating no additional benefit from tamoxifen beyond 5 years. The ATLAS trial also evaluated the use of tamoxifen for 5 years vs. 10 years in nearly 13,000 women across the world. This study showed that continuing tamoxifen for 10 years vs. 5 years produced a significant reduction in recurrence and mortality.³³⁴ Interestingly, the benefit was not seen in the second 5 years (i.e., years 5–9) while the patients were on treatment, but it was seen from years 10 to 15. One reason the NSABP B14 study was led to conclude that 10 years of tamoxifen was not beneficial was that the follow-up time was shorter. Results of the ATLAS study were also corroborated by the aTTom study. Similarly, extended adjuvant therapy with letrozole after 5 years of tamoxifen was shown to improve disease-free survival without improvement in overall survival except in node-positive patients.³³⁵

Tamoxifen therapy is also considered for women with DCIS that is found to be ER-positive. The goals of such therapy are to decrease the risk of an ipsilateral recurrence after breast conservation therapy for DCIS and to decrease the risk of a primary invasive breast cancer or a contralateral breast cancer event. Consequently, tamoxifen is not recommended for patients who have had bilateral mastectomies with ER-positive

DCIS. With the use of aromatase inhibitors in postmenopausal women, use of adjuvant tamoxifen has increasingly been limited to premenopausal women.

Aromatase Inhibitors. In postmenopausal women, aromatase inhibitors are now considered first-line therapy in the adjuvant setting. Currently, three third-generation aromatase inhibitors are approved for clinical use: the reversible nonsteroidal inhibitors anastrozole and letrozole and the irreversible steroidal inhibitor exemestane. While all the aromatase inhibitors have been shown to have similar efficacy with a similar spectrum of adverse effects, the Early Breast Cancer Trialists' Collaborative Group meta-analyses of 31,920 postmenopausal women with ER-positive early breast cancers treated with tamoxifen or aromatase inhibitors demonstrated that 5 years of aromatase inhibitors reduced the rate of recurrence by 30% and 10-year breast cancer mortality by about 15% compared to 5 years of tamoxifen.³³⁶⁻³³⁹ The NSABP B42 study evaluated whether an additional 5 years of letrozole improved disease-free survival in postmenopausal women who have completed 5 years of tamoxifen or an aromatase inhibitor. After a median follow-up of 6.9 years, while extended letrozole significantly improved breast cancer-free interval, no improvement in disease-free survival, the primary endpoint, was observed. Recently, the results of the MA-17R study, designed to assess the efficacy of adjuvant letrozole for 10 years, were reported.³⁴⁰ Similar to NSABP B42, extended letrozole improved disease-free survival without significant improvement in overall survival. Patients who are node-positive, have received adjuvant chemotherapy, with prior receipt of tamoxifen are likely to benefit from long-term use of an aromatase inhibitor.

The aromatase inhibitors are less likely than tamoxifen to cause endometrial cancer but do lead to changes in bone mineral density that may result in osteoporosis and an increased rate of fractures in postmenopausal women. The risk of osteoporosis can be averted by treatment with bisphosphonates. Joint pains are a side effect that affects a significant number of patients. Node-negative and node-positive breast cancer patients whose tumors express hormone receptors should be considered for endocrine therapy in the adjuvant setting. Women with hormone receptor-positive cancers achieve significant reduction in risk of recurrence of breast cancer and mortality from breast cancer through the use of endocrine therapies.

For postmenopausal women with ER-positive, HER2-negative, metastatic breast cancer, available endocrine therapies include nonsteroidal aromatase inhibitors (anastrozole and letrozole); steroidal aromatase inhibitors (exemestane); serum ER modulators (tamoxifen or toremifene); ER down-regulators (fulvestrant); progestin (megestrol acetate); androgens (fluoymesterone); and high-dose estrogen (ethinyl estradiol). A third generation nonsteroidal aromatase inhibitor or palbociclib, the CDK 4/6 inhibitor, in combination with letrozole may be considered as a treatment option for first-line therapy. Activation of CDK4/CDK6 cell cycle signaling axis has been implicated in mediating endocrine resistance. Consequently, PALOMA-1 evaluated the safety and efficacy of palbociclib in combination with letrozole vs. letrozole alone as first-line treatment for patients with ER-positive, HER2-negative advanced breast cancer. Median progression-free survival (PFS) was doubled with the combination compared to letrozole alone (20.2 months vs. 10.2 months for the letrozole).³⁴¹ Based on this, the FDA approved palbociclib in combination with letrozole for the treatment of postmenopausal women with ER-positive, HER2-negative advanced breast cancer as initial treatment. The

benefit of palbociclib in combination with letrozole was subsequently confirmed in a phase 3 trial (PFS 24.8 months vs. 14.5 months for letrozole).³⁴² Two additional CDK4/6 inhibitors, ribociclib and abemaciclib, have been approved for use in combination with endocrine therapy for patients with hormone receptor–positive advanced breast cancer.

On the other hand, PALOMA-3 compared the combination of palbociclib and fulvestrant to fulvestrant alone in pre- or postmenopausal ER-positive, HER2-negative metastatic breast cancer patients, whose disease progressed on prior endocrine therapy. Premenopausal women also received the GNRH agonist, goserelin. The median PFS was 9.2 months for the combination compared to 3.8 months with fulvestrant alone.³⁴³ Thus, fulvestrant with palbociclib is a potential option for women with metastatic breast cancer who have progressed on prior endocrine therapy. Additionally, abemaciclib in combination with fulvestrant or as single agent is approved for use in ER-positive advanced breast cancers previously treated with endocrine therapy.

In premenopausal women with stage IV ER-positive breast cancer without previous exposure to endocrine therapy, initial treatment with tamoxifen or ovarian suppression/ablation plus aromatase inhibitor with or without CDK4/6 inhibitors are reasonable options.

Activation of the PI3K/mammalian target of rapamycin (mTOR) signal transduction pathway has also been implicated in secondary resistance to estrogen targeting. BOLERO-2 evaluated the use of exemestane in combination with everolimus in postmenopausal women with ER-positive tumors who had progressed or recurred on a nonsteroidal aromatase inhibitor.³⁴⁴ An improvement in PFS was observed with combination compared to exemestane alone (11 vs. 4.1 months) leading to FDA approval. Similar improvement in PFS was observed with a combination of tamoxifen and everolimus.³⁴⁵ However, a phase 3 trial of letrozole in combination with temsirolimus, an mTOR inhibitor, did not show any improvement in PFS in aromatase inhibitor–naïve metastatic postmenopausal women.³⁴⁶ Trials evaluating the adjuvant use of mTOR inhibitors and CDK 4/6 inhibitors are currently in progress.

Women whose tumors respond to an endocrine therapy with either shrinkage of their breast cancer (objective response) or long-term stabilization of disease (stable disease) are considered to represent “clinical benefit” and should receive additional endocrine therapy at the time of progression because their chances of a further response remain high.²⁹⁴⁻²⁹⁶ Patients whose tumors progress de novo on an endocrine agent have a low rate of clinical benefit (<20%) to subsequent endocrine therapy; the choice of endocrine or chemotherapy should be considered based on the disease site and extent as well as the patient’s general condition and treatment preference.²⁹⁴

The adjuvant use of aromatase inhibitors and recent advances in tumor genome sequencing technologies have enabled the identification of secondary *ESR1* mutations.^{347,348} These mutations, typically present in the ligand binding domains, lead to ligand-independent activation of the receptor, mediate resistance to aromatase inhibitors, and are associated with shorter survival.³⁴⁹ Reported incidence of these mutations are variable (20%–30%) based on prior exposure to aromatase inhibitors and are uncommon in primary breast cancers. Clinical trials evaluating novel selective estrogen receptor degraders with potential activity against these mutations are in progress.

Ablative Endocrine Therapy

In the past, adrenalectomy and/or hypophysectomy were the primary endocrine modalities used to treat metastatic breast cancer, but today these approaches are seldom used. In women who are premenopausal at diagnosis, ovarian ablation can be accomplished by oophorectomy or ovarian radiation. Ovarian suppression can be accomplished by the use of gonadotrophin-hormone releasing hormone agonists, such as goserelin or leuprolide. Evaluation of the combination of goserelin with tamoxifen vs. cyclophosphamide/methotrexate/fluorouracil chemotherapy in premenopausal ER-positive early-stage breast cancers showed that relapse-free survival was superior with endocrine therapy combination, with a similar trend in overall survival.³⁵⁰ Data from the SOFT and TEXT trials on adjuvant endocrine therapy show that exemestane plus ovarian suppression significantly reduces recurrences as compared with tamoxifen plus ovarian suppression.^{351,352} In these trials, ovarian suppression was achieved with the use of the gonadotropin-releasing hormone agonist triptorelin, oophorectomy, or ovarian irradiation. The disease-free survival was 89% in the tamoxifen plus ovarian suppression group, while it was 93% in exemestane plus ovarian suppression group; however, there was no significant differences in overall survival. In the SOFT trial, while tamoxifen plus ovarian suppression was not superior to tamoxifen alone in terms of disease-free survival, improved outcomes were observed in ovarian suppression in women with a high risk of recurrence. In women who received no adjuvant chemotherapy, no meaningful benefit was obtained with ovarian suppression. Thus, ovarian suppression in combination with an aromatase inhibitor can be considered in select premenopausal women with high-risk features (age <40 years, positive lymph nodes) who warranted adjuvant chemotherapy.

Anti-HER2 Therapy

The determination of tumor HER-2 expression or gene amplification for all newly diagnosed patients with breast cancer is now recommended.³⁵³⁻³⁵⁶ It is used to assist in the selection of adjuvant chemotherapy in both node-negative and node-positive patients. Trastuzumab was initially approved for the treatment of HER2/neu-positive breast cancer in patients with metastatic disease. Once efficacy was demonstrated for patients with metastatic disease, the NSABP and the North Central Cancer Treatment Group conducted phase 3 trials that evaluated the impact of adjuvant trastuzumab therapy in patients with early-stage breast cancer. After approval from the FDA, these groups amended their adjuvant trastuzumab trials (B-31 and N9831, respectively), to provide for a joint efficacy analysis. The first joint interim efficacy analysis demonstrated an improvement in 3-year disease-free survival from 75% in the control arm to 87% in the trastuzumab arm (hazard ratio = 0.48, $P < .0001$). There was an accompanying 33% reduction in mortality in the patients who received trastuzumab (hazard ratio = 0.67, $P = 0.015$). The magnitude of reduction in hazard for disease-free survival events crossed prespecified early reporting boundaries, so the data-monitoring committees for both groups recommended that randomized accrual to the trials be ended, and the results were subsequently published.¹⁸¹

While anthracycline-based adjuvant chemotherapy was considered preferable in HER2-positive breast cancer, the BCIRG 006 compared the use of anthracycline with taxane and trastuzumab (AC-TH) versus taxane, carboplatin chemotherapy with trastuzumab (TCH).¹⁸² With 10 years of follow-up, no statistical significance with regard to disease-free and overall

survival was observed for anthracycline-based chemotherapy. While anthracycline chemotherapy was numerically superior, this was accompanied by an increase in the incidence of leukemia and congestive heart failure. A year of adjuvant trastuzumab is considered standard of care. Two years of adjuvant trastuzumab has been shown to be more effective, although it is associated with more toxicity than 1 year of trastuzumab.³⁵⁷ On the other hand, the PHARE trial examined 6 months vs. standard 12 months of trastuzumab. After 3.5 years of follow-up, the study failed to demonstrate that 6 months was noninferior compared to the standard therapy.³⁵⁸ Patients with HER2-positive tumors benefit if trastuzumab is added to taxane chemotherapy. Because of overlapping cardiotoxicities, trastuzumab is not usually given concurrently with anthracyclines.

Buzdar and colleagues reported the results of a randomized neoadjuvant trial of trastuzumab in combination with sequential paclitaxel followed by FEC-75 (5-fluorouracil, epirubicin, cyclophosphamide) vs. the same chemotherapy regimen without trastuzumab in 42 women with early-stage operable breast cancer. The pathologic complete response rates in this trial increased from 25% to 66.7% when chemotherapy was given concurrently with trastuzumab.³⁰¹ A subsequent report that included additional patients treated with concurrent chemotherapy and trastuzumab further confirmed the high pathologic complete response rates and continued to show that cardiac function was preserved.³⁰²

While novel agents have been approved for the treatment of women with metastatic HER2-positive breast cancers, currently trastuzumab is the only HER2-targeted agent approved for use in the adjuvant setting. Lapatinib is a dual tyrosine kinase inhibitor that targets both HER2 and EGFR. It was approved for use with capecitabine in patients with HER2-positive metastatic disease. Adjuvant lapatinib was shown to be inferior to trastuzumab, and the combination of lapatinib with trastuzumab did yield a significant improvement in disease-free survival compared to trastuzumab alone. Ado-trastuzumab emtansine (T-DM1) is approved for HER2-positive metastatic breast cancer patients who have previously received trastuzumab and a taxane either separately or in combination. T-DM1 is an antibody drug conjugate that incorporates the HER2 targeted activity of trastuzumab with the cytotoxic activity of DM1, a microtubule inhibitory agent leading to apoptosis.³⁵⁹

Pertuzumab is a humanized monoclonal antibody that binds at a different epitope of the HER2 extracellular domain (subdomain II) and prevents dimerization of HER2 with other members of the family, primarily HER3. In the metastatic setting, it is approved in combination with trastuzumab and docetaxel for patients with metastatic HER2-positive breast cancer who have not received prior HER2-targeted therapy or chemotherapy for metastatic disease.³⁶⁰ In the neoadjuvant setting, pertuzumab is approved in combination with trastuzumab and docetaxel in HER2-positive, early stage breast cancers that are greater than 2 cm or node-positive. However, this approval is based on improvement in pathologic complete response rate, and not data based on improvement in event free or overall survival.^{361,362} In the NeoSphere trial, neoadjuvant use of pertuzumab with trastuzumab and docetaxel led to nearly a 17% increase in pathologic complete response in the breast ($P = .0141$).³⁶¹ While in the TRYPHAENA study, pathologic complete responses ranging from 57% to 66% were observed with neoadjuvant pertuzumab and trastuzumab combination given with anthracycline-containing or nonanthracycline-containing

chemotherapy.³⁶² With the use of dual antibody therapy, currently there is significant interest in identifying patients who can avoid chemotherapy and potentially be treated with HER2-targeted agents alone. The NeoSphere study showed 27% pathologic complete response in HER2-positive, ER-negative, breast cancer patients treated with pertuzumab and trastuzumab alone. Pertuzumab was recently FDA approved in combination with trastuzumab and chemotherapy in the adjuvant setting in HER2 amplified breast cancers with high risk of recurrence. Approval is based on APHINITY trial showing that the addition of pertuzumab improved invasive disease free survival (7.1%) compared to placebo (8.7%) (HR 0.82, 95% CI: 0.67, 1.00; $p = 0.047$). Overall survival data is not mature.

The ExteNET study evaluated the use of neratinib, an irreversible inhibitor of EGFR, HER2, and HER4, in HER2-positive early stage patients who have completed adjuvant trastuzumab. A year of neratinib after completion of chemotherapy and trastuzumab-based adjuvant therapy significantly improved 2-year disease-free survival, the primary endpoint.³⁶³ After two years, invasive disease free survival was 94.2% in patients treated with neratinib compared with 91.9% in those receiving placebo (HR 0.66; 95% CI: 0.49, 0.90, $p = 0.008$) leading to FDA approval for HER2 amplified breast cancers following a year of adjuvant trastuzumab.

In addition to amplifications or copy number alterations, activating mutations or single nucleotide variants in HER2 have been described (2%).³⁶⁴ Typically observed in ER-positive breast cancers, a higher prevalence of *HER2* mutations have been reported in invasive lobular carcinomas, particularly in the pleomorphic subtype.³⁶⁵ These mutations, usually exclusive with *HER2* amplification, are observed in kinase or extracellular domains and predict for responses or resistance to HER2-targeting agents.^{366,367} A phase 2 trial of neratinib in HER2-mutated metastatic breast cancers showed a clinical benefit rate of 36% with one complete response and one partial response in a heavily pretreated population. A clinical trial evaluating the combination of neratinib with fulvestrant, in HER2-mutated, ER-positive breast cancers, is in progress.

SPECIAL CLINICAL SITUATIONS

Nipple Discharge

Unilateral Nipple Discharge. Nipple discharge is a finding that can be seen in a number of clinical situations. It may be suggestive of cancer if it is spontaneous, unilateral, localized to a single duct, present in women ≥ 40 years of age, bloody, or associated with a mass. A trigger point on the breast may be present so that pressure around the nipple-areolar complex induces discharge from a single duct. In this circumstance, mammography and ultrasound are indicated for further evaluation. A ductogram also can be useful and is performed by cannulating a single discharging duct with a small nylon catheter or needle and injecting 1.0 mL of water-soluble contrast solution. Nipple discharge associated with a cancer may be clear, bloody, or serous. Testing for the presence of hemoglobin is helpful, but hemoglobin may also be detected when nipple discharge is secondary to an intraductal papilloma or duct ectasia. Definitive diagnosis depends on excisional biopsy of the offending duct and any associated mass lesion. A 3.0 lacrimal duct probe can be used to identify the duct that requires excision. Another approach is to inject methylene blue dye within

the duct after ductography. The nipple must be sealed with collodion or a similar material so that the blue dye does not discharge through the nipple but remains within the distended duct facilitating its localization. Localization with a wire or seed is performed when there is an associated mass that lies >2.0 to 3.0 cm from the nipple.

Bilateral Nipple Discharge. Nipple discharge is suggestive of a benign condition if it is bilateral and multiductal in origin, occurs in women ≤ 39 years of age, or is milky or blue-green. Prolactin-secreting pituitary adenomas are responsible for bilateral nipple discharge in <2% of cases. If serum prolactin levels are repeatedly elevated, plain radiographs of the sellaturcica are indicated, and thin section CT scan is required. Optical nerve compression, visual field loss, and infertility are associated with large pituitary adenomas.

Axillary Lymph Node Metastases in the Setting of an Unknown Primary Cancer

A woman who presents with an axillary lymph node metastasis that is consistent with a breast cancer metastasis has a 90% probability of harboring an occult breast cancer.³⁰³ However, axillary lymphadenopathy is the initial presenting sign in only 1% of breast cancer patients. Fine-needle aspiration biopsy or core-needle biopsy can be used to establish the diagnosis when an enlarged axillary lymph node is identified. When metastatic cancer is found, immunohistochemical analysis may classify the cancer as epithelial, melanocytic, or lymphoid in origin. The presence of hormone receptors (estrogen or progesterone receptors) suggests metastasis from a breast cancer but is not diagnostic. The search for a primary cancer includes careful examination of the thyroid, breast, and pelvis, including the rectum. The breast should be examined with diagnostic mammography, ultrasonography, and MRI to evaluate for an occult primary lesion. Further radiologic and laboratory studies should include chest radiography and liver function studies. Additional imaging of the chest, abdomen, and skeleton may be indicated if the extent of nodal involvement is consistent with stage III breast cancer. Suspicious findings on mammography, ultrasonography, or MRI necessitate breast biopsy. When a breast cancer is found, treatment consists of an axillary lymph node dissection with a mastectomy or preservation of the breast followed by whole-breast radiation therapy. Chemotherapy and endocrine therapy should be considered.

Breast Cancer During Pregnancy

Breast cancer occurs in 1 of every 3000 pregnant women, and axillary lymph node metastases are present in up to 75% of these women.³⁶⁸ The average age of the pregnant woman with breast cancer is 34 years. Fewer than 25% of the breast nodules developing during pregnancy and lactation will be cancerous. Ultrasonography and needle biopsy specimens are used in the diagnosis of these nodules. Mammography is rarely indicated because of its decreased sensitivity during pregnancy and lactation; however, the fetus can be shielded if mammography is needed. Approximately 30% of the benign conditions encountered will be unique to pregnancy and lactation (galactoceles, lobular hyperplasia, lactating adenoma, and mastitis or abscess). Once a breast cancer is diagnosed, complete blood count, chest radiography (with shielding of the abdomen), and liver function studies are performed.

Because of the potential deleterious effects of radiation therapy on the fetus, radiation cannot be considered until the

fetus is delivered. A modified radical mastectomy can be performed during the first and second trimesters of pregnancy, even though there is an increased risk of spontaneous abortion after first-trimester anesthesia. During the third trimester, lumpectomy with axillary node dissection can be considered if adjuvant radiation therapy is deferred until after delivery. Lactation is suppressed. Chemotherapy administered during the first trimester carries a risk of spontaneous abortion and a 12% risk of birth defects. There is no evidence of teratogenicity resulting from administration of chemotherapeutic agents in the second and third trimesters. For this reason, many clinicians now consider the optimal strategy to be delivery of chemotherapy in the second and third trimesters as a neoadjuvant approach, which allows local therapy decisions to be made after the delivery of the baby. Pregnant women with breast cancer often present at a later stage of disease because breast tissue changes that occur in the hormone-rich environment of pregnancy obscure early cancers. However, pregnant women with breast cancer have a prognosis, stage by stage, that is similar to that of nonpregnant women with breast cancer.

Male Breast Cancer

Fewer than 1% of all breast cancers occur in men.^{369,370} The incidence appears to be highest among North Americans and the British, in whom breast cancer constitutes as much as 1.5% of all male cancers. Jewish and African-American men have the highest incidence. Male breast cancer is preceded by gynecomastia in 20% of men. It is associated with radiation exposure, estrogen therapy, testicular feminizing syndromes, and Klinefelter's syndrome (XXY). Breast cancer is rarely seen in young males and has a peak incidence in the sixth decade of life. A firm, nontender mass in the male breast requires investigation. Skin or chest wall fixation is particularly worrisome.

DCIS makes up <15% of male breast cancer, whereas infiltrating ductal carcinoma makes up >85%. Special-type cancers, including infiltrating lobular carcinoma, have occasionally been reported. Male breast cancer is staged in the same way as female breast cancer, and stage by stage, men with breast cancer have the same survival rate as women. Overall, men do worse because of the more advanced stage of their cancer (stage II, III or IV) at the time of diagnosis. The treatment of male breast cancer is surgical, with the most common procedure being a modified radical mastectomy. SLN dissection has been shown to be feasible and accurate for nodal assessment in men presenting with a clinically node-negative axilla. Adjuvant radiation therapy is appropriate in cases in which there is a high risk for local-regional recurrence. Approximately 80% of male breast cancers are hormone receptor-positive, and adjuvant tamoxifen is considered. Systemic chemotherapy is considered for men with hormone receptor-negative cancers and for men with large primary tumors, multiple positive nodes, and locally advanced disease.

Phyllodes Tumors

The nomenclature, presentation, and diagnosis of phyllodes tumors (including cystosarcoma phyllodes) have posed many problems for surgeons.³⁷¹ These tumors are classified as benign, borderline, or malignant. Borderline tumors have a greater potential for local recurrence.

Mammographic evidence of calcifications and morphologic evidence of necrosis do not distinguish between benign, borderline, and malignant phyllodes tumors. Consequently, it is difficult to differentiate benign phyllodes tumors from the

malignant variant and from fibroadenomas. Phyllodes tumors are usually sharply demarcated from the surrounding breast tissue, which is compressed and distorted. Connective tissue composes the bulk of these tumors, which have mixed gelatinous, solid, and cystic areas. Cystic areas represent sites of infarction and necrosis. These gross alterations give the gross cut tumor surface its classical leaf-like (phyllodes) appearance. The stroma of a phyllodes tumor generally has greater cellular activity than that of a fibroadenoma. After microdissection to harvest clusters of stromal cells from fibroadenomas and from phyllodes tumors, molecular biology techniques have shown the stromal cells of fibroadenomas to be either polyclonal or monoclonal (derived from a single progenitor cell), whereas those of phyllodes tumors are always monoclonal.

Most malignant phyllodes tumors (Fig. 17-38) contain liposarcomatous or rhabdomyosarcomatous elements rather than fibrosarcomatous elements. Evaluation of the number of mitoses and the presence or absence of invasive foci at the tumor margins may help to identify a malignant tumor. Small phyllodes tumors are excised with a margin of normal-appearing breast tissue. When the diagnosis of a phyllodes tumor with suspicious

A

B

malignant elements is made, reexcision of the biopsy specimen site to ensure complete excision of the tumor with a 1-cm margin of normal-appearing breast tissue is indicated. Large phyllodes tumors may require mastectomy. Axillary dissection is not recommended because axillary lymph node metastases rarely occur.

Inflammatory Breast Carcinoma

Inflammatory breast carcinoma (stage IIIB) accounts for $<3\%$ of breast cancers. This cancer is characterized by the skin changes of brawny induration, erythema with a raised edge, and edema (peau d'orange).³⁷² Permeation of the dermal lymph vessels by cancer cells is seen in skin biopsy specimens. There may be an associated breast mass (Fig. 17-39). The clinical differentiation of inflammatory breast cancer may be extremely difficult, especially when a locally advanced scirrhous carcinoma invades dermal lymph vessels in the skin to produce peau d'orange and lymphangitis (Table 17-15). Inflammatory breast cancer also may be mistaken for a bacterial infection of the breast. More than 75% of women who have inflammatory breast cancer present with palpable axillary lymphadenopathy, and distant metastases also are frequently present. A PET-CT scan should be considered at the time of diagnosis to rule out concurrent metastatic disease. A report of the SEER program described distant metastases at diagnosis in 25% of white women with inflammatory breast carcinoma.

Surgery alone and surgery with adjuvant radiation therapy have produced disappointing results in women with inflammatory breast cancer. However, neoadjuvant chemotherapy with an anthracycline-containing regimen may affect dramatic regressions in up to 75% of cases. Tumors should be assessed for HER2 and hormone receptors with treatment dictated based on receptor status. Modified radical mastectomy is performed after demonstrated response to systemic therapy to remove residual cancer from the chest wall and axilla. Adjuvant chemotherapy may be indicated depending on final pathologic assessment of the breast and regional nodes. Finally, the chest wall and the

Figure 17-39. Inflammatory breast carcinoma. Stage IIIB cancer of the breast with erythema, skin edema (peau d'orange), nipple retraction, and satellite skin nodules.

Table 17-15

Inflammatory vs. noninflammatory breast cancer

INFLAMMATORY	NONINFLAMMATORY
Dermal lymph vessel invasion is present with or without inflammatory changes.	Inflammatory changes are present without dermal lymph vessel invasion.
Cancer is not sharply delineated.	Cancer is better delineated.
Erythema and edema frequently involve >33% of the skin over the breast.	Erythema is usually confined to the lesion, and edema is less extensive.
Lymph node involvement is present in >75% of cases.	Lymph nodes are involved in approximately 50% of the cases.
Distant metastases are more common at the initial presentation (25% of cases).	Distant metastases are less common at presentation.

supraclavicular, internal mammary, and axillary lymph node basins receive adjuvant radiation therapy. This multimodal approach results in 5-year survival rates that approach 30%. Patients with inflammatory breast cancer should be encouraged to participate in clinical trials.

Rare Breast Cancers

Squamous Cell (Epidermoid) Carcinoma. Squamous cell (epidermoid) carcinoma is a rare cancer that arises from metaplasia within the duct system and generally is devoid of distinctive clinical or radiographic characteristics.³⁷³ Regional metastases occur in 25% of patients, whereas distant metastases are rare.

Adenoid Cystic Carcinoma. Adenoid cystic carcinoma is very rare, accounting for <0.1% of all breast cancers. It is typically indistinguishable from adenoid cystic carcinoma arising in salivary tissues. These cancers are generally 1 to 3 cm in diameter at presentation and are well circumscribed. Axillary lymph node metastases are rare, but deaths from pulmonary metastases have been reported.

Apocrine Carcinomas. Apocrine carcinomas are well-differentiated cancers that have rounded vesicular nuclei and prominent nucleoli. There is a very low mitotic rate and little variation in cellular features. However, apocrine carcinomas may display an aggressive growth pattern.

Sarcomas. Sarcomas of the breast are histologically similar to soft tissue sarcomas at other anatomic sites. This diverse group includes fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, leiomyosarcoma, malignant schwannoma, rhabdomyosarcoma, osteogenic sarcoma, and chondrosarcoma. The clinical presentation is typically that of a large, painless breast mass with rapid growth. Diagnosis is by core-needle biopsy or by open incisional biopsy. Sarcomas are graded based on cellularity, degree of differentiation, nuclear atypia, and mitotic activity. Primary treatment is wide local excision, which may necessitate mastectomy. Axillary dissection is not indicated unless there is

biopsy proven lymph node involvement. Angiosarcomas are classified as de novo, as postradiation, or as arising in association with postmastectomy lymphedema. In 1948, Stewart and Treves described lymphangiosarcoma of the upper extremity in women with ipsilateral lymphedema after radical mastectomy.³⁷⁴ *Angiosarcoma* is now the preferred name. The average interval between modified radical or radical mastectomy and the development of an angiosarcoma is 7 to 10 years. Sixty percent of women developing this cancer have a history of adjuvant radiation therapy. Forequarter amputation may be necessary to palliate the ulcerative complications and advanced lymphedema.

Lymphomas. Primary lymphomas of the breast are rare, and there are two distinct clinicopathologic variants. One type occurs in women ≤ 39 years of age, is frequently bilateral, and has the histologic features of Burkitt's lymphoma. The second type is seen in women ≥ 40 years of age and is usually of the B-cell type. Breast involvement by Hodgkin's lymphoma has been reported. An occult breast lymphoma may be diagnosed after detection of palpable axillary lymphadenopathy. Treatment depends on the stage of disease. Lumpectomy or mastectomy may be required. Axillary dissection for clearance of disease may be necessary. Recurrent or progressive local-regional disease is best managed by chemotherapy and radiation therapy. The prognosis is favorable, with 5- and 10-year survival rates of 74% and 51%, respectively. More recently anaplastic large cell lymphoma has been described in association with breast implants for cosmetic or reconstructive purposes. This disease is treated with complete excision of the implant capsule with any associated soft tissue mass. More advanced cases may require systemic therapy and radiation treatment.

COMPLEX ANATOMY AND FUNCTION

The anatomy of the head and neck is complex because of the proximity of vital structures such as framework, nerves, and arteries. Functionally, these structures afford most of the human senses: vision, taste, smell, and hearing. Even more fundamental, the upper aerodigestive tract is critical for breathing, speech, and swallowing. Otolaryngology—head and neck surgery is the field that predominantly deals with disorders of the head and neck; however, a multidisciplinary approach is required to achieve optimal outcomes. The multidisciplinary team can include audiology, speech language pathology, allergy/immunology, neurology, neurosurgery, radiation, and medical oncology. This chapter aims to provide an overview of the most common diseases presenting to and treated by the otolaryngologist—head and neck surgeon. It reviews benign conditions, trauma, malignancies, reconstruction, tracheotomy, and rehabilitation.

BENIGN CONDITIONS OF THE HEAD AND NECK

Otology

Infectious. Infectious processes of the ear may be considered by their location (external, middle, or inner ear), their time course (acute or chronic), and the presence of complications. The external ear or pinna consists of a cartilaginous framework, perichondrium, and a relatively thin layer of skin. Erysipelas (St Anthony's Fire) or impetigo are causes of external ear infection affecting the dermis or hypodermis of the auricle, typically caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, respectively, that may be encountered posttraumatically or related to ear piercing. Treatment is oral antibiotic therapy targeting these organisms. History and clinical features such as

presence of bullae and golden crusting distinguish erysipelas and impetigo from other benign entities causing erythema and edema of the auricle, such as relapsing chondritis, which is typically diffuse, lobule-sparing, and steroid-responsive.

Acute otitis externa, often referred to as “swimmer’s ear,” denotes infection of the skin of the external auditory canal.¹ Typically, the pathology is incited by moisture within the canal leading to skin maceration and pruritus. Subsequent trauma to the canal skin by scratching (i.e., instrumentation with a cotton swab or fingernail), erodes the normally protective skin/cerumen barrier. Hearing aid use and comorbid dermatologic conditions such as eczema or other forms of dermatitis may similarly serve as predisposing factors. The milieu of the external ear canal—dark, warm, humid—is ideal for rapid microbial proliferation. The most common offending organism is *Pseudomonas aeruginosa*, although other bacteria and fungi may also be involved. Symptoms and signs of otitis externa include itching during the initial phases and pain with marked swelling of the canal soft tissues as the infection progresses. Treatment involves removal of debris under otomicroscopy and application of appropriate ototopical antimicrobials, such as neomycin/polymyxin or quinolone-containing eardrops. The topical steroid component of these drops (e.g., hydrocortisone or dexamethasone) addresses swelling and, as a result, decreases the often intense pain associated with this infection. In cases of marked ear canal edema, the use of an otowick is required to facilitate delivery of ototopical medication medially into the ear canal. Fungal infections may call for the addition of 2% acetic acid to reestablish the premorbid pH balance. Patients with otitis externa should also be instructed to keep the ear dry. Systemic antibiotics are reserved for those with severe infections, diabetes, and immunosuppression.

Key Points

- 1▶ One of the most common benign head and neck disorders includes sinonasal inflammatory disease which can present as acute or chronic rhinosinusitis.
- 2▶ Acute adeno-tonsillitis is a major cause of morbidity in children and adenotonsillectomy can significantly improve symptoms of both sleep disordered breathing and of symptoms during acute infections.
- 3▶ Squamous cell carcinoma comprises >90% of all of the malignant pathology of the mucosal lining of the upper aerodigestive tract.
- 4▶ The ideal treatment protocol for these cancers varies by subsite, stage, patient comorbidity, and center preference/experience. Early stage disease is treated with unimodality and late stage disease is treated with multiple modalities in the form of primary surgery with adjuvant radiotherapy or primary concurrent chemoradiotherapy.
- 5▶ Free flap reconstruction of head and neck defects is integral to help improve patient-reported quality of life and to re-establish form and function.

Malignant otitis externa, a fulminant necrotizing infection of the soft tissues of the external ear canal combined with osteomyelitis of the temporal bone, is a potentially life-threatening form of otitis externa seen most commonly among elderly patients with insulin-dependent diabetes mellitus or immunodeficiency.^{2,3} The classic physical finding is granulation tissue along the floor of the external auditory canal near the bony cartilaginous junction. Symptoms include persistent otalgia for longer than one month and purulent otorrhea. Biopsy is called for in order to exclude malignancy. Computed tomography (CT) and magnetic resonance imaging (MRI) define the extension of disease. Technetium 99-m scans are useful in gauging extent of bony involvement in early disease. Gallium-67 scans are valuable for monitoring disease during the course of treatment and for determining duration of antibiotic therapy. These patients require aggressive medical therapy including ototopical and IV antibiotics targeting *Pseudomonas*. Other gram-negative bacteria and fungi are occasionally implicated, necessitating culture-directed therapy. Patients who do not respond to medical management require surgical debridement. This condition may progress to involvement of the adjacent skull base and soft tissues, meningitis, brain abscess, and death.

Acute otitis media (AOM) typically implies a bacterial infection of the middle ear.⁴ This diagnosis accounts for 25% of pediatric antibiotic prescriptions and is the most common bacterial infection of childhood. Most cases occur before 2 years of age and are secondary to immaturity of the Eustachian tube. Well-recognized contributing factors include upper respiratory viral infection and daycare attendance, as well as craniofacial conditions affecting Eustachian tube function, such as cleft palate.

It is important to distinguish between acute otitis media and otitis media with effusion (OME). The latter denotes uninfected serous fluid accumulation within the middle ear space. In children not already considered “at risk” for developmental difficulties, OME is generally observed for resolution for a period of 3 months.⁵ Age-appropriate hearing testing should be performed when OME persists for ≥ 3 months or at any time when language delay, learning problems, or a significant hearing loss is suspected. In the absence of these factors, the child with OME should be reexamined at 3- to 6-month intervals until the effusion is no longer present or until significant hearing loss is identified or structural abnormalities of the eardrum or middle ear are suspected. When hearing, speech, or structural concerns exist, myringotomy with tympanostomy tube placement is indicated.

Signs and symptoms of infectious otitis media occurring for <3 weeks denote AOM. In this phase, otalgia and fever are the most common symptoms and physical exam reveals a bulging, opaque tympanic membrane (Fig. 18-1). If the process lasts 3 to 8 weeks, it is deemed subacute. Chronic otitis media, lasting more than 8 weeks, usually results from an unresolved acute otitis media. The most common organisms responsible are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.

In order to minimize antibiotic resistance and obviate complications of antimicrobial therapy such as allergic reaction and diarrhea, guidelines have been established for the treatment of AOM.^{6,7} Pain associated with AOM should be recognized and treated with oral analgesics. In children older than 6 months who are not otherwise considered “high risk” for complications (e.g., immunocompromised, previous cochlear implantation, developmental anomalies of the inner ear) with symptoms consistent with unilateral AOM without otorrhea, an initial period of observation is offered. If initial observation is selected by the physician and family, a mechanism for reexamination in 48 to 72 hours to evaluate for clinical improvement must be in place. When these criteria are not met, or clinical improvement is not observed within 48 to 72 hours, oral antibiotics are begun. First-line therapy is high-dose amoxicillin or amoxicillin-clavulanate, for β -lactamase coverage. Chronic otitis media is frequently

Figure 18-1. Acute otitis media.

Figure 18-2. Myringotomy and tube.

treated with myringotomy and tube placement (Fig. 18-2). This treatment is indicated for frequent acute episodes and in the setting of COME as discussed previously. The purpose of this procedure is to remove the effusion and provide a route for middle ear ventilation. Episodes of AOM following tube placement are still possible. Myringotomy tubes, however, allow for prevention of painful tympanic membrane distension, risk of perforation and other complications, and permit delivery of ototopicals into the middle ear space, in most cases obviating the need for systemic antibiotic therapy.

Spontaneous tympanic membrane perforation during acute otitis media provides for drainage of purulent fluid and middle ear ventilation and frequently results in immediate resolution of severe pain. In the majority of cases, these perforations will heal spontaneously after the infection has resolved.⁸ Chronic otitis media, however, may be associated with nonhealing tympanic membrane perforations. Patients may have persistent otorrhea, which is treated with topical drops. Preparations containing aminoglycoside are avoided because this class of drugs is toxic to the inner ear. Solutions containing alcohol or acetic acid may be irritating or caustic to the middle ear and are also avoided in the setting of a perforation. Nonhealing perforation requires surgical closure (tympanoplasty) after medical treatment of any residual acute infection.

Chronic inflammatory changes from otitis media intersect with and share common etiological factors with cholesteatoma. Cholesteatoma is an epidermoid cyst of the middle ear and/or mastoid cavity that develops as result of Eustachian tube dysfunction. While several theories exist regarding causes of cholesteatoma, most cholesteatoma arises from squamous epithelium drawn into the middle ear via retraction pockets, most commonly in the pars flaccida.⁹ Squamous epithelium may also migrate into the middle ear via a perforation. Chronic mastoiditis that fails medical management or is associated with cholesteatoma is treated by mastoidectomy. Chronic inflammation and destruction of middle ear structures by osteolytic enzymes of cholesteatoma matrix may also be associated with erosion of the ossicular chain, which can be reconstructed with various prostheses or autologous ossicular replacement techniques.

Complications of otitis media with or without cholesteatoma may be grouped into two categories: intratemporal (otologic) and intracranial.¹⁰ Fortunately, complications are rare in the antibiotic era, but mounting antibiotic resistance necessitates

an increased awareness of these conditions. Intratemporal complications include acute coalescent mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. In acute coalescing mastoiditis, destruction of the bony lamellae by an acute purulent process results in severe pain, fever, and fluctuance behind the ear. The mastoid air cells coalesce into one common space filled with pus. Mastoid infection may also spread to the petrous apex, causing retro-orbital pain and sixth-nerve palsy. These diagnoses are confirmed by computed tomographic scan. Facial nerve paralysis may also occur secondary to an acute inflammatory process in the middle ear or mastoid.¹¹

Intratemporal complications of otitis media are managed by myringotomy tube placement in addition to appropriate IV antibiotics. In acute coalescent mastoiditis and petrositis, mastoidectomy is also performed as necessary to drain purulent foci. Labyrinthitis refers to inflammation of the inner ear. Most cases are idiopathic or are secondary to viral infections of the endolymphatic space. The patient experiences vertigo together with sensorineural hearing loss, and symptoms may smolder over several weeks. Labyrinthitis associated with middle ear infection may be serous or suppurative. In the former case, bacterial products and/or inflammatory mediators transudate into the inner ear via the round window membrane, establishing an inflammatory process therein. Total recovery is eventually possible after the middle ear is adequately treated.

Suppurative labyrinthitis, however, is a much more toxic condition in which the acute purulent bacterial infection extends into the inner ear and causes marked destruction of the sensory hair cells and neurons of the eighth-nerve ganglion. This condition may be a harbinger for meningitis and must be treated rapidly. The goal of management of inner ear infection, which occurs secondary to middle ear infection, is to “sterilize” the middle ear space with antibiotics and the placement of a myringotomy tube.

The most common intracranial complication of otitis media is meningitis. Otolgic meningitis in children is most commonly associated with an *H. influenzae* type B infection. Other intracranial complications include epidural abscess, subdural abscess, brain abscess, otitic hydrocephalus, and sigmoid sinus thrombophlebitis. In these cases, the otogenic source must be urgently treated with antibiotics and myringotomy tube placement. Mastoidectomy and neurosurgical consultation may be necessary.

Facial Nerve Disorders. Bell’s palsy is the most common etiology of facial nerve weakness/paralysis and is clinically distinct from that occurring as a complication of otitis media in that the otologic exam is normal.¹² Bell’s palsy is rapid, unilateral and, historically, considered idiopathic. It is now accepted, however, that the majority of these cases represent a viral neuropathy caused by herpes simplex. It is critical that clinicians distinguish Bell’s palsy from other causes of facial weakness/paralysis. Alternative diagnoses are suggested by weakness/paralysis that arise gradually (rather than <72 hours), is bilateral, is accompanied by other neurological deficits, or does not show some recovery within 2 to 3 weeks and complete recovery at 3 to 4 months. Treatment includes oral steroids plus antiviral therapy (i.e., valacyclovir). Complete recovery is the norm, but it does not occur universally, and selected cases may benefit from surgical decompression of the nerve within its bony canal. Electrophysiologic testing has been used to identify those patients in whom surgery might be indicated.¹³ The procedure involves decompression of the nerve via exposure in the mastoid and middle cranial fossa.

Varicella zoster virus may also cause facial nerve paralysis when the virus reactivates from dormancy in the nerve. This condition, known as *Ramsay Hunt syndrome*, is characterized by severe otalgia followed by the eruption of vesicles of the external ear and the soft palate. Treatment is similar to Bell's palsy, but full recovery is only seen in approximately two-thirds of cases.

Traumatic facial nerve injuries may occur secondary to accidental trauma or surgical injury. Iatrogenic facial nerve trauma most often occurs during mastoidectomy, most commonly to the vertical segment of the nerve.¹⁴ Detailed knowledge of facial nerve anatomy and adjunctive use of nerve integrity monitoring systems are imperative in this context. When the facial nerve is injured during an operative procedure, it is explored. Injury to >50% of the neural diameter of the facial nerve is addressed either with primary reanastomosis or reconstructed with the use of a nerve graft. Complete recovery of nerve function is uncommon in these cases.

Lesions of the Internal Auditory Canal and Cerebellopontine Angle. The most common lesion affecting the internal auditory canal (IAC) and the cerebellopontine angle (CPA) is vestibular schwannoma (formerly referred to as “acoustic

neuroma”). Less commonly encountered lesions of the IAC and CPA include meningioma and epidermoid tumors. Vestibular schwannomas are benign tumors that comprise 60% to 92% of all CPA lesions and 6% to 10% of intracranial tumors. They demonstrate an average growth rate of 1 to 2 mm per year.¹⁵ Vestibular schwannomas are most commonly unilateral and sporadic; bilateral tumors are the hallmark of neurofibromatosis type 2 (NF2), an autosomal dominant condition linked to mutation of a tumor suppressor gene mapped to chromosome 22. The most common presenting symptoms of vestibular schwannoma are asymmetric sensorineural hearing loss and speech perception deficits often out of proportion to degree of hearing loss indicated by audiometry. Unilateral tinnitus is also frequently reported. Disequilibrium or, less commonly, episodic vertigo may be present. Facial nerve weakness or paralysis is rare. Larger tumors may feature facial numbness and loss of the cornea reflex from compression of the trigeminal nerve. Very large lesions can lead to brainstem compression, obstructive hydrocephalus, and death.

Gadolinium-enhancement on T1-weighted MRI is the gold standard for diagnosis and detects even very small tumors (Fig. 18-3). The conventional armamentarium for vestibular

Figure 18-3. A. Axial T1 magnetic resonance imaging (MRI) post-contrast showing left cerebellopontine angle tumor with avid gadolinium enhancement. Minimal internal auditory canal involvement is noted. B. Axial T2 MRI showing left cerebellopontine angle tumor with thin cerebrospinal fluid cleft between tumor and brainstem/cerebellum. C. Axial T1 MRI post-contrast showing left cerebellopontine angle tumor with avid gadolinium enhancement. The lesion is confined to the internal auditory canal with minimal cerebellopontine angle involvement. D. Intraoperative photo during microsurgical resection via translabyrinthine approach. Black arrow indicates cochlear nerve.

schwannoma includes observation, microsurgical resection, and stereotactic radiation.¹⁶ Management of patients with vestibular schwannomas involves weighing a multitude of variables particular to the tumor (location, size, growth pattern), the patient (age, overall health, individual wishes), and the interaction between tumor and patient (symptoms currently experienced, symptoms likely to develop with lesion progression, degree of residual hearing). For patients who have hearing that may still benefit from acoustic amplification using a hearing aid, either a retrosigmoid or a middle fossa approach may be offered, depending on tumor location, size, patient preference, and provider experience. For patients without serviceable hearing preoperatively, a translabyrinthine approach is most commonly offered.

Sinonasal Inflammatory Disease

Rhinosinusitis. Rhinosinusitis is defined as symptomatic inflammation of the nasal cavity and paranasal sinuses. *Rhinosinusitis* is preferred over *sinusitis* because sinusitis almost always is accompanied by inflammation of the contiguous nasal mucosa. Rhinosinusitis is a significant health burden, affecting nearly 12% of the population.¹⁷ Rhinosinusitis is the fifth most common diagnosis responsible for antibiotic prescription and accounts for more than 20% of all antibiotics prescribed to adults. Rhinosinusitis may be broadly classified based on duration of symptomatology. Symptoms lasting <4 weeks may be classified as acute rhinosinusitis (ARS), while symptoms lasting >12 weeks may be classified as chronic rhinosinusitis (CRS). Rhinosinusitis lasting between 4 and 12 weeks has historically been defined as “subacute,” although the current clinical practice guideline published by the American Academy of Otolaryngology—Head and Neck Surgery does not distinguish rhinosinusitis in this time frame, noting that this group likely represents crossover symptoms from one of the other two subclasses. Hence, the decision on how to manage this group of patients must be individualized.¹⁸ Because common conditions such as atypical migraine headache, laryngopharyngeal reflux, and allergic rhinitis frequently mimic rhinosinusitis, diagnosis of rhinosinusitis is based not only on symptomatic criteria but also on objective evaluation with either imaging and/or endoscopy.

Figure 18-5. Computed tomography scan demonstrating a fungal ball of the right maxillary sinus, characterized by heterogeneous opacification of the sinus.

Acute Rhinosinusitis. Acute rhinosinusitis most commonly occurs in the setting of a viral upper respiratory tract infection (URI). Although it is believed that acute bacterial rhinosinusitis (ABRS) typically follows a viral URI, it has been estimated that only up to 2% of viral URIs lead to ABRS.¹⁹ The most common viruses involved in ARS include rhinovirus, influenza virus, and parainfluenza virus. It is not known whether the viral URI precedes or only occurs along with ABRS. Regardless, viral infection leads to mucosal edema with sinus ostium obstruction, mucus stasis, tissue hypoxia, ciliary dysfunction, and epithelial damage, which may enhance bacterial adherence.²⁰ Other conditions that may contribute to ABRS should be investigated, especially in the setting of recurrent ABRS. Such conditions include foreign body, sinus fungal ball (with bacterial secondary infection), and periapical dental disease (Figs. 18-4 and 18-5).

The symptomatic criteria used to define ABRS include up to 4 weeks of purulent nasal drainage accompanied by nasal obstruction, facial pain with pressure and fullness, or both.¹⁸

Figure 18-4. A. Right periapical abscess (arrow) leading to acute bacterial rhinosinusitis. B. Follow-up scan of the same patients after administration of antibiotics demonstrating resolution of the sinonasal inflammatory changes. Therapy subsequently directed at the offending tooth will prevent recurrent symptoms.

Figure 18-6. Nasal endoscopy is commonly performed in the clinic setting to aid in the diagnosis and management of rhinosinusitis.

Other historical factors that may predict the development of ABRs include persistence of symptoms beyond 10 days, or worsening of symptoms, following initial improvement, within 10 days (“double worsening”). Although routine head and neck examination may identify anteriorly or posteriorly draining purulent secretions, the utilization of a rigid endoscope may improve diagnostic sensitivity and may also facilitate culture acquisition (Fig. 18-6).

The management of ABRs is heavily dependent on antibiotics, either culture-directed or empirically chosen to cover the most common isolates of ABRs, including *S pneumoniae*, *H influenzae*, and *M catarrhalis*. Nosocomial ABRs more commonly involves *P aeruginosa* or *S aureus*. Methicillin-resistant *S aureus* (MRSA) has been isolated with increasing frequency.²⁰ Other treatments include topical and systemic decongestants, nasal saline spray, topical nasal steroids, and oral steroids in selected cases. In the acute setting, surgery is reserved for complications or pending complications, which may include extension to the eye (orbital cellulitis or abscess) or the intracranial space (meningitis or intracranial abscess).

Chronic Rhinosinusitis. Chronic rhinosinusitis (CRS) is characterized by symptomatic inflammation of the nose and paranasal sinuses lasting over 12 weeks. CRS has been clinically classified into two main groups: those with CRS with nasal polyps (CRSwNP) tend to exhibit a Th2-biased inflammatory profile, and those with CRS without nasal polyps (CRSsNP) tend to exhibit a Th1-biased profile. Although the etiology of CRS is unclear and the development of the clinical subtypes may be distinct, there exists significant overlap not only in physiologic manifestations but also in symptomatology. Hence, the sinonasal cavities of patients with both subtypes of CRS tend to exhibit mucosal edema, ostial obstruction, ciliary dysfunction, and an abhorrent inflammatory milieu.

Two of the following symptomatic criteria must be present to diagnose CRS: purulent nasal drainage, nasal obstruction, facial pain-pressure-fullness, and decreased sense of

smell. These patients may also experience acute exacerbation, generally signified by an escalation of symptoms. Frequently, this is due to bacterial infection. However, patients with acute exacerbation of CRS may be distinguished from patients with recurrent acute bacterial rhinosinusitis (four or more episodes of ABRs per year) through baseline comparison: patients with CRS are symptomatic, even while at baseline, while patients with recurrent acute bacterial sinusitis are normal at baseline. As with ARS, the diagnosis of CRS requires objective confirmation utilizing either nasal endoscopy, CT scans, or, less commonly, MRI.

Nasal endoscopy is a critical element of the diagnosis of CRS. Abnormalities that may confirm the diagnosis of CRS include

- Purulent mucus in the middle meatus or anterior ethmoid region
- Edema in the middle meatus or ethmoid region
- Polyps in nasal cavity or the middle meatus

In addition to establishing the diagnosis, nasal endoscopy can be valuable in antibiotic selection by facilitating specific culture acquisition. Furthermore, simple polypectomy or steroid injection can be performed under topical anesthesia in the appropriate clinical setting.

Imaging is also an important clinical tool in the diagnosis of CRS. In general, CT is the modality of choice for diagnosis and management of CRS. Usual diagnostic criteria include mucosal thickening, sinus opacification, and bony remodeling (erosion or hyperostosis). It should be underscored, however, that CT scan is not the positive gold standard because many asymptomatic patients will demonstrate findings on a sinus CT scan, and many patients with presumed sinusitis will have negative findings.¹⁹ CT scan has excellent negative predictive value when performed in the setting of active symptoms. Thus, if a patient complains of rhinosinusitis-like symptoms but has no specific physical (endoscopic) findings, and the scan

Figure 18-7. Point-of-care computed tomography system. All components can be fit within an 8' × 10' room in an outpatient office setting.

is negative, other diagnoses (e.g., allergic rhinitis, migraine headache, tension headaches, and laryngopharyngeal reflux) should be sought. This has led to the utility of point-of-care CT (POC-CT) scan that can be performed in the physician's office. POC-CT utilizes cone beam technology,²¹ which acquires the equivalent of >100 axial slices in approximately 1 minute at an effective resolution of 0.3 mm or less. The equipment occupies a room of 8' × 10' and can thus be accommodated in almost any office setting (Fig. 18-7). Perhaps most important, the radiation dosing for even the most sophisticated protocol is

0.17 mSv, which is <10% the dose of a conventional head CT and equivalent to approximately 20 days of background radiation. One theoretical shortcoming of this technology is that it does not permit soft tissue imaging. This is seldom a concern in sinonasal evaluation, as this is typically undertaken in bone windows. The acquired data are immediately formatted into triplanar (axial, sagittal, coronal) reconstructions and is also compatible with devices used for intraoperative stereotactic navigation, which can be used to confirm relationships between the disease process, medial orbital wall, and skull base during surgery (Figs. 18-8 and 18-9).

Medical management of CRS is heavily dependent on topical intranasal therapy. The reasons for this lie not only in established effectiveness but also in tolerability and safety—the chronic nature of CRS generally lends to requisite long-term medication administration despite other measures such as surgery. Nasal irrigation and topical nasal steroids are commonplace in the management of CRSwNP and CRSsNP. Oral steroids have demonstrated effectiveness in patients with CRSwNP, although the role in CRSsNP is less clear. Although otolaryngologists commonly utilize antibiotics in the management of CRS, indications and administration practices are not uniform. Oral antibiotic therapy given for short duration (<4 weeks) is generally useful in the management of acute exacerbation related to bacterial infection. Long-term utilization of antibiotics may be necessary in the setting of chronic infection or osteomyelitis. Additionally, long-term macrolide administration may be utilized for anti-inflammatory effects in the appropriate clinical setting.

In most cases, patients considering endoscopic sinus surgery (ESS) for CRS should have significant residual

Figure 18-8. Triplanar imaging revealing proximity to critical structures such as the orbital wall and skull base. This can be used for diagnosis of sinus opacification as well as stereotactic intraoperative navigation, where endoscope view (lower right) can be radiologically correlated with location in the three cardinal planes. This case reflects classic allergic fungal sinusitis where the opacified sinuses are filled with heterogeneous whitish material on computed tomography images. Polyps in the ethmoid cavity are seen on the endoscope image.

Figure 18-9. Sphenoid sinus fungal ball. The sinus has been opened revealing cheesy material during this intraoperative endoscopic view (lower right). The crosshairs stereotactically confirm location within the sphenoid sinus radiologically in the cardinal planes.

symptomatology despite medical therapy. However, there currently exists no consensus regarding what constitutes a “maximum” course of medical therapy. It should be noted that unless there is suspicion of neoplasm or pending complication of rhinosinusitis, the decision to proceed with surgery is highly individualized. This is because surgery for uncomplicated CRS is elective, and patients who “fail” medical management will exhibit significant variability in symptoms, physical signs, and CT findings. Furthermore, ESS is not necessarily curative—the intent of ESS is to remove the symptoms related to CRS rather than cure the underlying condition itself.

Surgery is typically performed endoscopically where the goals are to remove polyps, enlarge or remove obstructing tissue surrounding the natural sinus ostia (Fig. 18-10), and remove chronically infected bone and mucosa to promote both ventilation and drainage of the sinus cavities. In spissated mucin or pus is drained and cultured. Eventual resolution of the chronic inflammatory process can be attained with a combination of meticulous surgery and directed medical therapy, although the patient must understand that surgery may not alter the underlying immunologic pathophysiology. In cases where resection of inflammatory tissue and polyps are not required, recent trends have also included use of angioplasty-type balloons to dilate sinus ostia. The exact role for this technology is unclear, but it appears to have promise in outpatient office management of patients with focal or limited obstructive pathology.

Endoscopic Skull Base Surgery. Over the past three decades, the development and expansion of multidisciplinary skull base

teams has become somewhat commonplace at large academic institutions. Facilitated mainly by growing cooperation between otolaryngologists and neurosurgeons, a variety of approaches that utilize the sinonasal corridor to treat a plethora of pathologic processes of the anterior skull base have been developed.

Technological advances in endoscopy, instrumentation, and imaging have also facilitated the development of endoscopic endonasal approaches (EEAs), allowing team members to work simultaneously while maintaining optimal visualization of the relevant anatomy and freedom of movement within the corridor. Although historically the sphenoid sinus has been the common access route in the management of sellar pathology, a series of modular approaches of varied complexity have been developed that have broadened the reach of EEAs to address lesions at virtually all compartments of the ventral skull base, from the crista galli to the anterior arch of C2.²²

One of the key tenets of the EEA is that the sinonasal corridor presents the most prudent and safest path to the lesion of interest. Accordingly, the EEA is generally chosen for lesions adjacent to the skull base, without intervening brain parenchyma, cranial nerves, major vessels, or other important anatomical structures. Currently, EEAs are utilized to treat a significant number of pathologic process involving the skull base, including: cerebrospinal fluid leaks, encephaloceles, meningoceles, pseudomeningoceles, benign intracranial tumors (Fig. 18-11), benign sinonasal tumors, malignant sinonasal tumors, and inflammatory or traumatic conditions leading to compression at the craniovertebral junction. Although EEAs tend to be considered “minimally invasive,” the corridor created in the sinonasal cavity is nonetheless comprehensive enough to

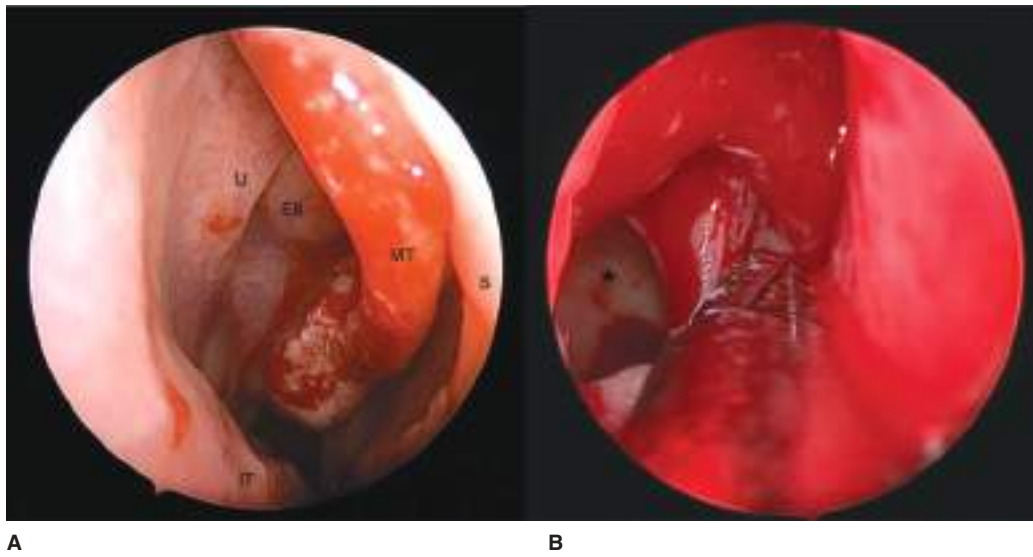

Figure 18-10. **A.** Endoscopic view of the right nasal cavity demonstrating the uncinate process (U), ethmoid bulla (EB), middle turbinate (MT), inferior turbinate (IT), and nasal septum (S). **B.** Endoscopic view of a microdebrider being used to widen the right maxillary sinus ostium.

Figure 18-11. Preoperative coronal (A) and sagittal (B) magnetic resonance images of a large olfactory groove meningioma removed using endoscopic endonasal approach. Postoperative coronal (C) and sagittal (D) images demonstrating removal of the tumor. The skull base can be reconstructed using local flaps (most commonly a nasoseptal flap pedicled on the posterior nasal artery).

Figure 18-12. Two-surgeon, three- to four-hand technique utilized in endoscopic endonasal surgery.

provide maximal freedom of movement for the critical component of the case (i.e., tumor resection near vital structures). Once the corridor is created by the otolaryngologist, the neurosurgeon joins, and a two-person, three- to four-hand technique is utilized to address the lesion of interest and reconstruct the skull base (Fig. 18-12).

Despite the relatively confined aperture provided by the nostrils, even large tumors can be removed using EEAs, albeit via piecemeal removal. For malignant tumors, this has required a philosophical shift whereby en bloc resection of the entire tumor is replaced by piecemeal removal of the bulk of the tumor followed by complete resection of the pedicle with sufficient margins. Outcomes utilizing EEAs for resection of malignant tumors, when chosen appropriately, parallel those of traditional open approaches. However, EEAs are not favored over traditional approaches when oncological principles would otherwise need to be violated.

Pharyngeal and Adenotonsillar Disease

Waldeyer's ring consists of the palatine tonsils between the anterior and posterior tonsillar pillars, the lingual tonsils (lymphoid tissue in the base of tongue), and the adenoid located in the nasopharynx. These four main sites of Waldeyer's ring are connected by other minor lymphoid tissue along the posterior and lateral pharyngeal wall completing the ring. These are all considered mucosa-associated lymphoid tissue (MALT). These tissues react to inflammatory disease, infection, trauma, acid reflux, and radiotherapy. Even the vibratory effects of chronic snoring have been implicated in the development of adenotonsillar disease. Inflammation of these tissues can lead to referred pain through cranial nerves IX and X to the throat and ear. Adenotonsillar tissue does not have any afferent lymphatics and receives antigen presentation directly, with appropriate production of memory cells. However, there is no clear immune compromise after removal.

Microbiology and Complications. Adenotonsillar infections present with three temporal patterns: acute, recurrent acute, and chronic. Acute infection is typically viral in origin but secondary bacterial invasion may initiate chronic disease. Viruses do not cause chronic infections; however, Epstein-Barr Virus (EBV) can cause significant hypertrophy. Systemic EBV infection, also known as mononucleosis, can mimic bacterial pharyngitis, but the progression of signs and symptoms demonstrates lymphadenopathy, splenomegaly, and hepatitis. This can be diagnosed on bloodwork (heterophile antibody or atypical lymphocytes). The most common bacterial causes of acute tonsillitis are group A β -hemolytic streptococcus species (GABHS) and *S pneumoniae*.²³ If GABHS is confirmed, then antibiotic therapy is warranted in the pediatric population to decrease the risk (3%) of developing rheumatic fever. A positive test for GABHS historically meant a throat swab with culture and sensitivity; however, rapid antigen assays have been demonstrated to be reasonably sensitive and specific (85% and 95%, respectively), thus largely replacing cultures.²⁴ If the rapid assay is negative, then a culture is warranted. The remainder of the bacteriology for adenotonsillar disease is similar to otitis media and sinusitis, which includes *H influenzae* and *M catarrhalis*. Atypical infections include *Corynebacterium diphtheria*, *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*.

Complications of GABHS pharyngitis, typically from *S pyogenes*, can be systematic and include poststreptococcal glomerulonephritis, scarlet fever, and rheumatic fever. Antibiotic therapy does not decrease the incidence of glomerulonephritis. Scarlet fever, caused by blood-borne streptococcal toxins, causes a strawberry tongue and a punctate rash on the trunk that spreads distally while sparing the palms and soles. Peritonsillar abscess is also a common complication that is treated in an ambulatory setting through a transoral approach after appropriate topicalization and local anesthetic. Deep neck space infections are rare from pharyngitis but can occur from odontogenic and salivary gland infections. These typically require a transcervical approach for incision and drainage.

Adenoids and Adenoidectomy. Acute adenoiditis typically presents with purulent rhinorrhea, nasal obstruction, and fever and can be associated with otitis media, particularly in the pediatric population. Recurrent acute adenoiditis is defined as four or more acute infections in a 6-month period, but in an adult, this may be difficult to distinguish from recurrent acute sinusitis, and endoscopy with or without imaging of the sinuses may be warranted to distinguish between the two diagnoses. Chronic adenoiditis presents with persistent nasal discharge, halitosis, chronic congestion, and postnasal drip. In children, obstructive adenoid hyperplasia often requires surgical intervention to help relieve obstructive symptoms such as snoring, obligate mouth breathing, and hyponasal voice.

The management of adenoid disease is slightly different than that for tonsillar disease. Chronic infection can be treated with antibiotics, although this often does not lead to a full resolution of symptoms. If the adenoid bed appears hyperplastic on lateral X-ray imaging or endoscopy, a 2-month trial of nasal steroids may be helpful. Adenoidectomy is indicated for recurrent and chronic infections that have failed conservative management. These infections are not limited to the adenoid bed but also involve the sinuses and the middle ear. Adenoidectomy with a myringotomy and ventilation tube placement is beneficial for recurrent or chronic otitis media in children because the

adenoid functions as a reservoir for bacteria that can enter the middle ear through the Eustachian tube.²⁵

Adenoidectomy is also the first line of surgical management for children with chronic sinusitis because the adenoid can obstruct mucociliary clearance from the sinonasal tract into the choana and ultimately into the pharynx. Patients with obstructive systems attributable to the adenoids and suspected benign or malignant neoplasms of the adenoid bed are also candidates. However, the procedure is contraindicated in patients with velopalatine insufficiency (VPI) and in patients with a cleft palate. Prior to adenoidectomy, patients should be examined for a submucous cleft, a lack of midline muscular tissue of the soft palate. Clinical signs of this include a bifid uvula, a translucent portion of the muscular diastasis of the soft palate (zona pellucida), and a palpable notched hard palate.²⁶ A number of different methods can be used to perform an adenoidectomy: cold steel, suction coagulator, microdebrider, and coblation. Adenoid regrowth and bleeding rates are both low, and no study has been able to demonstrate the superiority of one technique over the other for either outcome.^{27,28} Adenoidectomy is not without complications though, beyond VPI and bleeding, halitosis and adenoid bed regrowth (~1%) are common complications. Rare complications include torticollis secondary to inflammation of the prevertebral fascia, nasopharyngeal stenosis, and cervical spine subluxation, which is more common in patients with Down syndrome.

Tonsils and Tonsillectomy Patients with acute tonsillitis present with sore throat, fever, dysphagia, and tender cervical nodes with erythematous or exudative tonsils. The Centor Criteria is used to identify the likelihood of bacterial infection in adult patients complaining of sore throat in the emergency department or walk-in clinic, a point is given for each of the following: fever, tonsillar exudate, lymphadenopathy, and lack of cough.²⁹⁻³¹ A score of 0 to 1 warrants no treatment, a score of 2 to 3 warrants GABHS testing, and a score of 4 warrants initiation of antibiotic therapy. First-line treatment is with penicillin or a cephalosporin; however, in those with an allergy, a macrolide can be considered. Documentation of recurrent acute infections should include a temperature (>38.3°C), cervical adenopathy, tonsillar exudate, and a positive test for GABHS. According to the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) clinical practice guideline on tonsillectomy in children, tonsillectomy is indicated when children have more than 7 documented episodes per year, 5 episodes per year in the past 2 years, or 3 episodes per year in the past 3 years.²³ Tonsillectomy can still be considered in children who do not meet these criteria if they have multiple antibiotic allergies or intolerances, have a history of peritonsillar abscess after the acute inflammation has resolved, or have PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and adenitis). A peritonsillar abscess is an infection of the peritonsillar salivary gland (Weber's gland), located between the tonsil capsule and the muscles of the tonsillar fossa. In selected cases of active peritonsillar abscess, tonsillectomy is required in the acute setting to treat systemic toxicity or impending airway compromise. Multiple techniques have been described, including electrocautery, sharp dissection, laser, and radiofrequency ablation. There is no consensus as to the best method.

Sleep Disordered Breathing and Adenotonsillar Disease. Patients with sleep-disordered breathing (SDB) and tonsillar hypertrophy may also benefit from tonsillectomy if they

have growth retardation, poor school performance, enuresis, or behavioral problems. The benefits may be accentuated in children with abnormal polysomnography; however, DB may require further treatment after tonsillectomy when it is multifactorial. Clinical documentation of tonsillar grade/size is based on the percentage of the transverse oropharyngeal space measured between the anterior tonsillar pillars: grade 1+ <25%; grade 2+ 25% to 49%; grade 3+ 50% to 74%; grade 4+ ≥75% or more sometimes referred to as “kissing tonsils.”³² Tonsillectomy is effective for control of SDB in 60% to 70% of patients with tonsillar hypertrophy, although this much lower (10%–25%) in obese children, and it is therefore not curative in obese children but may improve some of their symptoms nonetheless. In patients with Down syndrome, obesity, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidoses, polysomnography (PSG) should be performed prior to tonsillectomy.³³ When the need for surgery is uncertain or when there is a discordance between tonsillar size on physical examination and the reported severity of SDB, physicians should advocate for PSG prior to tonsillectomy. Tonsillectomy, usually with adenoidectomy if the adenoids are enlarged, is often performed on an outpatient basis unless the patient has documented or strongly suspected obstructive sleep apnea (OSA), is <3 years of age, or has severe OSA (in children, an apnea-hypopnea index ≥10 or more, oxygen saturation <80%, or both). Other reasons for admission include a home >1 hour from a hospital, patients with craniofacial abnormalities, or any other medical issue. There is strong evidence to suggest the routine administration of a single intraoperative dose of IV dexamethasone in children undergoing tonsillectomy, though antibiotics should not be administered or prescribed perioperatively in children. The complications from tonsillectomy include perioperative bleeding (3%–5%), airway obstruction, death, and readmission from postoperative dysphagia leading to dehydration.³⁴ It is recommended that surgeons calculate and quote their own primary and secondary posttonsillectomy hemorrhage rates yearly.²³ A rare but serious complication in patients with obstructive adenotonsillar disease post adenotonsillectomy is postobstructive pulmonary edema syndrome, which presents with decreased oxygen saturation and frothy, blood-tinged oral secretions. Patients usually recover with reintubation, positive pressure, diuresis, and supportive care.

Multilevel Sleep Surgery. SDB surgery is often multilevel and is not limited to adenotonsillar disease. Patients with nasal obstruction may benefit from septoplasty and turbinate reduction, although in the adult population this is most commonly used to allow patients to tolerate their OSA appliances. Similarly, patients with significant lingual tonsillar hypertrophy and a large base of tongue may benefit from a base of tongue reduction, tongue base advancement, or genioglossopexy. A base of tongue reduction alone does not often provide enough apnea-hypopnea index reduction (30%–60%) for resolution of symptoms and is fraught with a high morbidity rate.³⁵ Rarely, maxillomandibular advance is required to open up the retrolingual space. In patients with life threatening symptoms (right heart failure/cor pulmonale, oxygen saturation <70%, comorbid cardiopulmonary disease) who have failed other measures, the only “cure” for OSA is a tracheotomy.

Other Tonsillar Pathology. Unilateral tonsillar hypertrophy is mostly likely benign but can also be the result of *Mycobacterium tuberculosis*, atypical mycobacterium, fungi, or *Actinomyces*. With the epidemic rise in incidence of oropharyngeal

cancers, neoplasms (squamous cell carcinoma and lymphoma) have increasingly also presented as tonsillar asymmetry.³⁶ Management of these lesions is dependent on the pretest probability of malignancy and the type of malignancy. If squamous cell carcinoma is suspected, then a biopsy alone is sufficient so as to not impact the possibility of other future surgical interventions such as transoral robotic surgery. If lymphoma or a nonmalignant pathology is suspected, tonsillectomy is often recommended for diagnostic and therapeutic reasons, and the specimen should be sent fresh to pathology for a lymphoma protocol workup, bacterial and fungal culture, and gram stain. Pharyngitis may also be seen in immune-mediated conditions such as erythema multiforme, bullous pemphigoid, and pemphigus vulgaris.

Benign Conditions of the Larynx

Hoarseness is the most common presenting symptom for patients with a voice complaint. Other complaints include breathiness, weakness/hypophonia, aphonia, and pitch breaks. Voice disorders affect a large range of patient ages, occupations, and socioeconomic statuses and affect both genders equally. They can be associated with dysphagia, globus sensation, laryngopharyngeal reflux (LPR) disease and, rarely, airway obstruction.³⁷ Smoking can both cause and aggravate preexisting benign laryngeal conditions and raises the suspicion of malignancy often requiring a biopsy to exclude this diagnosis.

Any discussion of laryngeal disorders should start with a review of the anatomy of the vocal cords (Fig. 18-13). The true vocal cords are formed from stratified squamous epithelium, beneath which is the superficial lamina propria (in Reinke's space). Beneath this is the ligament that includes the middle

and deep lamina propria. Beneath this ligament is the muscular layer that includes the thyroarytenoid muscle or vocalis. The cover-body theory describes the freely mobile cover (mucosa and Reinke's space) over the more rigid body (vocal ligament and vocalis).³⁸

Membranous vocal cord lesions have been notoriously difficult to classify reliably; however, increased availability of videostroboscopic examination and standardized definitions have improved the classification of these lesions.³⁹ These lesions are usually mid cord because that is the site of maximal lateral displacement and amplitude. *Vocal fold nodules* are typically bilateral, fairly symmetric, and with normal or mild impairment of the mucosal wave, and they almost always resolve with voice therapy. A *vocal fold polyp* is more often unilateral than bilateral, is exophytic, and is associated with unorganized gelatinous debris in the subepithelial space. These can be hemorrhagic as is often seen in males secondary to capillary rupture within the mucosa by shearing forces during voice abuse. Hemorrhagic polyps are seen more often in patients on anticoagulants. These lesions usually fail conservative measures (voice rest, voice therapy, smoking cessation, and reflux management) usually requiring microlaryngeal surgery to remove the lesion while preserving normal mucosa. *Vocal fold cyst* is an encapsulated lesion within the subepithelial or ligamentous space and is associated with reduced mucosal wave. It typically does not resolve with voice therapy. These lesions require microlaryngeal surgery for complete removal of the cyst while preserving the overlying mucosa, and this surgery can be performed with cold steel or carbon dioxide (CO₂) laser. A *fibrous mass* of the vocal fold is amorphous fibrous material within the subepithelial space or

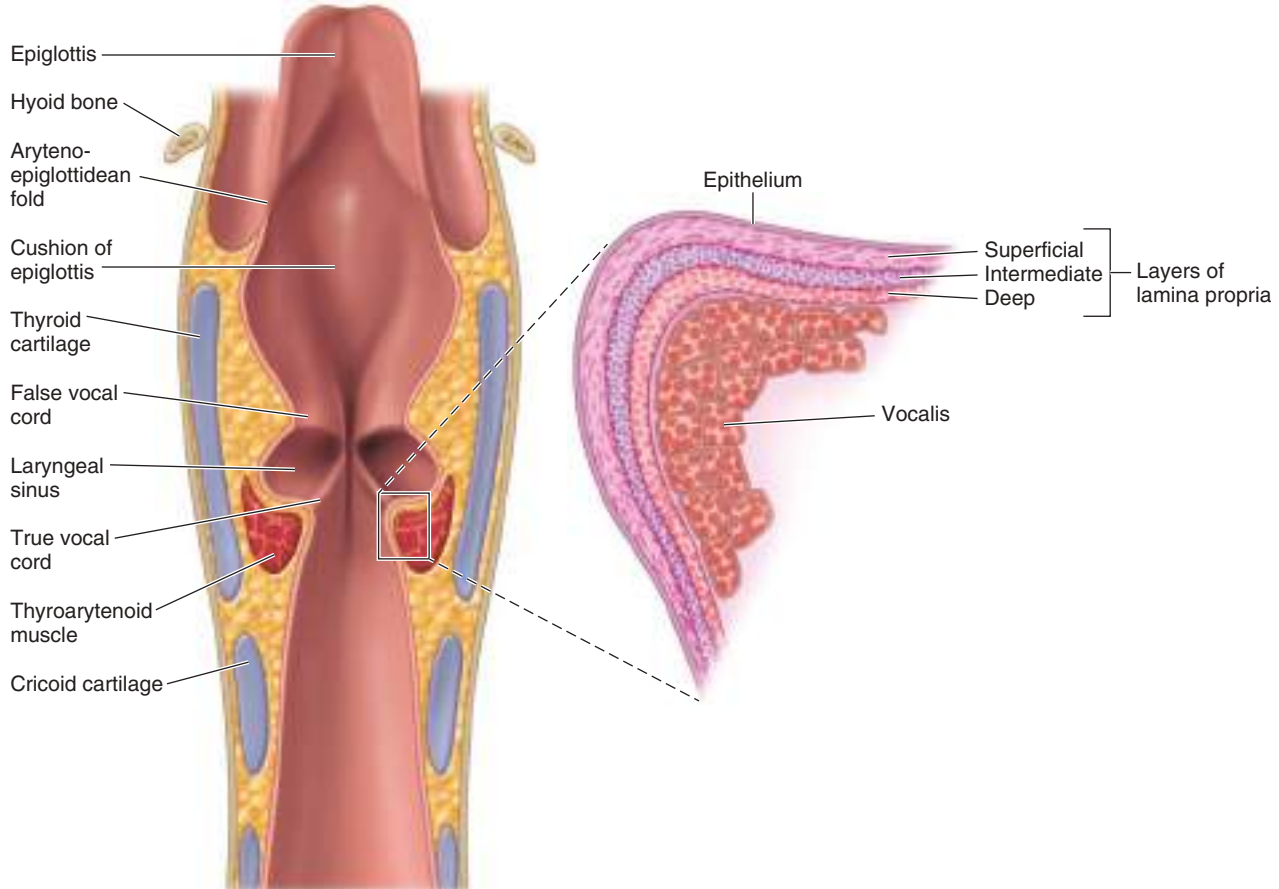

Figure 18-13. Coronal view of the larynx demonstrate the supraglottic, glottic and subglottic (LEFT) and the layers of the true vocal cord (RIGHT).

ligament often associated with reduced mucosal wave, and it also does not resolve with voice therapy.

Reinke's edema is characterized by edema in the superficial lamina propria of the vocal cord. Edema is thought to arise from injury to the capillaries that exist in this layer, with subsequent extravasation of fluid. The etiology is multifactorial: smoking, LPR, hypothyroidism, and vocal misuse.⁴⁰ This pathology is more common in women (because they present early due to a deep vocal pitch change in their voice) and heavy smokers. The physical examination findings are typically bilateral. Surgery typically involves microlaryngoscopy with removal of the gelatinous debris in Reinke's space with trimming of the excess mucosa. However, smoking cessation and surgery do not fully reverse the structural abnormalities due to the presence of possible structure alterations in fibroblasts caused by the toxicity of cigarette components, resulting in uncontrolled production of fibrous matrix in the lamina propria, thus preventing complete vocal recovery.⁴¹

Laryngeal granulomas typically occur in the posterior larynx on the arytenoid mucosa (Fig. 18-14). These lesions are typically multifactorial: chronic throat clearing, phonotrauma, endotracheal intubation, compensatory supraglottic squeeze from vocal fold paralysis, and LPR.⁴² The majority of these lesions (82%) disappear within 48 weeks with conservative measures such as voice therapy, vocal rest, oral steroids, inhaled steroids, and proton pump inhibitors.⁴² Botulinum toxin of thyroarytenoid and lateral cricoarytenoid muscles can be used as first-line treatment in patients who prefer a chemically activated voice rest regiment.⁴² LPR appears to be the most important contributing factor,⁴² and when aggressive conservative and medical therapy has failed, a Nissen fundoplication may be indicated. Surgery is rarely required for patients with laryngeal granulomas because it does not address the underlying etiology and is frequently associated with recurrence. Nonetheless, excision is sometimes required in patients with airway obstruction or the suspicion of malignancy. Careful preservation of the arytenoid perichondrium intraoperatively is required to assist with reepithelialization and to decrease the risk of recurrence postoperatively.

Recurrent respiratory papillomatosis (RRP) is pathophysiologically associated with human papillomavirus (HPV) within the mucosa of the upper aerodigestive tract. The glottis and supraglottis are the two most common involved subsites. HPV 6 and

Figure 18-14. Laryngeal granuloma.

11 are the most often implicated types; however, LPR and herpes simplex virus (HSV) type-2 are risk factors of adult-onset RRP.⁴³ The disorder typically presents in early childhood (juvenile-onset RR; JoRRP) secondary to HPV acquisition during vaginal delivery; however, children born by caesarean section are also at risk for the disease. JoRRP usually resolves around puberty but can progress into adulthood. Adult-onset RRP is less severe and is more likely to involve extralaryngeal subsites. There is no cure for RRP. Surgery excision is used to improve voice and airway symptoms in a palliative fashion. Surgical excision in the operating room involves microlaryngoscopy with the use of the laser (CO₂ for bulky disease or KTP for more superficial disease) or the use of a microdebrider. The microdebrider has been demonstrated to have superior voice outcomes in JoRRP; however, CO₂ laser is the most commonly used operative ablative technique used in adults.⁴⁴ Recent advances have made it possible to treat a select group of adult RRP patients in the office using the KTP laser, typically for those with a lower disease burden.⁴⁵ Several adjuvant treatments are used to increase the intersurgical interval, including intralesional cidofovir injection, oral indole-3-carbinol, oral methotrexate, and retinoic acid. In addition to preventing RRP in some patients, the HPV vaccine has also been demonstrated to increase the intersurgical interval in the most aggressive JoRRP patients.^{46,47}

Leukoplakia is a white patch seen on mucosa that can be wiped off on physical examination. This can be seen anywhere in the upper aerodigestive tract. In the larynx, this is typically seen on the superior surface of the true vocal cords and may represent squamous hyperplasia, dysplasia, and/or carcinoma with an associated risk of malignant transformation of 1% to 3% in hyperplastic lesions and 10% to 30% in dysplastic lesions. Lesions that are not overtly suspicious for malignancy, particularly in patients without a strong smoking or alcohol history, can be managed conservatively (increased hydration, elimination of poor vocal habits, phonotrauma, and management of LPR) for 1 month before reevaluation with fiberoptic laryngoscopy. Any lesions that progress, persist, or recur could have microlaryngoscopy with complete excision. Similarly, because erythroplasia and ulceration are more suggestive of malignancy, these lesions also require an excisional biopsy in the operating room.

The most common cause of *unilateral vocal cord paresis* is iatrogenic in origin, following surgery to the thyroid, parathyroid, carotid, spine through an anterior approach,⁴⁸ or cardiothoracic structures.⁴⁹ It is therefore very important that all patients undergoing thyroid surgery receive preoperative visualization of the larynx, usually in the form of fiberoptic nasolaryngoscopy, although an indirect mirror exam can be used if adequate visualization is possible.⁵⁰ Postthyroidectomy visualization may also be required to document normal vocal cord movement. Less common causes include malignancy of structures near the recurrent laryngeal nerve (RLN) from the skull base jugular foramen to the mediastinum. In the pediatric population, there can be neurologic causes, the most common of which is the Arnold-Chiari malformation.⁵¹ Overall, the left vocal cord is more commonly involved secondary to the longer course of the RLN on that side. Other rare etiologies include trauma, intubation injury, atypical infections, and neurotoxic medications. Patients typically present with a weak breathy voice and may have aspiration secondary to diminished supraglottic sensation if the proximal vagal nerve or superior laryngeal nerve is involved. RLN injury is also associated with delayed relaxation

of the cricopharyngeus muscle that can lead to dysphagia and decreased sensation in the hypopharynx, which can cause pooling of secretions. In children, stridor, weak cry, and airway compromise may be presenting symptoms, whereas in adults this is rarely the case unless there is *bilateral vocal cord paralysis*. When an obvious cause is not identified after a thorough history and physical examination including fiberoptic nasolaryngoscopy, then a more comprehensive workup is required. A workup should not include autoimmune serology as a screen because this is low yield, but this can be included if there is a suspicion of autoimmune disorders. Imaging, in the form of a CT scan, is the mainstay of the workup and should include the skull base to the mediastinum. Repeat imaging is beneficial in this population within a 2-year period because many patients have undiagnosed small malignancies as the primary cause of their paralysis that are too small to detect on initial imaging.⁵² Laryngeal electromyography can assist with identifying whether the paresis is a result of a paralysis or cricoarytenoid joint fixation/dislocation. It can also help prognosticate a paralysis. This is, however, rarely used in practice. Despite an extensive workup, 20% to 35% of cases are idiopathic.

The management of bilateral vocal cord paralysis almost always requires a tracheotomy because the cords are left in a paramedian position leaving a slit light glottic aperture. If the paralysis is permanent, then a cordectomy with or without arytenoidectomy can be used to open up the airway in an attempt to eventually decannulate the patient. However, this has obvious implications for voice with a weak and breathing voice. Many patients with a unilateral paralysis compensate when the cord is in the paramedian position using supraglottic structure and the contralateral cord on their own or with speech therapy. However, in patients with a less than adequate voice-related quality of life, four techniques have been used to surgically manage patients with a unilateral vocal cord paralysis: *injection laryngoplasty*, *medialization thyroplasty*, *arytenoid adduction*, and *laryngeal reinnervation*. Injection laryngoplasty involves injecting a temporary filler medial to the vocalis into the ligament at the posterior and midmembranous vocal cord. This can be performed in the office or in the operating room, depending on the comfort of the surgeon and patient characteristics. Materials used include autologous (fat, collagen) or alloplastic (hydroxyapatite, hyaluronic acid, micronized cadaveric human collagen) compounds. Early medialization is recommended in patients with mediastinal and thoracic malignancies because it is safe and has been shown to improve quality of life in a palliative setting.⁵³ Teflon is historic and is no longer used because of its granulomatous side effects on the larynx. A more permanent medialization can be performed using a medialization thyroplasty, during which a small window is created in the inferolateral aspect of the thyroid cartilage and a submucosal-carved silastic block is placed in the operating room with the patient under neurolept anesthetic so that vocalization and flexible laryngoscopic visualization of the larynx can be improved (Fig. 18-15). In some cases, this is not enough of a medialization due to a large posterior glottic chink, and an arytenoid adduction is required to provide better closure of the posterior glottis and supraglottis with ensuing improved vocal outcomes. This is a technically challenging procedure that is rarely required, but in select patients it is associated with significant improvements in voice. Lastly, laryngeal reinnervation, typically with the ansa cervicalis that supplies motor function to the strap muscles, can also be performed. This is the best approach in patients who

Figure 18-15. Hand carved silastic block for thyroplasty.

have had a recurrent laryngeal nerve severed during a central or upper mediastinal neck procedure because it is in the field.⁵⁴ Multiple studies demonstrate favorable outcomes; however, no significant differences between treatment arms has been demonstrated based on perceptual, acoustic, quality of life, and laryngoscopic outcomes.⁵⁵

Vascular Lesions

Vascular lesions can be broadly classified into two groups: hemangiomas and vascular malformations.⁵⁶

Hemangiomas. Hemangiomas are the most common vascular lesion present in infancy and early childhood. *Infantile hemangiomas* present largely within the first few weeks of life. Initially they proliferate (2 weeks to 1 year), and then they begin to involute (1–7 years) until they have fully involuted, leaving the child with redundant skin, scar, or a fatty lesion. Children with large facial infantile hemangiomas benefit from regular neurological examinations and brain MRI to rule out PHACES syndrome (*Posterior fossa malformations, Hemangiomas, Arterial lesions, Cardiac abnormalities/aortic coarctation, Eye abnormalities*). Only 10% of these lesions require early intervention because of impairment of vision or swallowing, or airway compromise. Early intervention can include medical management, such as systemic steroids, intralesional steroids, intralesional interferon α -2a, or photocoagulation therapy, and surgical management, including excision with CO₂ laser/microdebrider and tracheotomy. Systemic steroids assist with rapidly proliferating lesions until the child reaches approximately one year of age; however, it is associated with growth retardation and immune suppression. Intralesional interferon α -2a has been largely abandoned because it is a daily subcutaneous injection and is associated

with significant neurological side effects, including spastic diplegia. Photocoagulation therapy with either the flashlamp-pumped pulsed-dye laser (FPDL), the potassium titanyl phosphate (KTP) laser, or the neodymium yttrium-aluminum garnet (Nd:YAG) laser, is repeated every 4 to 6 weeks until the lesion disappears. A randomized trial recently demonstrated that propranolol was effective at a dose of 3mg/kg per day for 5 months in the treatment of infantile hemangioma with a very acceptable and low side-effect profile.⁵⁷ Other groups have had success at discontinuing propranolol at 1 year of age with excellent outcomes.⁵⁸ For patients who do not require early intervention, the lesion is observed every 3 months for involution after the proliferative phase has ended. Surgery is considered if regression has not occurred by 5 years of age because the cosmetic result is less likely to be satisfactory.

Congenital hemangiomas differ from infantile hemangiomas in that they reach their maximal size at birth and do not have a proliferative phase. There are two subtypes: rapidly involuting (RICH), which typically disappears by 1 of age with minimal fatty appearance upon resolution, and noninvoluting (NICH). The management is similar to infantile hemangiomas with the exception that medical management is not typically necessary.

Vascular Malformations. Vascular malformations, in contrast to infantile hemangioma, are always present at birth, although they may not be apparent for a few months. Although they do not have a proliferative phase, they grow with the patient, have hormonal growth spurts and do not involute.⁵⁹ Vascular malformations can be classified as low flow (capillary, venous, lymphatic, and mixed), which comprise approximately two-thirds of all vascular malformations, or high flow (arteria and arteriovenous).

Capillary malformations arise from the cutaneous superficial plexus and are made up of capillary and postcapillary venules with a pink, red, or purple macular-papular appearance. Venous malformations arise from dilated vascular channels lined by normal endothelium; therefore, they are soft, compressible, and nonpulsatile. If they are superficial, they will increase in size with Valsalva or dependent positioning. They can grow suddenly with trauma or in association with hormonal changes. Lymphatic malformations typically present at birth with the majority (90%) being identified by 2 years of age. They can be macrocystic (>2 cm), microcystic (≤2 cm), or a combination. They are most commonly found in the head and neck, particularly on the neck, and on physical examination they are soft and doughy with normal overlying skin. Infrahyoid lesions tend to be macrocystic, well circumscribed, and discrete and can be totally excised, whereas suprahyoid lesions are typically microcystic, infiltrative, and excision is usually incomplete. On MRI, the best imaging modality for this malformation, a septated mass with low-intensity signal on T1 and high-intensity signal on T2 is noted. They grow slowly with the patient but can have a sudden increase in size with hemorrhage or infection. Rarely, they cause airway compromise, feeding difficulties, and failure to thrive.

Treatment of vascular malformations is based on depth, size, and growth pattern. Capillary malformations are typically treated with the pulsed dye laser (585 nm). Venous lesions can be treated with the KTP laser (532 nm) or the Nd:YAG laser (1064 nm), sclerotherapy, and, in select cases, complete surgical excision is possible. Arteriovenous malformations are rare

but typically require surgical excision with negative margins often after embolization. Lymphatic malformations are typically treated at least in part with surgical excision, although this is less successful for microcystic lesions. OK-432 is lyophilized low virulence *S pyogenes* cultured in penicillin. It is used as a sclerotherapy agent for lymphatic malformations and has a 94% response rate in macrocystic lesions, a 63% response rate in mixed macromicrocystic lesions, and no response in microcystic lesions.⁶⁰

TRAUMA OF THE HEAD AND NECK

Soft Tissue

Soft tissue trauma of the head and neck is managed with the same general surgical principles as any other body subsite with a few particularities. Most lacerations can be closed primarily if there is not soft tissue loss; even some devitalized soft tissue should be preserved because of the excellent blood supply to head and neck tissue that allows it to recover at a higher rate. Thus, minimal debridement is usually required. Thorough irrigation to remove foreign bodies and clean the tissue is required. This is followed by a careful layered closure. On the face, the deep layers are usually closed with a 3-0 or 4-0 Vicryl/Polysorb after a minimal amount of undermining, and interrupted 5-0 or 6-0 Prolene or Nylon is used for the skin. These sutures are removed at 5 days on the face. Antibiotics are reserved for through-and-through mucosal lacerations, contaminated wounds, bite injuries, and when delayed closure is performed (>72 hours). The chosen antibiotic should cover *S aureus*. Patients are instructed to avoid sunlight because this can cause pigmentary abnormalities in the suture line as it heals and matures over the first year.

Eyelid lacerations are closed in layers with careful reapproximation of the orbicularis oculi as a separate layer. Another important layer to reapproximate separately is the gray line (conjunctival margin) so as to avoid height mismatch or lid notching. Lip injuries follow the same principle with a three-layer closure involving the orbicularis oris, which is the strength layer, followed by careful reapproximation of the vermilion border to avoid a step-deformity (Fig. 18-16). Of course, a mucosal layer closure may also be required for through-and-through defects. Rarely, locoregional flaps or grafts are required for closure when greater than one-fourth of the eyelid width or one-third of the lip width is missing. Auricular hematoma is managed with prompt incision and drainage followed by bolstering technique; anteriorly and posteriorly placed dental pledgets secured with through-and-through sutures. These are to remain in place for at least 4 days to prevent reaccumulation of the hematoma and to prevent a cauliflower ear deformity. Auricular lacerations are typically closed primarily with perichondrial sutures to preserve the precarious cartilage blood supply followed by a primary closure of the skin, making sure to cover the cartilage to prevent chondritis. Given the rich vascular supply to the face and neck, many soft-tissue components that appear devitalized will indeed survive, and therefore minimal debridement of devitalized tissue is required.

Facial lacerations resulting in facial nerve injury are not explored if they are anterior to a vertical line dropped from the lateral cantus as there is excellent collateral innervation in the anterior midface. Posterior to this line, the nerve should be repaired, primarily if possible, using 8-0 to 10-0 monofilament suture to approximate the epineurium under the operative

Figure 18-16. Approximation of the vermilion border is the key step in the repair of lip lacerations.

microscope. If primary reapproximation is not possible due to a missing segment, cable nerve grafts can be performed using the sural nerve or the greater auricular nerve. If the buccal branch is injured, this raises suspicion regarding injury to the parotid duct, which lies along an imaginary line drawn from the tragus to the midline upper lip. The duct should be repaired over a 22-gauge stent or marsupialized into the oral cavity.

Facial Fractures

The most common facial fracture involves the mandible. Fig. 18-17 demonstrates the most common sites of fracture, which include the condyle (36%), body (35%), and angle (20%). In most cases, more than one site is involved due to reciprocating forces. The vector forces from the muscles of mastication, vertical from the masseter and horizontal from the pterygoid muscles, can cause a fracture to be favorable or unfavorable depending on the angle of the fracture line. After taking a history and performing a physical examination, imaging is performed in the form of a Panorex or a CT scan. Where closed reduction can be achieved, patients are placed in maxillomandibular fixation (MMF) with arch bars applied via circumdental wiring, and these are left in place for 4 to 6 weeks depending on patient factors and the fracture location. In elderly patients, this is kept in for 6 to 8 weeks. In children and patients with condylar fractures only 2 to 3 weeks is required, and this is important to prevent condylar ankylosis. During this time, patients are placed on a liquid diet and are provided with wire cutters in case of aspiration or airway emergency. Open reduction and fixation is indicated in patients with open, comminuted, displaced, or unfavorable fractures. In these patients, MMF is usually only temporary with a soft diet starting almost immediately in the postoperative setting. Because the MMF is temporary with rigid fixation, it is performed usually using the 4-point fixation technique, where the

Figure 18-17. Sites of common mandible fractures.

maxilla and mandible are held in occlusion by wires attached to intraoral cortical bone screws, with two screws above and below the occlusal line anteriorly. This is a benefit of open reduction and internal fixation because prolonged MMF is associated with gingival and dental disease, as well as with significant weight loss and malnutrition, during the fixation period. After fixation, the fracture is exposed, more commonly from a transcervical compared to a transoral approach. Care is made not to injure the marginal mandibular branch of the facial nerve during this exposure. A rigid, locking, load-bearing mandibular plate is used. In edentulous patients, determining the baseline occlusion is of less significance because dentures may be refashioned once healing is complete.

Midface fractures are rarely isolated and include multiple subsites. However, isolated zygoma fractures are typically displaced inferiorly and medially with disruption of the suture lines between the temporal, frontal, and maxillary bones and the zygoma. If multiple zygoma fractures are present or if the zygomatic arch is significantly displaced, a coronal incision is required to perform the reduction and fixation. However, if it is an isolated depressed fracture, a Gilles reduction can be achieved inferiorly (transorally) or superiorly (along temporalis muscle). The pathophysiology of orbital blow-out fractures is (a) hydraulic from increased intraocular pressure or (b) buckling from direct bone conduction. This requires surgical intervention if there is a defect of $>2 \text{ cm}^2$ or $>50\%$ of the floor with herniation.⁶¹ A forced duction test, where the muscular attachment of the inferior oblique is grasped with forceps and manipulated to determine passive ocular mobility, is performed to ensure that there is not inferior rectus entrapment. If there is entrapment, this would also result in diplopia with upward gaze. Blowout fractures demonstrating significant entrapment or enophthalmos are treated by orbital exploration and reinforcement of the floor with titanium mesh, hydroxyapatite, or split calvarial bone grafts. Sometimes, the anterior maxillary bone that has been fractured and is accessed in the process of repairing other fractures can also be used.⁶²

There are three classic patterns of more extensive midface fractures: Le Fort I, II, and III. However, fractures rarely follow this exact pattern, and the two sides of the face may have different Le Fort fractures. Nonetheless, a full understanding of midface buttresses is central in understanding these fractures (Fig. 18-18). There are three vertical buttresses: the nasofrontal-maxillary, the frontozygomaticomaxillary, and

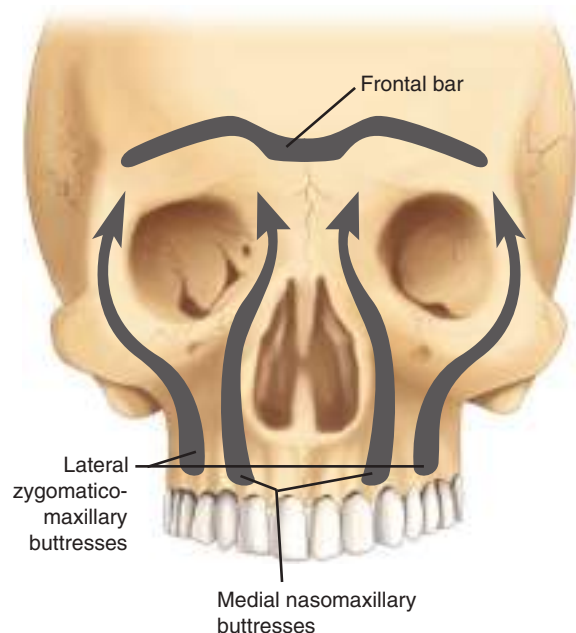

Figure 18-18. Major buttresses of the midface.

pterygomaxillary. There are five horizontal buttresses: the frontal bone, nasal bones, upper alveolus, zygomatic arches, and the infraorbital region.⁶³ Signs of midface fractures include subconjunctival hemorrhage, ocular signs/symptoms, malocclusion, facial asymmetry, midface hypoesthesia (V2), hematoma, and a mobile maxillary complex. Transverse maxillary alveolus fractures above the teeth are Le Fort I fractures, which may result in a mobile hard palate. When this fracture extends superiorly to include the nasofrontal buttress, medial orbital wall, and even as high as the infraorbital rim and zygomaticomaxillary articulation laterally, it is considered a Le Fort II. Mobility includes the palate, nasal dorsum, which is separated from the upper face, and the inferomedial aspect of the orbital rim. When the fracture disrupts the frontozygomaticomaxillary, frontomaxillary, and frontonasal suture line, there is craniofacial disjunction, a Le Fort III fracture. Of note, all of the Le Fort fractures involve the pterygoid plates posteriorly (Fig. 18-19).

Temporal Bone Fractures

Temporal bone fractures occur in approximately one fifth of skull fractures. Temporal bone fractures were previously classified as longitudinal or transverse describing the path along the temporal bone of the fracture line, but this has been largely replaced by the more relevant otic capsule sparing or involving classification given that most fractures are oblique.⁶⁴ Otic capsule sparing fractures present with conductive hearing loss, ossicular injury, bloody otorrhea, and labyrinthine concussion.⁶⁵ The facial nerve is rarely injured nor cerebrospinal fluid (CSF) leak common with this fracture pattern. However, in patients with otic capsule involving temporal bone fractures, typically caused by occipitomastoid impact, sensorineural hearing loss, vestibular dysfunction, facial nerve paralysis, and CSF leak are far more common.⁶⁵ Regardless of the fracture pattern, when CSF leak is suspected, it usually resolves with conservative measures including bed rest, elevation of the head of the bed, stool softeners, and avoiding sneezing or straining. In some cases, a CSF drain can be placed if there is a delay in spontaneous resolution. Rarely will surgical repair be required. Unlike

Figure 18-19. Classic Le Fort fracture patterns.

CSF leaks with temporal bone fractures, the facial nerve needs to be assessed and managed urgently. An incomplete or delayed facial nerve paralysis almost always resolves spontaneously with conservative measures, including oral steroids. An immediate complete paralysis that does not recover within 1 week should be prognosticated to consider nerve decompression. Electroneurography (ENoG), EMG, and nerve stimulation tests have been used to help determine which patients with delayed-onset complete paralysis will benefit from surgical decompression. The finding of >90% degeneration more than 72 hours after the onset of complete paralysis is considered an indication for surgery.⁶⁶ A nerve excitability test, where thresholds are increased to elicit visible muscle contraction on each side, can indicate advanced degeneration when there is a difference of >3.0 to 3.5 mA between sides. Whether surgical intervention is indicated or not for facial nerve paresis, it is crucial to protect the eye because a corneal drying and abrasion can lead to blindness in the absence of eye closure and a blink reflex. This requires application of ocular lubricant at night with the eye taped shut, frequent artificial tears application while awake, and a humidity chamber.⁶⁷

TUMORS OF THE HEAD AND NECK

Squamous cell carcinoma (SCC) comprises >90% of all of the malignant pathology of the mucosal lining of the upper aerodigestive tract. Naturally, a discussion of tumors of the head and neck typically focuses on this pathology presenting from the lips and oral cavity to the larynx and hypopharynx. Management of these tumors requires a systematic approach.

The ideal treatment protocol varies by subsite, stage, patient comorbidity, and center preference/experience. Given the relative rarity of these tumors, multidisciplinary management is of the utmost importance to provide the patient with a balanced perspective. This can be performed in the form of a multidisciplinary clinic where radiation and surgical oncologists simultaneously see the patient or through a tumor board where a new patient's history, physical examination findings, imaging, and prior pathology

specimens are reviewed. This encourages discussion from multiple points of view concerning the most appropriate treatment options available. In addition to radiation and surgical oncology, medical oncology, dentistry, speech language pathologists, radiologists, and pathologists contribute to the decision-making in this patient population. Some of the greatest advances in head and neck oncology over the last several decades include the development of standardized organ preservation protocols, advances in free flap reconstruction with microvascular techniques, and vaccinations. The future of head and neck oncology is bright with advances in molecular biology, immunotherapy, and preventative methods with vaccination. These have the potential of significantly decreasing incidence rates and improving survival and quality of life for those with the disease.

Etiology and Epidemiology

The main etiological factors associated with head and neck cancers are tobacco products and alcohol. Overall, there has been a decline in incidence of head and neck cancers of the oral cavity and larynx/hypopharynx subsites,⁶⁸ likely related to public health campaigns and government taxation policies as it relates to cigarette consumption.⁶⁹ Similarly, the incidence of head and neck cancer between countries varies widely and is strongly associated with the incidence of cigarette smoking. Cigarette smoking triples the likelihood of developing an oral cavity cancer, while the addition of alcohol synergistically increases the likelihood by 10- to 15-fold.⁷⁰ The risk increases as the number of years smoking and number of cigarettes smoked per day increases. Individuals who both smoke (two packs per day) and drink (four units of alcohol per day) had a 35-fold increased risk for the development of a carcinoma compared to controls.⁷¹

The preoperative and perioperative periods are excellent opportunities for head and neck oncologists to pursue a smoking cessation intervention. Continued smoking after completion of treatment is associated with a 3- to 4-fold increased risk of developing a second primary or recurrent tumor.⁷²⁻⁷⁴ A study assessing patients diagnosed with a new head and neck cancer demonstrated that of the patients that were smoking at diagnosis, only 54% were able to quit, highlighting the difficulty this population has with smoking cessation.⁷⁵

Betel nut/quid chewing, which is a product of the areca catechu tree, is endemic to some parts of Asia and India, and in these regions oral cavity cancer is one of the most common cancers.^{76,77} Betel nut when chewed acts as a mild stimulant similar to that of coffee but can be associated with submucous fibrosis that adds an additional challenge in the management of patients who present with a concurrent oral cavity cancer.⁷⁷ These products are associated with particular subsites secondary to direct contact (e.g., buccal mucosa) as well as subsites with dependent saliva drainage (e.g., floor of mouth, mandibular alveolus, and wet lip). Reverse smoking, where the lighted portion of the tobacco product is placed within the mouth during inhalation is also associated with oral cavity cancer, specifically hard palate carcinoma. The risk for this cancer is 47 times greater in patients that exhibit this behavior compared to nonsmokers.⁷⁸

In Europe and North America there has been an increasing interest in decriminalizing marijuana smoking. There is a strong correlation between this activity and head and neck cancers (OR 2.5; 95% CI 1.1–6.6) when compared to nonusers.⁷⁹ Furthermore, there is a dose-response relationship that is stronger in young patients (55 years of age or less). Ultraviolet light

exposure is associated with cutaneous malignancies of the head and neck as well as lip cancer. The lower lip is at a higher risk due to its increased anterior-posterior projection, and the majority of squamous cell carcinomas of the lip arise along the vermilion border of the lower lip. Immunocompromised patients, particularly those who have received solid organ and bone marrow transplants are at an increased risk of head and neck cancers.⁸⁰ Similarly, HIV-infected patients have a higher incidence of head and neck cancers, and despite aggressive treatment have poorer results compared to HIV-negative patients.^{81,82} Other conditions associated with oral cancer include Plummer-Vinson syndrome (iron-deficiency anemia, dysphagia, glossitis, cheilosis, and esophageal webs), dyskeratosis congenita,^{83,84} Bloom's syndrome,^{85,86} and Fanconi anemia.⁸⁷

HPV is a double stranded DNA virus that is transmitted through sexual contact. Over the last two decades, this virus, specifically the 16 and 18 subtypes,⁸⁸ has been associated with an epidemic rise in oropharyngeal squamous cell carcinoma.^{89,90} The p16 protein is a surrogate for HPV positivity. HPV status in oropharynx cancer has prognostic and therefore treatment-related implications.^{91,92}

Anatomy and Histopathology

The upper aerodigestive tract is divided into several distinct sites that include the oral cavity, pharynx, larynx, and nasal cavity/paranasal sinuses. Each of these sites has separate subsites as alluded to earlier with specific etiological, pathological, prognostic, and treatment-related peculiarities. Locoregional tumor spread is determined by weaknesses in the framework, fascial planes, and the course of neurovascular and lymphatic channels.

The oral cavity extends from the vermilion border of the lip to the hard-palate/soft-palate junction superiorly, to circumvallate papillae inferiorly, and to the anterior tonsillar pillars laterally. It is divided into eight subsites including the (a) mucosal lip, (b) the mandibular alveolus, (c) floor of mouth, (d) tongue (anterior two-thirds), (e) buccal mucosa, (f) retromolar trigone, (g) maxillary alveolus, and (h) hard palate (Fig. 18-20). Advanced oral cavity cancer can present with mandibular and/or maxillary invasion requiring resection, at least in part, of these structures. Oral cavity cancers typically metastasize to the submental, submandibular, and upper jugular lymph nodes (levels I-III).

Figure 18-20. Oral cavity landmarks.

Figure 18-21. Sagittal view of the head and neck demonstrating the distinction between the nasopharynx, oropharynx and larynx/hypopharynx including the boundaries of each.

The pharynx is divided into three regions: nasopharynx, oropharynx, and hypopharynx (Fig. 18-21). The nasopharynx extends from the posterior nasal septum and choana to the skull base and includes the fossa of Rosenmüller and torus tubarius of the Eustachian tubes laterally. The inferior margin of the nasopharynx is the superior surface of the soft palate. In adults, the adenoids are typically absent secondary to involution during late adolescence, but these can be seen in some adults in the posterior aspect of this subsite. Isolated posterior triangle (level V) lymphadenopathy in an adult should be considered nasopharyngeal carcinoma (NPC) until proven otherwise. Due to its midline location, bilateral regional metastatic spread is common in nasopharyngeal carcinoma. Given the epidemic rise oropharyngeal cancers, isolated level V adenopathy in an adult may also represent oropharyngeal cancer, although cancers at this site typically drain to the upper and lower cervical nodes (levels II–IV) as well as the retropharyngeal nodes. The oropharynx has a number of subsites including the tonsillar region, base of tongue, soft palate, and posterolateral pharyngeal walls. The hypopharynx extends from the vallecula to the lower border of the cricoid posterior and lateral the larynx. It includes several subsites as well including the pyriform fossa, the postcricoid space, and the posterior pharyngeal wall. Lymphatic drainage is to the mid and lower cervical nodes (levels III–IV); however, usually the upper cervical nodes (level II) are addressed at the same time for tumors at this site.

The larynx is divided into three regions: the supraglottis, glottis, and subglottis (Fig. 18-22). The supraglottis includes several subsites: the epiglottis, false vocal cords, medial surface of the aryepiglottic folds, and the upper half of the laryngeal ventricles. The glottic larynx includes the true vocal cords, the anterior and posterior commissure, and the lower half of the laryngeal ventricles. The subglottis extends from below the true vocal

Figure 18-22. Sagittal view of the larynx with the divisions of the supraglottis, glottis, and subglottis demonstrated.

cords to the superior cricoid border from within. The supraglottis has a high rate of bilateral metastatic spread secondary to its rich lymphatic drainage, whereas isolated glottic cancers rarely have lymphatic spread. Laryngeal cancers, in addition to having the propensity for lymphatic spread, particularly in advanced cases, can have preepiglottic and paraglottic invasion as well as invasion of the laryngeal framework (thyroid and cricoid cartilage). Furthermore, glottic and subglottic lesions, in addition to potential spread to the upper and lower cervical nodes (levels II–IV), have the propensity for spread to the central neck (level VI) in the paralaryngeal and paratracheal region.

Second Primary Tumors in the Head and Neck

Patients with head and neck squamous cell carcinoma (HNSCC) are at increased risk for the development of a second primary malignancy (SPM), which is defined as a second malignancy that presents either simultaneously or after the diagnosis of an index tumor. A synchronous SPM is diagnosed simultaneously or within 6 months of the index tumor, while a metachronous SPM is diagnosed >6 months after the index tumor. SPMs need to be distinguished from local recurrences or metastasis of the primary tumor. The incidence of SPM ranges from 2% to 7% per year,⁹³⁻⁹⁵ and this risk remains constant from the time of initial diagnosis throughout the lifetime of the patient.⁹³ Second primary malignancies represent the second leading cause of death in patients with HNSCC.⁹⁶ One-quarter to one-third of deaths in these patients are attributable to SPM,⁹⁶⁻⁹⁸ highlighting the importance of SPM in the successful management of HNSCC.

The classic criteria for defining second primary malignancy (SPM) were proposed by Warren and Gates and are: (a) histologic confirmation of malignancy in both the index and secondary tumors; (b) two malignancies that are anatomically

separated by normal mucosa; and (c) the possibility of the SPM being a metastasis from the index tumor must be excluded. Most investigators use these criteria to define an SPM. However, disagreement exists regarding the application of the second and third criteria. For example, when both tumors appear in the same anatomic subsite, there is no agreement on the distance that should exist between the tumors, with some investigators favoring 1.5 cm⁹⁹ and others requiring 2 cm.¹⁰⁰ Furthermore, when the tumors occur in the same anatomic subsite, some investigators add that the SPM must present at least three years after the diagnosis of the index tumor,¹⁰⁰ while others require that the SPM present at least five years after the index tumor.¹⁰¹ Others suggest that molecular analysis is required to classify a tumor as an SPM.¹⁰²

Treatment of SPMs of the upper aerodigestive tract is site specific. In general, the SPM should be treated as a separate entity, in the same manner as a primary index tumor at the anatomic subsite. In many cases, particularly in metachronous SPMs, patients have already received a full complement of treatment, including primary or adjuvant radiation and/or chemoradiation treatment. In these cases, surgical treatment of the SPM is often indicated when feasible. Reirradiation is an option in carefully selected cases when salvage surgery is not possible. Proper patient selection for reirradiation is critical, and only patients with minimal comorbidity and toxicity of previous radiation treatment should be considered.¹⁰³ Patients at high risk for local recurrence after salvage surgery may benefit from increased locoregional control from adjuvant reirradiation, although there is no survival advantage compared with salvage surgery alone.¹⁰³ Survival in patients with SPM depends upon the stage and location of the primary site of the SPM. Patients with SPM arising in the head and neck have significantly improved survival when compared with patients with SPM arising in the lung and esophagus.¹⁰⁴

Staging

Staging for upper aerodigestive tract malignancies is defined by the American Joint Committee on Cancer and follows the TNM (primary tumor, regional nodal metastases, distant metastasis) staging format which was recently updated in the 8th edition in 2017.¹⁰⁵ The T stage for each subsite incorporates relevant anatomy; for instance, T3 lesions of the glottis are associated with vocal cord immobility. Recent changes have incorporated HPV/P16 status for oropharynx cancer (Tables 18-1 and 18-2) and depth of invasion for oral cavity cancers (Table 18-3).

The N classification for head and neck sites is nearly uniform for all sites (Tables 18-4 and 18-5) except for the nasopharynx and for HPV-associated (p16-positive) oropharynx cancer. Recent changes have also incorporated extracapsular extension into this nodal staging to improve the discrimination and prognostication of the classification.

Upper Aerodigestive Tract

There are similarities in the initial assessment and management of all patients with a newly diagnosed upper aerodigestive tract malignancy. The frequently reviewed clinical practice guidelines (National Comprehensive Cancer Network; NCCN) provide valuable information by site and stage with regard to workup and management and should be used to direct care.¹⁰⁶ After a thorough history that should include assessment of the previously discussed risk factors, a comprehensive physical examination should follow. A full head and neck examination

Table 18-1

Clinical and pathologic T category for HPV-associated (p16-positive) oropharyngeal cancer

T CATEGORY	T CRITERIA
T0	No primary identified
T1	Tumor 2 cm or smaller in greatest dimension
T2	Tumor larger than 2 cm but not larger than 4 cm in greatest dimension
T3	Tumor larger than 4 cm in greatest dimension or extension to lingual surface of epiglottis
T4	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible or beyond*

*Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of the larynx.

anesthesia, CN VII, CN XI, and CN XII function. Flexible fiberoptic nasolaryngoscopy should be carried out to better characterize tumor extent, assess vocal cord mobility in laryngeal cancers, assess airway patency, and rule out any synchronous second primary tumors, as previously discussed.

Investigations should include a diagnostic laryngoscopy and esophagoscopy to rule out second primaries and obtain tissue of any concerning lesions. A pathologic specimen is nearly always required before initiation of treatment. A metastatic work up including a CT of the neck and chest with contrast is indicated in all patients with a newly diagnosed head and neck cancer. In certain jurisdictions, a positron emission tomography (PET)-CT is used to rule out any distant metastases; however, this approach does lead to a high false positive rate.¹⁰⁷

Patients are then assessed in a multidisciplinary manner with radiation and surgical oncology. A dental evaluation is initiated before treatment because many patients undergoing primary or adjuvant radiotherapy require dental extraction to decrease the risk of osteoradionecrosis in the posttreatment period. Assessment by speech language pathology in the preoperative period is imperative in all patients, but it is especially important in patients with laryngeal/hypopharyngeal pathology because speech and swallowing dysfunction needs to be characterized and often helps drive management. Smoking cessation is initiated as early as possible.

Lip. The lips starting at the vermilion border represent a transition between external skin to internal mucosa. The sphincter function of the lip is created by activation of the circumferential musculature of the orbicularis oris, a critical structure in lip form and function. Lip cancers are most common in men and are often seen in those with fairer complexions. In addition to tobacco use and immunosuppression, UV exposure is an additional important risk factor unique to this head and neck subsite. The majority ($> 90\%$) of lip cancers present on the lower lip due to its increased protrusion and increased sun exposure.¹⁰⁸ Although the vast majority of lip cancers are SCC, other cutaneous malignancies such as basal cell carcinoma and malignant melanoma are not uncommon at this subsite.

Basal cell carcinoma presents more frequently on the upper lip than lower.

Negative prognostic factors for lip cancers include perineural invasion, invasion into bone (maxilla or mandible), upper

lip or oral commissure involvement, positive regional metastasis, and young age at diagnosis.

The primary management of lip cancer is a surgical resection of the primary site with an adequate margin (1 cm). This provides margin analysis and additional pathologic information that can help stratify which patients may benefit from adjuvant treatment. The primary regional nodal drainage basin for lip cancers is the submandibular, submental, and perifacial nodes (level I), and metastases occur in <10% of patients with a higher incidence in those with upper lip cancers.¹⁰⁹ When there are clinical evident notes, a neck dissection is indicated. Otherwise, in the clinically and radiographically negative neck observation is acceptable.¹⁰⁹ Unfortunately, many lip cancers are not appropriately staged, and advanced regional failure is not infrequently seen. Adjuvant (postoperative) radiotherapy is indicated in patients with close (<5 mm) or positive margins,

lymph node metastases, tumors with perineural invasion, and in thick (>4 mm) tumors.¹¹⁰ The overall 10-year survival rate is 84% to 92% for early stage disease but drops precipitously (11%–28%) for advanced stage disease predicted by regional and distant metastases.¹¹¹

The goals of lip reconstruction include providing oral competence, maintaining dynamic function, and achieving acceptable cosmesis, while avoiding severe microstomia. The proportion of the lip excised and whether the defect involves the oral commissure determines the reconstructive options. Regardless of the reconstructive technique, realignment of the vermilion border and reapproximation of the orbicularis oris are critical steps to a successful outcome. Defects of less than one-third of the lip are closed primarily, while defects between one-third and two-thirds of the lip borrow tissue from surrounding regions, mainly the upper lip and cheek to recreate the lip. This can be accomplished using an Abbe (lip switch) (Fig. 18-23) or Karapandzic flap (Fig. 18-24), if the commissure is preserved, or an Estlander flap (lip switch) if the commissure is resected. If there is insufficient lip tissue, rectangular excisions can be closed using upper Burrow's triangles in combination with bilateral advancement flaps made possible by mental crease relaxing incisions; this technique is called Bernard-Burrow (Fig. 18-25).¹¹² When more than two-thirds of the lip is excised, the Karapandzic can still be used when the defect is up to 80% as this provides a sensate lip with sphincter-like function; however, microstomia becomes a serious concern, and larger defects require free flap reconstruction. This typically does not achieve sphincter function even when a sling is used. Microstomia can be a problem in patients that are edentulous who then cannot insert their dentures and in the dentulous who may not be able to get dental work performed with significant negative impact on their dental health.

Oral Cavity. As previously mentioned, the oral cavity is composed of several sites. The anatomy of each subsite can uniquely impact the aggressiveness of disease, the function after resection, and the surgical approach. We therefore in this next section briefly review each subsite with a focus on the relevant anatomy and treatment options.

The preferred approach to management of these tumors is a surgical resection with adequate (1 cm) surgical margins with management of the regional nodal basin. In general, tumors of the oral cavity metastasize to the submandibular, submental, and upper cervical nodes and are almost always treated with a supra-omohyoid neck dissection at the time of primary resection with a few rare exceptions (T1 oral tongue lesions that have less than 4 mm depth of invasion). In the "Neck" section of this chapter, we will discuss this in more detail. Adjuvant radiotherapy is indicated in patients with close margins, regional lymphadenopathy, advanced stage tumors (T3/T4), perineural invasion, and lymphovascular invasion, while adjuvant chemoradiotherapy is reserved for those with positive margins or extracapsular invasion.^{113,114}

Oral Tongue The oral tongue is a muscular structure composed of intrinsic (longitudinal, vertical, and transverse muscle fibers) and extrinsic (genioglossus, hyoglossus, styloglossus, and palatoglossus) muscles separated by a midline raphe and has overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the circumvallate papillae beyond which the oropharynx begins while the ventral portion is contiguous with the anterior floor of mouth.

Tumors of the tongue typically start along the epithelial surface and can be endophytic or exophytic with or without ulceration (Fig. 18-26) and are typically seen on the lateral and ventral surfaces of the tongue. Lesions on the dorsal aspect of the tongue, particularly along the midline, are less likely to be malignant. What is seen on the surface is typically the tip of the iceberg, and palpation can provide further information regarding the depth of invasion of the tumor. These tumors can be extensive, and when they cross the midline and start to involve the base of tongue an extensive surgical resection

including a total glossectomy may be required. However, most tumors present at an early stage due to significant pain, otalgia, voice change secondary to difficulties with articulation, and dysphagia, which may lead to weight loss. On history and physical examination, ipsilateral paresthesias and deviation of the tongue protrusion with fasciculations or atrophy may indicate lingual nerve and hypoglossal nerve tumor invasion respectively (Fig. 18-27).

Early lesions (T1–T2) can be closed primarily, allowed to heal by secondary intention, or reconstructed with a split thickness

skin graft after partial glossectomy. This procedure allows reasonable speech and swallowing function as long as there is not significant tethering in the floor of the mouth if this has been resected. Articulation is determined by premaxillary contact of the tongue, and dental appliances can be used in the postoperative setting to improve this. Tongue protrusion and lateral movement predicts a patient's ability to swallow, and this is less difficult to repair secondarily. Therefore, many patients, even with small

Figure 18-26. Oral tongue squamous cell carcinoma.

tongue cancers that require significant floor of mouth resection, receive soft pliable fasciocutaneous free flap reconstruction to improve these functional outcomes.¹¹⁵ Advanced lesions that require a more radical resection require free flaps, which obliterate the oral cavity dead space while creating bulk in the posterior oropharynx to improve the pharyngeal swallowing phase.¹¹⁶

Figure 18-27. A and B. Anatomy of the floor of mouth and submandibular space. a. = artery; m. = muscle; n. = nerve.

Floor of Mouth The floor of mouth is a mucosal-covered semilunar area that extends from the anterior tonsillar pillar posteriorly to the frenulum anteriorly, and from the inner surface of the mandible to the ventral surface of the oral tongue. The ostia of the submaxillary and sublingual glands are contained in the anterior floor of mouth. The muscular floor of mouth is composed of the sling-like genioglossus, mylohyoid, and hyoglossus muscles, which serve as a barrier to the spread of disease. Invasion into these muscles can result in decreased tongue mobility and poor articulation.

The floor of mouth begins just below the lingual surface of the mandibular alveolus and ends at the ventral tongue where the frenulum connects the floor of mouth to the tongue along the midline and at the anterior tonsillar pillars posteriorly. Just deep to the floor of mouth mucosa is the submandibular (Wharton's) duct and sublingual minor salivary glands followed by the genioglossus, hyoglossus, and mylohyoid muscles. Direct invasion of these structures is not uncommon and can result in direct spread to the sublingual and submandibular spaces as well as decreased tongue mobility, leading to articulation complaints. The lingual nerve (a branch of V3) provides sensory innervation to this subsite and is in close proximity to it, often requiring resection of this structure. The contiguity of the floor of mouth mucosa with the lingual surface of the mandible can lead to mandibular invasion. This needs to be carefully examined bimanually on physical examination and using imaging (CT, MRI, or Panorex) because a marginal or segmental mandibulectomy may be required to excise these tumors (Fig. 18-28). If the lesion is not fixed to the mandibular cortex on physical examination, then a mandible-sparing procedure is feasible.¹¹⁷

Extension to the sublingual and submandibular ducts and spaces requires that the neck dissection specimen be removed en bloc with the primary tumor. Invasion of the intrinsic tongue musculature requires a partial glossectomy. In our experience, except for the smallest (T1) very superficial floor of mouth lesions, cancers at this subsite nearly always require a reconstructive procedure to separate the floor of mouth from the neck and to avoid tethering of the tongue using a pliable fasciocutaneous flap. If a segmental resection is performed, the vascularized osteocutaneous free flap is used. Given the anterior location of this tumor, a lip-splitting incision is rarely used unless resection of lip and chin skin is required as part of the resection in a select group of T4a tumors with through-and-through involvement.

Mandibular Alveolus and Gingiva The alveolar mucosa overlies the bone of the mandible and extends from the gingivobuccal sulcus to the mucosa of the floor of mouth to the second and third molar, which is the anterior border of the retromolar trigone subsite. Treatment of these lesions requires at the very least marginal resection of the mandibular bone given the proximity and early invasion of the periosteum in this region. A marginal resection is acceptable if there is only very early bony invasion (Fig. 18-29). If the inferior alveolar canal or the medullary cavity is invaded on physical examination or preoperative imaging, a negative locoregional prognostic factor, a segmental resection is recommended with appropriate reconstruction.^{118,119}

Retromolar Trigone The retromolar trigone (RMT) is bordered medially by the anterior tonsillar pillar, anteriorly by the

Figure 18-28. A and B. Differences in the transoral resection of a floor of mouth and alveolar ridge lesion.

Figure 18-29. Anterior mandibulotomy with mandibular swing to approach a posterior lesion.

second or third molar, posteriorly by the maxillary tuberosity, inferiorly by the posterior mandibular alveolus, superiorly by the coronoid process of the mandible, and laterally by the buccal mucosa. Negative margin resection often requires a marginal shave mandibulectomy, even when there is no evidence of mandibular cortical invasion, because of the close proximity to the mandibular periosteum. This is typically achieved through a transoral approach while carefully protecting the lips and cheek.¹²⁰ Extension to adjacent subsites including the buccal mucosa, maxillary tuberosity, floor of mouth, and posterolateral tongue often requires these structures be resected as part of the margin. Trismus at this and other subsites is an advanced indication of involvement of the muscles of mastication in the masticator space, which can extend to the skull base. These tumors are aggressive. Infiltration into the masticator space and bony invasion (maxilla more often than mandible) significantly worsens the prognosis.¹²¹

Buccal Mucosa The buccal mucosa includes all of the mucosal lining from the inner surface of the lips to the line of attachment of mucosa of the alveolar ridges and pterygomandibular raphe. The mucosa includes the parotid (Stenson's) duct opening adjacent to the first and second maxillary molars. An understanding of the layers of the cheek from medial to lateral is important because these layers are very closely adherent to the buccal mucosa. Therefore, tumors in this region have a high propensity for early deep invasion and early lymphatic spread. The layers of the cheek from medial to lateral are: (a) buccal mucosa, (b) pharyngobasilar fascia, (c) buccinator muscle, (d) buccopharyngeal fascia, (e) buccinator fat pad, (f) masseter muscle, (g) muscles of facial expression and the superficial muscular aponeurotic system (SMAS), (h) subcutaneous tissue, and (i) facial skin. It is not uncommon for tumors with deep invasion into the

cheek to require a through-and-through resection. Reconstruction aimed at providing both an internal and external lining may be accomplished with a folded fasciocutaneous free flap or a combination of a local flap for the external component and a free flap for the internal component. Marginal bone resection is often required in tumors that extend to the mandibular or maxillary alveolus.

Maxillary Alveolus and Hard Palate The hard palate and maxillary alveolus have classically been considered two separate subsites, but due to their anatomic contiguity and the similarities in their oncologic outcomes these two subsites should be discussed together.¹²² The junction between the hard palate and soft palate is the posterior border, while the maxillary tuberosity is the posterolateral border separating the retromolar trigone from the maxillary alveolus. The periosteum at this subsite is closely adherent to the mucosa, and as such, superficial lesions require resection of the bone to achieve a clear margin. An infrastructure maxillectomy may be required for larger lesions involving the palate or maxillary antrum. The greater palatine nerve and foramen can be a pathway for neuropathic spread, and it is important to identify perineural invasion on these tumors in the biopsy specimen.

Although SCC continues to be the primary malignant pathology at this subsite, minor salivary gland tumors such as adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma can also present in this location. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate.

Nonmalignant pathology includes necrotizing sialometaplasia, which appears as a butterfly-shaped ulcer on the hard palate that otherwise looks like a neoplasm. Treatment is symptomatic as these lesions typically disappear with time; however, a biopsy is warranted to confirm the diagnosis. A torus palatini is a benign bony outgrowth seen on midline of the hard palate. This does not require biopsy to confirm the diagnosis and only requires treatment to relieve symptoms.

Reconstruction of the maxillectomy defect depends on a number of variables, including patient preference, dentition, patient comorbidity, and extent of defect. A partial palatotomy or partial infrastructure palatotomy can often be reconstructed with a dental obturator or a soft tissue flap alone to separate the oral cavity from the nasal cavity and maxillary sinus. More extensive suprastructure maxillectomies can be reconstructed with a free flap composed only of soft tissue, although this will leave the patient with a significant malar asymmetry over an osseous free flap. The layered fibular free flap and the scapular tip have been recently popularized to reconstruct more extensive orbitomaxillary reconstruction.^{123,124} Supporting the orbital floor when it is resected is critical in supporting the orbital contents and avoiding eventual diplopia because there can be a drop in these contents when they are not supported.

Oropharynx The borders of the oropharynx start at the soft palate superiorly, the hyoid (vallecular root) inferiorly, the anterior tonsillar pillar anterolaterally, and the cricovallate papilla at the junction between the anterior two-thirds and posterior third of the tongue. There are five subsites in the oropharynx: the tonsillar region that includes the anterior and posterior tonsillar pillars, the soft palate, the posterior pharyngeal wall, the lateral pharyngeal wall, and the base of tongue. Tumors at this subsite can have direct extension laterally in the parapharyngeal space, posteriorly into the retropharyngeal space, anteriorly into the oral cavity, superiorly into the nasopharynx, or inferiorly into

the supraglottic larynx. Laterally, through the superior constrictor, invasion of the jugular vein, carotid artery, and cranial nerves IX to XII, as well as the sympathetic chain, is possible. The pharyngobasilar fascia (resectable) deep to the constrictor muscles is a natural barrier from invasion into the prevertebral fascia (unresectable). The ascending ramus of the mandible can be involved when tumors invade the medial pterygoid muscle.

Although SCC is the predominant pathology, minor salivary gland tumors can present as submucosal lesions in the soft palate or tongue base, and lymphoma can present in the tonsils as an asymmetric enlargement, underlying the importance of a tissue diagnosis before treatment.

Oropharyngeal cancers, other than those on the soft palate or tonsils, are often not obvious on oral cavity exam inspection; therefore, a high degree of suspicion should exist in patients with a muffled voice as would be experienced in tongue base tumors, patients with dysphagia and weight loss, or referred otalgia from the tympanic branches of CN IX and X. Trismus may indicate advanced disease with pterygoid involvement. As previously mentioned, because of the epidemic rise in incidence of oropharyngeal cancers, secondary to HPV-associated tumors, and the high regional metastatic rate for these tumors, the presenting symptom is often a nontender cervical lymphadenopathy, which should be investigated with a fine-needle aspiration (FNA) biopsy. Approximately 50% of patients have metastases at the time of diagnosis. Bilateral metastases are common in patients with soft palate and base of tongue tumors. Treatment of the neck should include the upper jugulodigastric nodes to which these tumors most commonly metastasize to, followed by levels II, IV, V, and the retropharyngeal lymph nodes.

A discussion about oropharyngeal cancer cannot be had without discussing the important prognostic information provided by the HPV status of these tumors. The incidence of oropharyngeal squamous cell carcinoma has increased significantly over the last four decades secondary to HPV-16 related development of this tumor.¹²⁵ HPV infection can induce the production of two viral oncoproteins, E6 and E7, which inactivate tumor suppressors p53 and Rb leading to tumor promotion.¹²⁶ HPV-positive tumors are more common in younger male patients and are associated with a history of a higher lifetime number of sexual partners and oral sex.¹²⁷ Ang et al demonstrated that oropharyngeal cancers can be stratified on overall survival into low risk (HPV-positive tumors in patients with ≤ 10 pack years of smoking or > 10 pack years of smoking but N0-N2a), intermediate risk (HPV-positive tumors with > 10 pack years of smoking and N2b-N3 or HPV-negative tumors in patients with ≤ 10 pack years of smoking and T2-T3 tumors), and high risk (HPV-negative tumors in patients with ≤ 10 pack years of smoking and T4 tumors or HPV-negative tumors in patients with > 10 pack years of smoking).⁹² The rate of distant metastases in the HPV-positive and HPV-negative tumors does not differ, and therefore the survival benefit in the HPV-positive group is due to improved locoregional control.

Management of squamous cell cancers of this region includes single modality (surgery or radiotherapy alone) treatment for early stage disease (stage I/II) and multimodality treatment for advanced stage (stage III/IV) disease (surgery followed by postoperative radiotherapy or concurrent chemoradiotherapy).¹⁰⁶ Historically, from 1971 to 2000, oropharyngeal cancers, at the time mostly HPV-negative, were treated heterogeneously with surgery followed by radiotherapy or primary radiotherapy similar survival until Parsons et al demonstrated in

a meta-analysis similar survival rates between the two treatment groups with improved locoregional control in the radiation-alone group and much higher complication rates in the surgery group (32% severe complications, 3.5% mortality) compared to the radiotherapy group (3.8% severe complications, 0.4% mortality).¹²⁸ For this reason, for many years, advanced-stage tumors were treated with primary concurrent chemoradiotherapy. However, this is now a moving target given the excellent results in early and some intermediate-stage HPV-positive disease regardless of treatment. More recently, there has been a push to study de-escalation, particularly in the aforementioned low and intermediate risk groups given the excellent survival rates. The standard of care, regardless of HPV status, for advanced tumors (T3/T4 or N2b-N3 or evidence of gross ECE) continues to be concurrent chemoradiotherapy.¹²⁹

The high complication and mortality rate in the surgical group analyzed by Parsons et al was associated not just with HPV-negative tumors but also with open resections for advanced tumors that necessitated a lip-splitting mandibulotomy approach. More recently, particularly for early stage tumors (T1, T2, N0-N2a), there has been a push towards minimally invasive transoral robotic surgery (TORS) using the da Vinci Surgical System. Oncologic outcomes are similar between surgery and radiotherapy in this group, and TORS has been demonstrated to be cost-effective in this setting.¹³⁰⁻¹³² Functional outcomes related to swallowing (G-tube dependency) and airway (tracheotomy dependency) are also similar between the groups.¹³⁰ These outcomes are heavily dependent on the surgeon's ability to achieve negative margins, which can be challenging, and on good preoperative predictive value of imaging to stage the neck, given that advanced nodal disease, particularly with ECE, continues to benefit from adjuvant chemoradiotherapy. Positive margins or ECE ultimately leads to adjuvant chemoradiotherapy. This results in triple modality treatment with its associated higher morbidity. Therefore, clinical recommendations based on these favorable early retrospective poorly controlled studies with small sample sizes is not yet possible. Meanwhile, clinical trial evidence is pending to help elucidate in which settings and patients this new approach may be beneficial.¹³³

Extensive oropharyngeal cancers that fail concurrent chemoradiotherapy are treated with resection. If the mandible is involved, a marginal mandibulectomy or segmental mandibulectomy may be required depending on the extent of bony invasion. Tongue base resection may necessitate total glossectomy depending on the contralateral extent of the tumor and the ability to save the lingual artery and to a lesser extent the hypoglossal nerve on that side. When the larynx is preserved many patients, if careful reconstruction is performed, 90% of patients can be decannulated and have acceptable voice outcomes.¹³⁴ However, it is not uncommon to have to perform a total laryngectomy at the same time as the total glossectomy for tumors with supraglottic extent, and this is associated with poor quality of life. Generally, these patients also have poorer survival.¹³⁵⁻¹³⁷

The primary goal of oropharyngeal reconstruction is swallowing rehabilitation. For soft palate defects, palatal obturators may assist in providing a seal between the nasopharynx and the posterior pharyngeal wall. The modified Gehanno technique sutures the posterior wall of the remaining soft palate to the remaining incised pharyngeal mucosa to close off the ipsilateral hemi-nasopharyngeal port.^{138,139} A flap can then be inset overlying this defect, which has effectively separated the nasopharynx from the oropharynx. This prevents nasal regurgitation of air

and liquids, therefore impacting both speech and swallowing. Similarly, total glossectomy reconstruction has several goals, including filling the oral cavity dead space, allowing the neotongue to reach the premaxilla to assist with articulation, and, most importantly, creating posterior bulk to allow the base of tongue to touch the posterior pharyngeal wall, which assists with the pharyngeal phase of swallowing. This is often achieved with a large rectus abdominis or anterolateral thigh free flap.¹³⁸ If the neotongue does not successfully touch the premaxilla and hard palate and speech is impeded, a palatal obturator can be used to bring down the palate and achieve better contact.

Hypopharynx and Cervical Esophagus The hypopharynx, which extends from the vallecular to the lower border of the cricoid cartilage (Fig. 18-30), has three subsites; the pyriform sinuses, the lateral and posterior pharyngeal walls, and the post cricoid space. SCC of the hypopharynx typically presents with progressive dysphagia, first to solids then to liquids, followed by weight loss. Similar to oropharyngeal tumors, patients can also present with voice change, referred otalgia or a neck mass. Rarely, when the larynx is involved, patients may present with stridor and airway compromise necessitating an urgent tracheotomy.

Unfortunately, there is significant delay in diagnosis of patients with hypopharyngeal cancer and late presentation is common.¹⁴⁰ Routine physical examination will not typically detect the tumor. Fiberoptic nasolaryngoscopy is important in assessing the extent of the tumor and laryngeal function. Vocal cord paralysis is a poor prognostic factor and indicates fixation of the cricoarytenoid joint from direct extension of the tumor or

recurrent laryngeal nerve invasion. A Valsalva maneuver during laryngoscopy allows for a better evaluation of the opened pyriform sinuses and postcricoid space. Functional endoscopic evaluation of swallowing (FEES) can be useful to assess laryngeal penetration and aspiration, but a modified barium swallow (MBS) is better at assessing inferior extent of the disease, multifocality within the esophagus, and aspiration. A thorough metastatic workup is required, with special attention paid to paratracheal and upper mediastinal metastases.

This site has the poorest survival outcomes of all head and neck subsites. There is no difference in survival when surgery is used as the primary modality of treatment followed by radiotherapy or chemoradiotherapy compared to primary radiotherapy or concurrent chemoradiotherapy followed by surgery.¹⁴¹ Concurrent chemoradiotherapy appears to be the modality of choice for laryngeal preservation; however, when surgical salvage is required, there is a low cure rate and increased wound complications.¹⁴² Early T1 lesions without clinical or radiographic evidence of adenopathy can be treated with primary radiotherapy, but this is relatively rare for this subsite due to a high rate of adenopathy and an advanced T stage at presentation.

Surgical resection, typically in the salvage setting, involves a total laryngopharyngectomy typically with a circumferential defect or a very small strip of mucosa preserved in continuity with the cervical esophagus. A total thyroidectomy and central neck dissection (level VI) is simultaneously performed and removed en bloc with the specimen. Bilateral neck dissection of levels II to IV is indicated. Careful dissection of the central neck, and in some cases the upper mediastinum (level VII), is required to clear regional disease, and this is critical in preventing a peristomal recurrence.

Given the circumferential or near circumferential defect, reconstruction is required to prevent saliva from accumulating in the wound and to create a neopharynx. A pedicled pectoralis major flap sutured to the prevertebral fascia has been described, but advances in free flap reconstruction has popularized a number of fasciocutaneous flaps for reconstruction of this defect, namely the radial forearm flap and the anterolateral thigh free flap.¹⁴³⁻¹⁴⁶ When total laryngopharyngoesophagectomy is required, a gastric pull-up may be performed for the pharyngeal reconstruction.

Larynx Laryngeal carcinoma typically presents with a progressive voice complaint in a long-time smoker (Fig. 18-31). A thorough understanding of laryngeal anatomy is critical in the proper diagnosis, staging, and treatment of laryngeal cancers. The larynx is divided into the supraglottis, glottis, and subglottis as previously described (Fig. 18-32). The larynx starts superiorly at the epiglottis and ends inferiorly at the inferior border of the cricoid cartilage of the larynx span from the epiglottis superiorly to the cricoid cartilage inferiorly. Laterally, it is separated from the hypopharynx by the aryepiglottic folds.

The supraglottis includes all of the laryngeal structures above the inferior half of the ventricle, and this includes the upper half of the ventricle, the false vocal cords, the arytenoids, the aryepiglottic folds, and the epiglottis. The membranes and cartilages of the larynx act as barriers to laryngeal spread: the thyroid and cricoid cartilage, conus elasticus, the quadrangular membrane, the ventricle, the hyoepiglottic ligament, thyrohyoid membrane, and cricothyroid membrane. Although the majority of tumors of the larynx are SCC, minor salivary glands, and their associated malignancies, can be found in the supraglottis and subglottis. Other rarer pathologies include granular cell

Figure 18-30. Relationship of nasopharynx, oropharynx, and hypopharynx.

Figure 18-31. Endoscopic view of a laryngeal squamous carcinoma.

tumors and laryngeal framework tumors, typically arising from the cricoid, such as chondroma and chondrosarcoma.

The larynx functions to (a) phonate, (b) protect the airway during swallowing, and (c) maintain airway patency. This is a fine balance. For instance, if the glottic aperture is enlarged and/or supraglottic structures are excised, phonation and airway protection suffer while airway patency is improved. It is

Figure 18-32. Total laryngectomy specimen featuring a locally invasive advanced stage glottic squamous carcinoma.

therefore not surprising that patients with laryngeal tumors can present with dysphonia (hot potato voice in supraglottic tumors and hoarseness in glottic tumors), dysphagia, and airway concerns. These patients can also present with dysphagia, weight loss, referred otalgia, and a neck mass. Vocal cord fixation can be a result of a mass effect from large obstructing masses, secondary to direct extension into the paraglottic space or through direct invasion of the cricoarytenoid joint involving either the muscle or the recurrent laryngeal nerve (RLN). Although subglottic tumors represent <1% of laryngeal cancers, they can also present with vocal cord paralysis and/or airway compromise.

Direct laryngoscopy is beneficial in the assessment of laryngeal tumors to assess the local extent of tumor spread. This is particularly important in assessing vallecula and base of tongue as there can be direct extension to the oropharynx. Similarly, glottic cancers can have subglottic extension, which necessitates a wider radiation field and/or a more extensive resection. Esophagoscopy and bronchoscopy are also recommended to assess second primary tumors. Furthermore, when a laryngectomy is planned, the direct laryngoscopy provides information about the best possible site of entry into the pharynx. Entry can be achieved through (a) a suprahyoid pharyngotomy, (b) lateral pharyngotomy (lateral to the thyroid cartilage), or (c) inferiorly through a postcricoid or hypopharyngeal pharyngotomy.

Appropriate preoperative staging with a CT scan with contrast is critical in assessing cervical lymphadenopathy and extralaryngeal spread. Erosion or invasion of the thyroid and cricoid cartilage can significantly impact outcomes and treatment as can extension into the preepiglottic or paraglottic spaces. The supraglottic and subglottic sites are lymphatic rich, and bilateral lymphadenopathy is not uncommon, whereas the glottic site has relatively poor lymphatic drainage (1%–4% regional metastasis for isolated larynx cancer). The supraglottis drains through the neurovascular bundle to the thyrohyoid membrane, mainly draining to the upper and lateral cervical nodes (levels II–IV), whereas the glottis and subglottis drain through the cricothyroid membrane and can have spread to the prelaryngeal (Delphian nodes), paratracheal, and lower cervical nodes (levels IV and VI), although in these cases we still treat levels II to IV surgically because of the significant occult nodes in this region.

The primary management of laryngeal cancer depends on a variety of factors, including tumor extent, patient comorbidities, and surgeon/center experience. In general, similar to other subsites, early-stage disease can be treated with single modality treatment (surgery or radiotherapy) while advanced stage disease is treated with at least two modalities, typically either surgery followed by radiotherapy (with or without chemotherapy) or concurrent chemoradiotherapy. Supraglottic and subglottic lesions are typically treated with primary concurrent chemoradiotherapy in an attempt to preserve the organ; however, in patients where the primary functions of the larynx are not being fulfilled preoperatively (tracheotomy- and gastrostomy tube-dependent), primary surgical management with a total laryngectomy (Fig. 18-33) can be considered. The original trials that popularized organ preservation techniques with concurrent chemoradiotherapy either excluded or had a very small sample size of large (T4) tumors.^{147,148} Similarly, advanced glottic cancers (T3/T4a), even when there is no evidence of nodal disease or supraglottic tumors of all stages, have superior survival outcomes when surgery is used as the primary treatment modality.^{149,150} This is particularly true for tumors that extend beyond the endolarynx or with cartilage destruction, for which total

Figure 18-33. Example of the resection of a vertical partial laryngectomy for an early stage glottic carcinoma.

laryngectomy followed by postoperative radiotherapy continues to be the standard of care. When primary chemoradiotherapy is used, surgical salvage is available if there is treatment failure or recurrent disease.

The early glottic and supraglottic lesions can be safely treated with CO₂ laser transoral microlaryngoscopic resection with excellent oncologic outcomes and laryngeal preservation rates.^{151,152} Patients with limited involvement of the arytenoid or anterior commissure are the best candidates for a good posttreatment vocal quality result with this approach. One of the benefits of this approach is that it does not burn any bridges to more invasive treatment. Often, multiple procedures are required to control the disease. Nonetheless, for early stage cancers of the glottis and the supraglottis, radiation therapy is equally as effective as surgery in controlling disease with excellent voice outcomes.

Laryngeal Preservation Techniques Beyond CO₂ laser transoral microlaryngoscopic resection for the most early of lesions, more advanced open laryngeal preservation techniques have been developed for the resection of select, moderately advanced supraglottic and glottic tumors. These techniques can be divided into vertical and horizontal partial laryngeal procedures.

Vertical partial laryngectomy (VPL) (Fig. 18-34) involves a midline thyrotomy followed by dissection of the inner perichondrium off of the thyroid cartilage with resection of the entire true cord and a portion of the false cords, followed by reconstruction with pedicle strap muscles and bipediced outer perichondrial flaps. A temporoparietal fascial free flap has also been used to reconstruct these defects with excellent voice outcomes.¹⁵³ This can be extended to include a frontal vertical VPL where the excision crosses the midline as far laterally as to leave only the posterior commissure and one functional

Figure 18-34. Example of the Ohngren's line and the relationship to the maxilla.

cricoarytenoid unit. This procedure is best reserved for recurrent glottic T1/T2 lesions involving only one vocal cord (although anterior commissure involvement is not a contraindication), <5 mm subglottic extension, with a mobile cord, and no cricoid cartilage or extralaryngeal extension. This technique leads to excellent locoregional control with improvements in voice related quality of life with advanced reconstructive techniques.¹⁵³

Supraglottic and supracricoid partial laryngectomies are horizontally oriented resections. In a supraglottic laryngectomy, a laryngectomy is performed below the hyoid and includes the upper portion of the thyroid cartilage while preserving a lower portion approximately the height of the cricoid cartilage. This is reserved for lesions not involving the vocal cords, false cords, or the arytenoids. Cartilage invasion and extensive base of tongue involvement are contraindications. Most lesions amenable for resection using this procedure are typically small enough that a laser or TORS procedure is adequate for resection, and therefore this procedure is rarely performed. For T3 glottic lesions without preepiglottic space or cricoarytenoid joint involvement, a supracricoid laryngectomy with a cricothyroidopexy or cricothyroidoepiglottopexy (CHEP) are options. A single cricoarytenoid unit is preserved to allow for phonation through apposition with the remnant epiglottis or base of tongue. The procedure is associated with excellent oncologic outcomes, tracheostomy decannulation rates, and swallowing function.¹⁵⁴ Phonation is reasonable after this procedure but can be characterized as breathy and coarse. Many surgeons prefer not to decannulate patients until the patient has had a significant period of time with good oral intake to allow for pulmonary toilet given the high initial rate of aspiration with this procedure.

All partial laryngeal procedures are associated with a high risk of aspiration. Therefore, patients should have excellent pulmonary reserve through pulmonary function tests. When this is not possible, a simple measure includes whether patients can climb two flights of stairs without stopping.

Speech and Swallowing Rehabilitation Speech and language pathology (SLP) assessment is critical in the management of patients with laryngeal and hypopharyngeal cancer. It is a critical part of the preoperative assessment and counseling and postoperative therapy. In the elderly larynx cancer population, Starmer et al demonstrated that SLP care is underutilized and is largely reserved for select patients in anticipation of total laryngectomy or after the onset of impaired airway and swallowing function. SLP care was, however, strongly associated with improved outcomes (lower rates of dysphagia, stricture, weight loss, and pneumonia).¹⁵⁵

SLP often discusses with the patient speech rehabilitation options after total laryngectomy, which include esophageal speech, tracheoesophageal puncture, and use of an electrolarynx. Esophageal speech is produced by actively swallowing and releasing air from the esophagus, resulting in vibrations of the esophageal walls and pharynx that can then be articulated into words. This requires a very motivated patient, and unfortunately, <20% of postlaryngectomy patients develop fluent esophageal speech.

The electrolarynx is a device that creates vibratory electric type sounds when held against the neck or cheek that the patient can articulate into speech. This device is typically used in the postoperative inpatient setting, but it can also be used by patients who are not able to create esophageal speech.

The ultimate speech rehabilitation for patients with laryngectomy is a tracheoesophageal puncture (TEP) with insertion of a voice prosthesis. This prosthesis is a one-way valve that allows air from the trachea to enter the upper esophagus while preventing retrograde passage of food or saliva into the trachea. Patients who undergo placement of a tracheoesophageal puncture have a success rate of >90% in achieving functional speech. Many surgeons do not like to place a TEP at the time of the primary laryngectomy, particularly in the salvage setting after radiotherapy due to wound complication concerns. However, primary and secondary TEP patients experience similarly high complication rates, and the extent of the pharyngeal reconstruction rather than preoperative exposure to radiotherapy appear to be more important factors in selection of TEP timing.¹⁵⁶ Free flap patients used their TEP more commonly for primary communication after secondary versus primary TEP.

Postoperative swallowing rehabilitation is another important task performed by SLPs. Modified barium swallows where the consistency and amount of food provided is varied to minimize aspiration can be critical particularly in the management of patients with partial laryngeal procedures. This is performed under fluoroscopy in the radiology suite to allow for the assessment of all phases of swallowing. A more limited examination in FEES utilizes the fiberoptic nasolaryngoscope to visualize the larynx during swallow and directly visualize whether there is any laryngeal penetration.

Unknown Primary Tumors Patients with cervical nodal metastases confirmed to be carcinoma without clinical or radiologic evidence of an upper aerodigestive tract primary tumor are referred to as having carcinoma of unknown primary (CUP). CUP comprise 2% to 5% of all head and neck cancers, although the true incidence is probably lower given advances in surgical visualization and radiological imaging to identify the primary site.¹⁵⁷⁻¹⁵⁹ Recently, there has been a rise in CUP likely related to the increase in HPV-associated oropharyngeal cancer, although CUP could also be from a primary thyroid or skin malignancy.¹⁶⁰ After a thorough history and physical examination including

fiberoptic nasolaryngoscopy, an FNA biopsy is used to confirm carcinoma in the cervical metastases. This is preferred over an open biopsy to avoid the risk of tumor spillage, challenging revision surgery secondary to disruption of fascial planes, and increased risk of recurrence and distant metastases.¹⁶¹ If the primary is not identified on physical examination, patients should undergo a PET-CT scan. A recent systematic review of 7 studies (246 patients) demonstrates an overall sensitivity of 44% and specificity of 97% with this technique, which can often detect tumors >1 cm in size.¹⁶² This should be followed by thorough diagnostic operative endoscopy (nasopharyngoscopy, direct laryngoscopy, esophagoscopy, and bronchoscopy). Operative manipulation of the tissues in the upper aerodigestive tract specifically with biopsy may lead to false positive results on the PET-CT scan, and therefore PET-CT should be performed before endoscopy. Furthermore, having the PET-CT results prior to operative endoscopy allows the surgeon to focus on specific high-risk sites for biopsy, particularly as it relates to the base of tongue.¹⁶³ When the primary site is not evident, bilateral tonsillectomies and bilateral base of tongue biopsies can be performed to try to identify the primary site. Patients in whom a primary is identified proceed to receive appropriate treatment, and if radiotherapy is part of this treatment regimen, a more limited radiation field is administered, highlighting the importance of identifying a primary site. When the primary site is not identified, primary chemoradiotherapy is advocated, treating all of the mucosal sources of the upper aerodigestive tract at risk (from nasopharynx to hypopharynx) and the cervical regional basin bilaterally. For patients with advanced neck disease (N2a or greater) or with persistent lymphadenopathy after radiation, a neck dissection may be necessary. In the preradiation setting, a neck dissection is preferred over radiotherapy for patients with N1 disease, according to the NCCN guidelines, because some of these patients will be upstaged, ECE is not accurately diagnosed on imaging alone, and because some patients without ECE and a pathologically N1 node benefit from radiation alone without chemotherapy.^{106,164} The additional prognostic information provided by a neck dissection can significantly impact treatment algorithms and is also associated with lower morbidity compared to postoperative neck dissection.

Nose and Paranasal Sinuses

Cancers of the nasal cavity and paranasal sinuses are exceedingly rare, and pathology in this anatomic subsite is dominated by infectious and inflammatory sources as previously discussed in the “Sinonasal Inflammatory Disease” section of this chapter. Malignant pathology at this site is often diagnosed after failed repeated treatment of suspected benign inflammatory sinonasal pathology. Concerning preoperative imaging findings (unilateral disease; extensive disease; bony, orbital or intracranial invasion) and unusual clinical features may raise concerns about malignancy, and in these cases referral to a tertiary head and neck oncology center is preferred. A concerning history is one that involves a slow progression and worsening of symptoms, which may include nasal obstruction, facial pain, headache, epistaxis, and facial numbness. Most tumors at this site present with advanced stage given the inevitable delay in diagnosis. Numbness in the V2 distribution suggests invasion of pterygopalatine fossa, and V3 distribution numbness can be an indication of extension to the infratemporal fossa and skull base invasion to foramen ovale. Proptosis, epiphora, diplopia, and change in vision (typically starting with loss of color vision) are

Figure 18-35. Examples of resection specimens for lateral temporal bone resection, subtotal temporal bone resection, and total temporal bone resection.

all signs of advanced orbital invasion. Maxillary sinus tumors, the most common site for cancers of this site, can be prognosticated simply using Ohgren's line (Fig. 18-35), an imaginary line from medial canthus to the angle of the mandible, which divides maxillary sinus into anterior-inferior and posterior-superior parts. Tumors from the anterior-inferior are more prognostically favorable.

Although the most common pathology at this site continues to be squamous cell carcinoma, a brief discussion of other histopathology is warranted given significant variety, prognostic, and treatment-related differences between these at this subsite. Benign pathology at this site includes inverted papilloma, hemangiomas, hemangiopericytomas, angiofibromas, minor salivary tumors, and benign fibrous histiocytomas. Fibro-osseous and osseous lesions, such as fibrous dysplasias, ossifying fibromas, osteomas, and myxomas, can also arise in this region. Additionally, encephaloceles and meningo-encephaloceles with herniation of intracranial content into the nasal cavity can present as sinonasal lesions; therefore, imaging, typically with an MRI, is warranted before biopsy of any sinonasal mass to prevent an iatrogenic CSF leak. In the evaluation of sinonasal malignant pathology, both CT and MRI are required because they provide complimentary information. MRI provides improved skull base, intracranial, and orbital invasion assessment, while CT provides better assessment of bony anatomy and invasion.

Beyond squamous cell carcinoma, the next two most common malignancies at this site include adenoid cystic carcinoma and adenocarcinoma. Other pathologies include sinonasal undifferentiated carcinoma (SNUC), mucosal melanoma, lymphoma, esthesioneuroblastoma (previously known as olfactory neuroblastoma), rhabdomyosarcoma, and angiosarcoma. Unlike other head and neck cancers, metastases to the regional lymphatic basis are extremely rare, and rarely will patients require or receive primary or adjuvant treatment to the neck unless there is clinical or radiographic evidence of neck disease (approximately 15%).¹⁶⁵

The standard treatment for malignant tumors of the paranasal sinuses is driven by the primary pathology; however, for most pathology, including SCC, the standard of care includes surgical resection followed by adjuvant radiotherapy.¹⁶⁶ Advances in EEAs has led to a shift in management of these tumors with minimally invasive approaches that are associated with significantly lower complication and morbidity rates with comparable oncologic outcomes.^{167,168} Open approaches are, however, indicated when there is tumor abutting the anterior wall of the frontal sinus, anterior extension into nasal bones, anterior maxillary wall invasion, facial skin or soft tissue invasion, dural involvement above the orbit or periorbital invasion, tumors with significant intratemporal fossa invasion, and extension into the oral cavity, including the hard palate or the floor of the maxillary sinus. Many tumors can be treated with an endoscopic approach such a medial maxillectomy when the tumor arises from the medial wall of the maxilla. Multidisciplinary assessment and treatment should include a skull base tumor board discussion with a head and neck oncologist/surgeon, a neurosurgeon, ophthalmologist including oculoplastic surgeons, prosthodontists, and reconstructive surgeons. Preoperative embolization within 24 hours of tumor excision can be useful for vascular tumors.

Extent of surgery and prognosis is dependent on the tumor location and extension. For tumors limited to the hard palate and lower maxillary sinus, an infrastructure maxillectomy is sufficient. A total maxillectomy without removal of the orbital floor may be warranted for more extensive tumors limited to the maxillary sinus. When the orbital periosteum is not invaded but tumor abuts this region, removal of the orbital floor with appropriate reconstruction is warranted. When there is invasion of periorbital, an orbital exenteration is warranted for most pathology. Tumors originating in the ethmoid sinuses may require excision of the cribriform plate and repair of subsequent skull base defect if the tumor originates or invades through the bony skull base. This is performed through an anterior craniofacial resection, where a neurosurgeon performs a frontal craniotomy for exposure of the anterior cranial fossa floor, while the head and neck surgeon performs a transfacial or endoscopic resection of the inferior bony and soft tissue structures. This approach often requires resection of dura and a dural repair to achieve negative margins. A less extensive surgery including a sphenoidectomy or medial maxillectomy can be entertained for smaller tumors originating in the lateral nasal wall through endoscopic or open approaches.

Tumors are deemed to be unresectable if both optic nerves are involved, if there is carotid artery invasion, or if there is extensive intracranial extension. Chemotherapy has a limited application in the management of tumors at this subsite with two exceptions: rhabdomyosarcoma, which is primarily treated with chemotherapy followed by radiation therapy with surgery reserved for the salvage setting, and SNUC, where triple modality treatment is required given tumor aggressiveness. Chemotherapy in this setting may help to reduce the tumor bulk and allow for orbital preservation.

Nasopharynx

The anatomic borders of the nasopharynx are superiorly the adenoid patch, superolaterally the fossa of Rosenmüller and the Eustachian tube orifices (torus tubarius), inferiorly the plane of the hard palate from the choana, anteriorly the posterior nasal cavity, and posteriorly the posterior pharyngeal wall. Malignant

tumors of the nasopharynx are typically well differentiated or lymphoepithelial SCC. However, other tumors can present in this region including lymphoma, chordoma, chondroma, nasopharyngeal cyst (Tornwaldt's cyst), angiofibroma, minor salivary gland tumor, paraganglioma, rhabdomyosarcoma, extramedullary plasmacytoma, and, rarely, sarcoma.

Unlike other head and neck cancers, the nasopharynx site has unique ethnic and geographic predilection, namely, a higher incidence in southern China, Africa, Alaska, and in Greenland Eskimos. EBV is also more commonly seen in patients with NPC, and EBV titers are helpful in following treatment response.

As previously discussed, a posterior (level V) neck mass should be considered NPC until proven otherwise. Other signs and symptoms include nasal obstruction, epistaxis, unilateral serous otitis media in an adult, and otalgia. Advanced disease can present with cranial neuropathies, particularly of the cranial nerves, which run in the cavernous sinus (CN VI, V2, III, IV, VI). Bilateral regional disease spread is common, and the lymphatic level involved include the posterior neck (level V), as well as the upper (level II) cervical nodes and retropharyngeal nodes. Distant metastatic disease is present in 5% of patients at diagnosis, highlighting the importance of a thorough staging workup.

Staging includes a thorough physical examination using either a flexible or rigid endoscope to assess the mucosal extent of the disease. CT and MRI are complimentary as in the assessment of nasal cavity and paranasal sinus tumors with CT providing better assessment of bony invasion and the MRI providing better soft tissue delineation, skull base invasion, and perineural spread with cranial nerve enhancement. Multimodality therapy with chemoradiotherapy is superior to radiotherapy alone in the management of nasopharyngeal carcinoma.¹⁶⁹ Recurrent tumors are treated typically with reirradiation; however, there has been recent success with surgical salvage procedures, particular in those patients in which a negative margin can be achieved.¹⁷⁰

When resection is contemplated for recurrent nasopharyngeal carcinoma or for low grade tumors such as some minor salivary gland tumors, a number of surgical approaches can be utilized for resection. These include endoscopic, transpalatal, transfacial via a maxillary swing procedure, and transcervical. In many cases, a combination of these techniques is required to achieve a negative margin. The transcervical approach provides the added benefit of early access and control of the carotid artery. For benign and low-grade tumors, advances in EEA have made use of the open approaches less common.

Ear and Temporal Bone

Temporal bone and ear tumors are rare account for <0.5% of all head and neck cancers. Subsites in this head and neck site from lateral to medial include the pinna (external ear), external auditory canal, middle ear, mastoid, and petrous portion of the temporal bone. Although the typical pathology at this site is squamous cell carcinoma, minor salivary gland tumors such as adenocarcinoma and adenoid cystic carcinoma can also present here. Given that the ear is in the high-risk region for aggressive skin cancers due to its unique exposure to ultraviolet light, cutaneous malignancies such as basal cell carcinoma and melanoma can also present here. In the pediatric population, soft tissue sarcomas, most commonly rhabdomyosarcoma, can present at this site. These tumors typically present with an advanced stage,¹⁷¹ and resection with clear margins and functional preservation is

challenging because of the close proximity of vital structures, namely the facial nerve and the external auditory canal.¹⁷² Tumors involving the petrous apex or intracranial structures may present with headache and palsies of CN V and VI as well.

Patients can present with ulceration, granulation, or bleedings from the external ear and auditory canal. This is often mistaken for an infectious or inflammatory process given the rarity of malignancy at this subsite; however, persistent granulation tissue in the ear should be biopsied and imaged to rule out malignancy. Patients can then present with otorrhea, otalgia, hearing loss, vertigo, and facial nerve paralysis. Appropriate imaging with CT and MRI is often required to appropriately delineate the lesion and stage and assist with the appropriate management plan.

Cutaneous malignancies of the pinna and tragus can usually be locally excised. However, at this subsite, spread into the perichondrium and cartilage can lead to rapid spread long that tissue plane. The importance of negative margins cannot be overstated at this subsite. Mohs microsurgery has been advocated for select tumors at this subsite for this reason; however, some tumors are so extensive that a total auriculectomy provides the best oncologic and cosmetic result. When there is extension of tumor to the bony cartilaginous EAC junction, spread to parotid, temporomandibular joint, and skull base is possible. Advanced tumors anterior to a vertical line along the EAC from a sagittal view benefit from a parotidectomy as well as a supraomohyoid neck dissection (levels I–III), whereas those behind this line benefit from a posterolateral neck dissection (levels II–V). As with other cutaneous malignancies, adjuvant radiotherapy is indicated for positive margins, perineural spread, or multiple involved lymph nodes.

Tumors involving the EAC and middle ear require different management, including a sleeve resection of the external auditory canal, a lateral temporal bone resection, or a subtotal temporal bone resection (Fig. 18-36). A sleeve resection of the EAC skin and cartilage is rarely enough to achieve negative margins with the exception of some basal cell carcinomas of the skin overlying the cartilaginous EAC. For more extensive

Figure 18-36. Levels of the neck denoting lymph node bearing regions.

tumors and more aggressive pathology, a lateral temporal bone resection may be required removing the cartilaginous and bony external auditory canal as well as the middle ear en bloc.¹⁷³ A subtotal temporal bone resection also removes the inner ear and facial nerve as part of the resection and is indicated when the tumor extends into the middle ear and a deeper resection margin is required. Both of these procedures are followed by postoperative radiotherapy, which provides improved locoregional control.¹⁷³ The neck is managed in a similar fashion to pinna and external auditory canal malignancies typically requiring a supraomohyoid (levels I–III) neck dissection. Survival outcomes are poor with a 5-year overall survival of <40%.¹⁷⁴ Important predictors of disease free survival include margin status, perineural invasion, and regional lymphatic spread; the most important of these on multivariate analysis being lymphatic spread of disease.¹⁷¹

Lateral temporal bone resections often require reconstruction to close the wound, provide bulk, and vascularize tissue. If dura is encountered and even resected, a watertight dural closure is required to prevent a CSF leak and meningitis. Vascularized tissue has the added benefit of preparing the surgical bed for postoperative radiotherapy. These defects can be reconstructed with regional pedicled flaps (e.g., submental flap) or free flaps. The most common free flaps used are the anterolateral thigh, although depending on body habitus and the depth of the defect, the radial forearm, lateral arm, and rectus abdominus may also be used.¹⁷⁵ The deformity resulting from a total auriculectomy is often not reconstructed primarily, but an auricular prosthesis can be designed for further rehabilitation. Facial nerve reconstruction when sacrifice is required is typically performed with cable grafts from the proximal facial nerve to select distal facial nerve branches. Because of the long distance between the proximal and distal branches, facial movement is typically delayed 6 to 12 months. However, if the masseteric nerve is connected through a cable graft to select distal facial nerve branches (typically the zygomatic branch), a shorter cable graft is required, and facial movement can be achieved earlier. A variety of other static and dynamic procedures can be provided secondarily. The most important of these procedures are related to preserving eye closure to avoid corneal abrasions or desiccation, which can ultimately lead to blindness. In the immediate postoperative period, taping of the eyelids and generous application of eye lubrication is required to prevent exposure keratitis. Upper lid gold weight implants, lower lid shortening procedures, and tarsorrhaphy can be performed secondarily to assist with eye closure.

Neck

An undiagnosed neck mass needs to be carefully evaluated and worked up so as to not interfere with the definitive management of the patient and future treatment options. The patient's age, social history, including alcohol and smoking history, preceding illness history, and synchronous upper aerodigestive tract physical examination findings can significantly impact the differential diagnosis and the investigation to work up a neck mass. A thorough history and head and neck examination, including fiberoptic nasolaryngoscopy, are therefore paramount to complete evaluation. With regard to age, in children, a neck mass is far more likely to be congenital, inflammatory, or infectious, whereas in adults, neck masses >2 cm have a >80% probability of being malignant. Typically, the first investigation is an FNA biopsy, which can be performed with ultrasound or CT guidance when the mass is not easily palpable or largely cystic with

a small solid component. Imaging is critical in characterizing the neck mass, particularly assessing the borders, consistency, and location which then impacts the differential diagnosis. For instance, a cystic neck mass can be a branchial cleft cyst or a regional metastasis from an oropharynx cancer or metastatic papillary thyroid cancer. Therefore, the imaging findings also significantly impact the differential diagnosis.

When the imaging and FNA does not provide adequate information for a diagnosis, a core biopsy can be considered, particularly if the diagnosis of lymphoma is suspected and an open biopsy wants to be avoided. For a suspected carcinoma, an open biopsy may be required; however, in that case, the incision needs to be planned such that the procedure can be converted to a neck dissection, and a frozen section can be sent. If the diagnosis of squamous cell carcinoma is confirmed on frozen section, then a neck dissection should be performed to further prognosticate the disease. In the case of lymphoma, biopsy does not need to remove the entire lymphoma, particularly if there is an added risk of injuring normal anatomical structures.

Patterns of Lymph Node Metastasis. The lymphatic drainage into the neck is divided into seven levels with standardized reporting within and across specialties, particularly as radiologists, pathologists, surgeons, radiation oncologists, and radiologists share the findings^{176,177} (Fig. 18-37). The levels include

- *Level I*—the submental and submandibular nodes
- *Level Ia*—the submental nodes; medial to the anterior belly of the digastric muscle bilaterally, symphysis of mandible superiorly, and hyoid inferiorly; this level does not have any laterality as it includes both right and left sides
- *Level Ib*—the submandibular nodes and gland; posterior to the anterior belly of digastric, anterior to the posterior belly of digastric, and inferior to the body of the mandible

Figure 18-37. Shaded region indicates the region included in a supraomohyoid neck dissection.

- *Level IIa*—upper jugular chain nodes; anterior to the posterior border of the sternocleidomastoid (SCM) muscle, posterior to the posterior aspect of the posterior belly of digastric, superior to the level of the hyoid, inferior to spinal accessory nerve (CN XI)
- *Level IIb*—submuscular recess; superior to spinal accessory nerve to the level of the skull base
- *Level III*—middle jugular chain nodes; inferior to the hyoid, superior to the level of the cricoid, deep to SCM muscle from posterior border of the muscle to the strap muscles medially
- *Level IV*—lower jugular chain nodes; inferior to the level of the cricoid, superior to the clavicle, deep to SCM muscle from posterior border of the muscle to the strap muscles medially
- *Level V*—posterior triangle nodes
- *Level Va*—lateral to the posterior aspect of the SCM muscle, inferior and medial to splenius capitis and trapezius, superior to the spinal accessory nerve
- *Level Vb*—lateral to the posterior aspect of SCM muscle, medial to trapezius, inferior to the spinal accessory nerve, superior to the clavicle
- *Level VI*—anterior compartment nodes; inferior to the hyoid, superior to suprasternal notch, medial to the lateral extent of the strap muscles bilaterally
- *Level VII*—paratracheal nodes; inferior to the suprasternal notch in the upper mediastinum

There is a well-established pattern of regional spread from upper aerodigestive tract primary tumors.¹⁷⁸ Lesions of the lip and oral cavity typically metastasize to levels I to III and skip metastases to the lower basin (levels III–IV) without involvement of the upper level (levels I–II). Oropharyngeal, laryngeal, and hypopharyngeal tumors most commonly spread to the lateral neck (levels II–IV). It is rare for any of these tumors to have isolated regional metastases to level V; however, nasopharyngeal, thyroid, and head and neck malignant melanoma can metastasize to this level. Other sites for metastasis include the retropharyngeal nodes (oropharyngeal, nasopharyngeal, and hypopharyngeal tumors), paratracheal and level VII nodes (thyroid, hypopharynx, and cervical esophageal tumors), and pretracheal (Delphian) nodes (thyroid and advanced glottic tumors with subglottic extension).

Historically, a *radical neck dissection (RND)* was performed for all upper aerodigestive tract malignancies with sacrifice of the SCM, internal jugular vein (IJV), and accessory nerve (CN XI) and removal of all lymphatic level (levels I–V). This was because cervical metastasis decreased the 5-year overall survival rate by approximately 50%. However, growing evidence demonstrated that this was not necessary, and now a neck dissection is only recommended for upper aerodigestive tract malignancies when the risk of occult disease is >20% in the clinically negative neck.¹⁷⁹ When the neck is clinically positive, the level discussed in the previous paragraph for each site are excised with every attempt to preserve the SCM, IJV, and CN XI (*selective neck dissection; SND*). When there is direct extension of the tumor or extralymphatic spread into these structures, sacrifice may be necessary in a *modified radical neck dissection (MRND)*. The RND has been largely abandoned because the SND and MRND have been demonstrated to be equally effective when it comes to oncologic outcomes with far improved functional outcomes.^{180,181}

SND has become the standard of care for most patients who are clinically node negative (cN0) and in those with limited

Figure 18-38. Shaded region indicates the region included in a lateral neck dissection.

cN1 disease. Patients with oral cavity cancer typically receive a supraomohyoid (Fig. 18-38) neck dissection (levels I–III). Many surgeons will include a portion of level IV just below the omohyoid muscle given the rate of skip metastases previously discussed. Approximately 80% of patients with oral cavity cancer present cN0; however, the rate of occult metastatic disease is approximately 30% and differs by subsite.¹⁸² This rate is further impacted by tumor thickness at the tongue subsite, with tumors 4 mm or thicker having a higher rate of occult disease.¹⁸³ A recent prospective, randomized trial demonstrated the oncologic benefit of an elective neck dissection in cN0 oral cavity patients regardless of tumor thickness over an observation followed by therapeutic neck dissection in those with regional failures.¹⁸⁴ An additional role of SND is as a staging tool to determine the need for postoperative radiation therapy. The lateral (Fig. 18-39) neck dissection (levels II–IV) is typically used in laryngeal and hypopharyngeal cancers. The posterolateral (Fig. 18-40) neck dissection (levels II–V) is typically recommended in thyroid cancers, although recent evidence has demonstrated that a partial level V dissection may be all that is necessary for equivalent outcomes to a full level II to V neck dissection.^{176,185,186}

Despite advances in the surgical management of neck disease, in clinically advanced nodal disease (with the exception of uncomplicated N1 disease), an MRND remains the treatment of choice. When the neck disease is advanced with extranodal extension (ENE), perineural invasion (PNI), lymphovascular invasion (LVI), and the presence of multiple involved nodes, postoperative radiotherapy improves locoregional control.¹⁰³ If there is a positive margin or ENE, then the addition of adjuvant chemotherapy to radiotherapy provides a survival benefit.^{113,187,188}

In patients receiving primary radiotherapy with advanced N stage disease (N2a or greater) or only a partial response to

Figure 18-39. Shaded region indicates the region included in a posterolateral neck dissection.

treatment, a planned postradiotherapy neck dissection can be performed 6 to 8 weeks after completion of radiotherapy. This is to consolidate the treatment and provide prognostic information.

Tumor factors that preclude surgery include prevertebral fascia invasion, skull base invasion, and $>270^\circ$ circumferential encasement of the internal carotid artery. These factors are associated with very poor 5-year survival ($<20\%$). In such cases, sacrifice of the carotid is not indicated given the risk of stroke and death. Surgical debulking is also not associated with improved survival. However, there is a role for neoadjuvant chemotherapy, and in those that respond and if the disease becomes resectable, survival benefit has been demonstrated.¹⁸⁹ Recurrent neck metastasis after radiotherapy to the neck or a comprehensive neck dissection is associated with very poor survival.¹⁹⁰

Parapharyngeal Space Masses. The parapharyngeal space is a potential inverted pyramidal space bordered superiorly at the skull base along the sphenoid and inferiorly at the greater cornu of the hyoid. Medially it is bordered by the buccopharyngeal fascia covering the superior constrictor, anteriorly the pterygomandibular raphe, posteriorly the prevertebral fascia, and laterally by the deep surface of the parotid gland and ramus of the mandible. The differential diagnosis for parapharyngeal masses is very much dependent on the anatomy and contents of this space which is divided into the pre- and poststyloid spaces by the tensor-styloid fascia. This fascia attaches the tensor veli palatini muscle to the styloid. The contents of the prestyloid parapharyngeal space include fat, the deep lobe of the parotid, and lymph nodes, and branches of V3 (lingual, inferior alveolar, and auriculotemporal nerves), whereas the contents of the poststyloid space including cranial nerves IX to XII, the internal jugular vein, the internal carotid artery, and the sympathetic chain. Nearly half of all parapharyngeal masses are of parotid

Figure 18-40. Parapharyngeal mass—prestyloid with prominent oropharyngeal presentation typical of a dumbbell tumor.

origin, while 20% to 25% are of neurogenic origin, such as paragangliomas (glomus vagale, carotid body tumor), schwannomas, and neurofibromas. Lymphatic origin masses such as lymphoma and lymph node metastases represent 15% of tumors at this subsite. Therefore, most prestyloid lesions are considered of salivary gland origin, whereas poststyloid lesions are typically vascular or neurogenic.

Tumors of the parapharyngeal space can displace the lateral pharyngeal wall medially into the oropharynx (Fig. 18-41) and can thus cause obstructive sleep apnea, voice change, and dysphagia in addition to cranial neuropathies, Horner's syndrome, or vascular compression. In addition to CT and MRI, poststyloid lesions should be investigated with a 24-hour urinary catecholamine collection because some paragangliomas are functional and this should be managed preoperatively.

Surgical access to these tumors can be performed using a purely transcervical approach with the excision of the submandibular gland for access. A transfacial or transparotid approach can be used as an adjunct for certain tumors by removing the parotid gland. This ensures identification of the facial nerve

include three separate layers: the superficial deep (investing) layer, the pretracheal (visceral) layer, and the prevertebral layer. The investing layer forms a cone around the neck and surrounds the SCM muscle and the anterior and posterior neck. It spans from the mandible to the clavicle and manubrium. The visceral layer surrounds the trachea, thyroid, and esophagus and blends laterally with the carotid sheath extending inferiorly to the upper mediastinum. Between this layer and the prevertebral fascia is the retropharyngeal space. The prevertebral fascia covers the prevertebral musculature and space and extends down to the thoracic vertebra and diaphragm. Infections of the prevertebral space between this fascia and the prevertebral musculature are considered to be in the prevertebral space and can extend all the way down to the sacrum. Therefore, neck infections can extend to the mediastinum or beyond and need to be treated aggressively.

Salivary Gland Tumors

Primary malignant tumors of the salivary glands are relatively rare and account for <2% of all head and neck malignancies. As previously mentioned, minor salivary gland malignancies can present anywhere in the upper aerodigestive tract, particularly on the palate; however, the major salivary glands are the parotid, submandibular, and sublingual glands. The majority of tumors (80%) arise in the parotid gland (Fig. 18-44); however, 80% of these are benign, most commonly, pleomorphic adenomas (benign mixed tumors). As the salivary gland gets smaller, the proportion of tumors that are malignant increases; 50% of submandibular/sublingual tumors and 80% of minor salivary gland tumors are malignant.

Patients typically present with a mass because these tumors are well circumscribed and slow growing. However, certain signs and symptoms, such as pain, paresthesia, facial nerve weakness, or rapid growth, raise the concern for malignancy. If there is facial nerve weakness (10%–15% of cases), this usually represents tumor invading the facial nerve. Submandibular and sublingual tumors present with a mass or swelling in the neck or floor of the mouth, respectively. Tumors in this region can invade the lingual nerve leading to tongue paresthesia or the hypoglossal nerve invasion leading to paralysis. The close proximity to the mandible and tongue necessitates a thorough bimanual palpation to assess for fixation to these structures.

The decision to dissect the neck in parotid cancers is fraught with uncertainty. However, parotid malignancies, particularly carcinomas, have a propensity for regional lymphatic spread, first to the intra- and periglandular nodes followed by the upper cervical chain (levels I–III). Occult nodal metastases are present in 30% of cases and are predicted by intra- or periglandular nodes, high-risk histology (high histological grade), and extraparotid extension.¹⁹³ Patients with advanced tumor stage (T3/T4a), perineural invasion, high risk histology, or clinically involved adenopathy should have their neck dissected. Submandibular gland cancers metastasize to the submental (Ia) and submandibular triangle lymph nodes followed by the upper cervical chain (levels II–III). Extraglandular extension and regional metastases are poor prognostic factors.

Following a thorough history and physical examination, an FNA biopsy should be performed to provide an accurate preoperative diagnosis in 70% to 80% of cases when reviewed by an experienced cytopathologist. If the biopsy is nondiagnostic, a repeat biopsy should be performed under image-guidance, typically with an ultrasound. An open or incisional

biopsy should be avoided because of the risk of tumor spillage and cutaneous spread. Also, this approach is fraught with risk to the facial nerve. Salivary gland tumors are worked up with appropriate imaging, typically with an MRI because of the increased soft tissue definition. FNA and imaging results are critical in guiding the surgeon to the extent of surgery. The minimal extent of surgery for salivary gland tumors is a superficial parotidectomy, removing all of the salivary gland tissue superficial to CN VII, which is meticulously dissected during this procedure.

The final histopathologic diagnosis in salivary gland tumors can be challenging. Nonetheless, there is a well-outlined histological classification used by pathologists.¹⁹⁴ Benign and malignant tumors of the salivary glands are divided into epithelial, nonepithelial, and metastatic neoplasms. Benign epithelial tumors are most commonly pleomorphic adenoma (85%), monomorphic adenoma, Warthin's tumor (papillary cystadenoma lymphomatosum), oncocytoma, or sebaceous neoplasm. Nonepithelial benign lesions include lipoma and hemangioma. Treatment of benign neoplasms is surgical excision for diagnostic and therapeutic purposes. The parotid superficial lobe is usually dissected off of the facial nerve, which is preserved. For pleomorphic adenoma, an extracapsular dissection is favored over enucleation due to tumor pseudopods, incomplete excision, and a higher risk of tumor spillage, all of which are associated with higher recurrence rates.¹⁹⁵ Recurrence is associated with a high degree of morbidity.

Malignant epithelial tumors range in aggressiveness based on tumor histology, grade, perineural invasion, and regional metastases. Mucoepidermoid carcinoma is the most common primary malignancy of the salivary glands and can be high grade (more epidermoid) or low grade (more mucinous). High grade mucoepidermoid carcinoma can be hard to differentiated from squamous cell carcinoma, particularly on FNA. Adenoid cystic is the second most common primary salivary gland malignancy and has three histological subtypes: tubular, cribriform, and solid. Higher grade/risk tumors have a higher degree of solid differentiation.¹⁹⁴ Adenoid cystic cancers are known for perineural invasion and late recurrences and distant metastases. Carcinoma ex pleomorphic adenoma is an aggressive malignancy that arises from a preexisting benign mixed tumor highlighting the importance of removing these benign masses before malignant transformation.

Surgical excision remains the standard of care, typically with facial nerve preservation unless the nerve is directly invaded by tumor. For tumors that extend beyond the superficial lobe, nerve branches can be splayed, and a total parotid can be performed by removing parotid tissue deep to the nerve while preserving the integrity and function of the nerve. Whenever possible, the nerve is preserved even if microscopic disease is left on the nerve, so long as gross tumor is not left behind (i.e., the nerve is not encased). If this is not possible or if the nerve is not working preoperatively, nerve sacrifice is usually recommended.

Elective neck dissection is warranted in high-grade mucoepidermoid carcinomas and other high-risk pathology and grade where the risk of occult disease is greater than 15% to 20%. Therapeutic neck dissection is recommended in patients with clinically or radiographically evident disease. Postoperative radiotherapy is indicated in patients with perineural invasion, advanced local disease (T4a), extraglandular disease including regional metastases, and high-grade histology.

RECONSTRUCTION

Local Flaps and Skin Grafts

Local flaps are commonly used for cutaneous reconstruction in the head and neck. Local flaps are most commonly utilized for reconstruction after Mohs micrographic surgery for cutaneous malignancy, or for reconstruction of melanoma defects. Skin grafts are also commonly used for reconstruction of scalp defects after surgical resection of cutaneous malignancies. Skin grafts may also be utilized in the oral cavity for resurfacing of superficial defects of the tongue, floor of mouth, and buccal mucosa.

Regional Flaps

Three regional flaps deserve mention as potential flaps for head and neck reconstruction. The first is the pectoralis major myocutaneous flap, based upon the thoracoacromial artery.¹⁹⁶ This flap may be used as a primary option for hypopharyngeal reconstruction after total laryngectomy. This flap may also be utilized to protect the great vessels from becoming exposed, or as a salvage reconstructive procedure should the great vessels become exposed. Another commonly utilized regional flap is the submental flap, based upon the submental vessel branches of the facial artery. This flap may be utilized for intraoral reconstruction and/or parotid and temporal bone reconstruction.¹⁹⁷ Care must be taken during the neck dissection in order to preserve the submental vessels that supply this flap. Finally, the supraclavicular flap is based upon the supraclavicular artery, arising from the transverse cervical artery.¹⁹⁸ This is a thin, fasciocutaneous

flap that is commonly used for external neck and facial reconstruction in which thin tissue is desired.

Free Tissue Transfer

The majority of major defects of the head and neck require free tissue transfer for optimal reconstruction.¹⁹⁹ A full discussion of head and neck reconstructive microsurgery is beyond the scope of this chapter; however, a brief overview of free tissue transfer is provided in this section. Free tissue transfer allows the surgeon to transplant tissue from a wide array of donor sites, each of which have distinct advantages.²⁰⁰ For example, for floor of mouth reconstruction, where thin tissue is desired, the surgeon may select the radial forearm as the donor site. On the other hand, when presented with a total glossectomy defect, where thick tissue is desired for adequate volume reconstruction, the rectus may be the optimal donor site. Considering osseous defects, for reconstruction of a segmental mandible defect with minimal soft tissue deficit, the fibula osseocutaneous free tissue transfer may be the optimal choice.²⁰¹ On the other hand, reconstruction of an osseous mandible defect with a large mucosal and external soft tissue deficit may be best served by the scapula donor site, where vascularized bone can be combined with a large skin paddle, and an additional latissimus dorsi myocutaneous free tissue transfer, if needed.²⁰² The ability to harvest tissue from multiple donor sites is critical to obtaining the optimal reconstructive result. Table 18-6 lists the commonly utilized donor sites and their reconstructive advantages and disadvantages.

Table 18-6

Free tissue transfer donor sites for head and neck reconstruction

FLAP	BLOOD SUPPLY	CHARACTERISTICS	COMMON DEFECTS
Radial forearm	Radial artery	Thin, pliable, long pedicle	Partial and hemiglossectomy, floor of mouth, buccal defects
Anterolateral thigh	Descending branch of lateral femoral circumflex artery	Thicker adipose than radial forearm, can have myocutaneous (most common) or septocutaneous perforators	Hypopharynx, external neck/facial skin, extended hemiglossectomy/total glossectomy
Lateral arm	Posterior radial collateral artery	Outstanding color match for facial skin, resists ptosis, diminutive pedicle	Parotid, temporal bone, external face and neck skin
Rectus	Deep inferior epigastric artery	Thick adipose tissue for large volume defects, long pedicle, poor external skin color match	Total glossectomy, skull base
Latissimus dorsi	Thoracodorsal artery	Large surface area of muscle, requires semi-lateral position, can be difficult for two-team harvest	Extensive scalp and skull base defects
Fibula osseocutaneous	Peroneal artery	Excellent bone stock and length, long pedicle, thin skin paddle	Segmental mandible and maxilla
Scapula osseocutaneous	Circumflex scapular artery	Less bone length compared to fibula, large scapular or parascapular skin paddles ideal for large composite defects	Segmental mandible and maxilla defects with extensive soft tissue components
Radial forearm osseocutaneous	Radial artery	Long pedicle, diminutive bone stock	Partial mandible defects, orbit
Iliac crest	Deep circumflex iliac artery	Up to 16 cm of bone available, limited soft tissue, significant donor site morbidity	Segmental mandible defects with small intraoral component and large external skin component

Figure 18-43 shows a prototypical hemiglossectomy defect from a T2 N0 oral tongue cancer that was reconstructed with a rectangle template radial forearm free tissue transfer.²⁰³ The radial forearm free tissue transfer provides thin, pliable tissue, with a long pedicle, and is a staple for hemiglossectomy and partial glossectomy reconstruction.

Figure 18-44 shows a composite mandible defect from a T4a N0 mandibular alveolus cancer, after segmental mandibulectomy, reconstructed with a fibula osseocutaneous free tissue transfer.²⁰⁴ The 2.5-mm titanium reconstruction plate was bent to a mandible model. A template of the osseous defect is made and transferred to the fibula, and wedge osteotomies are made in the bone so that it can be snug fit into the bone defect.

Figure 18-45 shows a palate defect after an infrastructure maxillectomy for a T2 N0 maxillary alveolus cancer. The defect resulted in direct communication with the buccal space, nasal cavity, and maxillary sinus. A radial forearm free tissue transfer was utilized to achieve oronasal separation.

TRACHEOTOMY

Indications and Timing

The most common cause for tracheotomy is prolonged intubation typically in critically ill intensive care unit patients. Prolonged intubation increases the risk of laryngeal and subglottic injury, which may lead to stenosis. In the critically ill patient, it has been hypothesized that early tracheotomy may improve inpatient survival and decreased intensive care unit length of stay while increasing patient comfort. However, a large randomized clinical trial demonstrated no benefit from early tracheotomy on short- or long-term survival and other important secondary outcomes.²⁰⁵ Furthermore, clinicians are poor predictors of which patients require extended ventilatory support. Another study demonstrated no evidence that early tracheotomy reduced mortality, duration of mechanical ventilation, intensive care unit stay, or ventilatory associated pneumonia.²⁰⁶ It did, however, provide a shorter duration of sedation. Beyond prolonged intubation, tracheotomy is also indicated in patients who require frequent pulmonary toilet, in patients with neurologic deficits that impair protective airway reflexes, and in head and neck upper aerodigestive tract surgery as a temporary airway in the perioperative period to bypass airway obstruction.

Technique and Complications

The procedure can be performed using an open or a percutaneous technique. Complications of tracheotomy include pneumothorax, tracheal stenosis, wound infection/stomatitis with large-vessel erosion, and failure to close after decannulation. A meta-analysis of 15 randomized studies assessing nearly 1000 patients demonstrated no difference between the open and percutaneous techniques, although there was a trend toward fewer complications in the percutaneous approach.²⁰⁷ The percutaneous approach was also found to be cheaper and had the added benefit of being performed at the bedside outside of the operating room. A Cochrane review on the topic lower wound infection/stomatitis and unfavorable scarring rates with the percutaneous approach.²⁰⁸ Mortality and serious adverse events did not differ between the two techniques.

The use of cricothyroidotomy, typically in the emergency setting, is inferior to a tracheotomy due to higher incidence of vocal cord dysfunction and subglottic stenosis. Therefore, soon after a cricothyroidotomy is performed, a formal

tracheotomy should be used with decannulation of the cricothyroidotomy site. Most tracheostomies are not permanent and can be reversed simply by removing the tube and applying a pressure dressing. The stoma usually spontaneously heals within 2 to 3 weeks.

Speech with Tracheotomy and Decannulation

When a large cuffed tracheostomy is initially placed, speech is not possible, particularly when the cuff is up. However, when the tube is downsized to a cuffless tracheostomy tube,

intermittent finger occlusion or placement of Passy-Muir valve can allow the patient to voice while still bypassing the upper airway obstruction in inspiration. Prior to decannulation, the patient has to tolerate capping for 24 to 48 hours, but this period can be extended in patients with concerns for pulmonary toilet and an inability to clear secretions.

LONG TERM MANAGEMENT AND REHABILITATION

Palliative Care

For patients with unresectable disease (greater than 180° of encasement around the carotid artery, prevertebral fascia invasion, and skull base invasion) or distant metastases, palliative care options exist. The NCCN guidelines recommend clinical trials for patients in this category because there is not a single accepted regimen for patients with incurable disease but the goal of treatment is to control symptoms and maintain quality of life while minimizing the side effects of treatment.¹⁰⁶ This may include a combination of radiotherapy, usually in a hypofractionated pattern with high dose per fraction regimen, chemotherapy, or simply pain management. A recent trial demonstrated the utility of immunotherapy, specifically, Nivolumab, in the management of recurrent unresectable head and neck cancer, showing a higher response rate (13.3%) compared to standard therapy (5.8%) with lower treatment-related adverse events (13.1% vs. 35.1%, respectively).²⁰⁹ From a surgical perspective, some patients require tracheostomy or gastrostomy tube placement to manage airway compromise and dysphagia, respectively. Palliative care facilities and hospice care allow patients to retain dignity when they have a limited short-term outlook.

Follow-Up Care

Patients diagnosed and treated for a head and neck tumor require follow-up care aimed at monitoring for recurrence and the side effects of therapy. The NCCN guidelines recommend follow-up assessment every 3 months for the first year after treatment, every 4 months during the following year, and then every 6 months until year 4, with an annual follow-up at 5 years post treatment and thereafter.¹⁰⁶ This regimen is not well followed in North America, and further investigation is required to assess why this might be and to improve adherence rates.²¹⁰ Follow-up should consist of a thorough history to assess for any emerging symptoms such as pain, otalgia, or dysphagia as these are often the first sign of a recurrence. Assessment by speech language pathology and a dietician is often beneficial to ascertain swallowing function and nutritional intake, respectively. Some patients require dilation or reinsertion of a gastrostomy tube if they develop pharyngeal strictures and are unable to maintain their weight. The history should be followed with a thorough head and neck examination, including fiberoptic nasolaryngoscopy, because of the significant risk of developing a second primary in the upper aerodigestive tract.⁹⁵ Patients should have their thyroid stimulating hormone (TSH) checked once a year, especially in those that have radiation as they may develop hypothyroidism at an earlier age than the general population. Shoulder dysfunction after neck dissection with extensive accessory nerve dissection or in patients who have had a scapular system free flap should be managed with physiotherapy to minimize the long-term effects and improve function. Chronic pain can occur in head and neck cancer patients, and this is often assessed and managed by a pain specialist. Ongoing dental

evaluation is needed in some patients to treat caries and prevent osteoradionecrosis.

TRACHEA

Anatomy

The trachea is composed of cartilaginous and membranous portions, beginning with the cricoid cartilage, the first complete cartilaginous ring of the airway. The cricoid cartilage consists of an anterior arch and a posterior broad-based plate. Articulating with the posterior cricoid plate are the arytenoid cartilages. The vocal cords originate from the arytenoid cartilages and then attach to the thyroid cartilage. The subglottic space, the narrowest part of the trachea with an internal diameter of approximately 2 cm, begins at the inferior surface of the vocal cords and extends to the first tracheal ring. The remainder of the distal trachea is 10.0 to 13.0 cm long, consists of 18 to 22 rings, and has an internal diameter of 2.3 cm (Fig. 19-1).¹

Bronchoscopically, the tracheal rings are visible as C-shaped hyaline cartilaginous structures that provide rigidity to the anterior and lateral tracheal walls. The open ends of the C-rings are connected by the trachealis smooth muscle and encased in a dense band of connective tissue called perichondrium. The first tracheal ring is attached directly to the cricoid cartilage; there are approximately two rings for every 1 cm of tracheal length.

The tracheal blood supply, which includes the inferior thyroid, subclavian, supreme intercostal, internal thoracic, innominate, and superior and middle bronchial arteries, enters the

airway near the junction of the membranous and cartilaginous portions (Fig. 19-2). Each arterial branch supplies a segment of 1.0 to 2.0 cm, thereby limiting circumferential mobilization to that same distance. The vessels are interconnected along the lateral surface of the trachea by an important longitudinal vascular anastomosis that feeds transverse segmental vessels to the soft tissues between the cartilages.

Tracheal Injury

Tracheal injury can result from a variety of causes, including inhalation of smoke or toxic fumes, aspiration of liquids or solid objects, endotracheal intubation, blunt and penetrating trauma, and iatrogenic injury during operative procedures. Early diagnosis is critical to avoid subsequent complications, including respiratory infection and tracheal stenosis. Management of smoke or toxic fume inhalation and liquid aspiration is commonly supportive; use of antibiotics, respiratory support, and airway clearance with flexible bronchoscopy is dictated by the patient's condition. In rare circumstances, extracorporeal membrane oxygenation is required if there is associated injury to the more distal airways and lung parenchyma.

Despite ubiquitous use of high-volume–low-pressure cuffs, overinflation of the endotracheal cuff is the most common cause of injury secondary to endotracheal intubation. High cuff pressures can cause ischemia of the contiguous airway wall in as short as 4 hours. Prolonged overinflation can lead to scarring

Key Points

- 1▶ Lung cancer continues to be a highly lethal and extremely common cancer, with 57% of patients presenting with distant metastasis and 5-year survival of 18%. Lung cancer incidence is second only to the incidence of prostate cancer in men and breast cancer in women, with 222,500 estimated new cases in 2017. Squamous cell carcinoma and adenocarcinoma of the lung are the most common subtypes and are rarely found in the absence of a smoking history. Nonsmokers who live with smokers have a 24% increased risk of lung cancer compared to nonsmokers who do not live with smokers.
- 2▶ A multidisciplinary approach to evaluation of NSCLC, with standardized criteria and terminology for diagnosis in cytologic and small biopsy specimens, and routine molecular testing for known mutations, such as *EGFR* mutations and *EML4-ALK* fusion oncogenes is now recommended for the evaluation and management of lung nodules due to major advances in targeted therapy. Adequate tissue acquisition at the time of diagnostic workup is critical and facilitates patient care while minimizing the number of procedures to which the patient is subjected.
- 3▶ The terms *bronchioloalveolar carcinoma* and *mixed subtype adenocarcinoma* have been eliminated from the classification of lung adenocarcinoma as a result of increased understanding of important clinical, radiologic, pathologic, and genetic differences between mucinous and nonmucinous adenocarcinomas. The classification system delineates a stepwise pathologic progression, from AAH to invasive adenocarcinoma based on the predominant histologic growth patterns.
- 4▶ The U.S. Preventive Services Task Force now recommends annual screening for lung cancer with low-dose computed tomography screening in high risk patients. Annual screening averted 14% of lung cancer deaths when applied to a population of asymptomatic adults age 55 to 80 years who have a 30 pack-year smoking history and are either currently smoking or have quit within the past 15 years. Patients should be healthy enough to tolerate curative treatment, specifically surgery per guidelines, and screening should be discontinued once the patient has not smoked for 15 years or develops a life-limiting health condition, becomes unable to tolerate lung surgery, or is unwilling to undergo curative lung resection. With this approach, it is expected that 50% of diagnosed cancers will be early stage. Screening of patients age 50 years or older with a 20 pack-year or greater history and additional risk factors (as determined by the Tammemagi lung cancer risk calculator or other validated risk scores) that increase the risk of lung cancer to 1.3% or greater should also be considered as part of lung cancer screening programs. In all cases, patient-physician shared decision-making should be undertaken, with a discussion of the risks and benefits of screening.
- 5▶ Assessment of patient risk before thoracic resection is based on clinical judgment and systematic assessment of cardiopulmonary status using established algorithms.
- 6▶ Maximum oxygen consumption ($\dot{V}O_{2max}$) values provide important additional information in those patients with severely impaired DLCO and forced expiratory volume in 1 second. Values of <10 mL/kg per minute generally prohibit any major pulmonary resection because the mortality in patients with these levels is 26% compared with only 8.3% in patients whose $\dot{V}O_{2max}$ is ≥ 10 mL/kg per minute; values of >15 mL/kg per minute generally indicate the patient's ability to tolerate pneumonectomy.
- 7▶ Tumor ablative strategies are viable alternatives to surgical resection for early stage lung cancer in inoperable patients. While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers and become primary therapy, even in operable patients, although limited resection with wedge (at least 2 cm margin and at least 1:1 tumor/margin ratio) and segmentectomy provide better margins of treatment and nodal sampling ensures occult nodal metastasis are identified. Multidisciplinary collaboration among thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.
- 8▶ The term *non-small cell lung carcinoma (NSCLC)* includes many tumor cell types, including large cell, squamous cell, and adenocarcinoma. The approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly. In particular, the evaluation and management of adenocarcinoma of the lung has shifted dramatically and firm establishment of NSCLC cell type prior to chemotherapy for advanced stage lung cancer is essential.
- 9▶ Increasing evidence suggests a significant role for gastroesophageal reflux disease in the pathogenesis of chronic lung diseases such as bronchiectasis and idiopathic pulmonary fibrosis, and it may also contribute to bronchiolitis obliterans syndrome in lung transplant patients.
- 10▶ Treatment of pulmonary aspergillosis/aspergilloma is individualized. Following colonization of a lung cavity or area of bronchiectasis, fungal growth within the cavity appears as an irregular cavitory lining, progressing over time as a late finding in chronic pulmonary aspergillosis to a fungal ball called an aspergilloma. Asymptomatic patients can be observed without any additional therapy. Similarly, mild hemoptysis, which is not life-threatening, can be managed with medical therapy, including antifungals and cough suppressants. Oral triazole therapy is now considered the standard of care for chronic, cavitory pulmonary aspergillosis. Massive hemoptysis had traditionally been an indication for urgent or emergent operative intervention. However, with the advancement of endovascular techniques, bronchial artery embolization in select centers with experience in these techniques has been effective.
- 11▶ In patients with malignant pleural effusion, poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result with pleurodesis and is the primary indication for placement of indwelling pleural catheters. These catheters have dramatically changed the management of end-stage cancer treatment because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.

Figure 19-1. Anatomy of the larynx and upper trachea. m. = muscle; n. = nerve.

and stenosis; full-thickness injury can result in fistulae between the innominate artery anteriorly and the esophagus posteriorly. Avoidance requires careful cuff management to keep pressures as low as possible; in circumstances of prolonged ventilatory support and high airway pressure, cuff pressure monitoring (to maintain pressures <20 mmHg) is advisable.

Historically, clinically significant tracheal stenosis after tracheostomy occurred in 3% to 12% of cases, with severe

stenosis in 1% to 2%.² With the use of low-pressure cuffs, the estimated incidence has decreased to 4.9 cases per million patients per year. Intubation-related risk factors include prolonged intubation; high tracheostomy through the first tracheal ring or cricothyroid membrane; transverse rather than vertical incision on the trachea; oversized tracheostomy tube; prior tracheostomy or intubation; and traumatic intubation. Stenosis is also more common in older patients, in women, after radiation, or after excessive corticosteroid therapy, and in the setting of concomitant diseases such as autoimmune disorders, severe reflux disease, or obstructive sleep apnea and the setting of severe respiratory failure. However, even a properly placed tracheostomy can lead to tracheal stenosis because of scarring and local injury. Mild ulceration and stenosis are frequently seen after tracheostomy removal. Use of the smallest tracheostomy tube possible, rapid downsizing, and a vertical tracheal incision minimize the risk for posttracheostomy stenosis.

Stridor and dyspnea on exertion are the primary symptoms of tracheal stenosis. In the setting of postintubation injury, a significant portion of the cartilaginous structural support to the airway is destroyed by regional ischemic necrosis; during healing, a weblike fibrous growth develops and narrows the airway (Fig. 19-3). In contrast, stenosis caused by tracheostomy is most commonly due to an excess of granulation tissue formation around the tracheal stoma site. Time to onset of symptoms after extubation or tracheostomy decannulation usually ranges from 2 to 12 weeks, but symptoms can appear immediately or as long as 1 to 2 years later. Frequently, patients are misdiagnosed as having asthma or bronchitis, and treatment for such illnesses can persist for some time before the correct diagnosis is discovered. Generally, symptom intensity is related to the degree of stenosis and to the patient's underlying pulmonary disease.

Figure 19-2. Arterial blood supply to the larynx and upper trachea. a. = artery.

Figure 19-3. Diagram of the principal postintubation lesions. **A.** A circumferential lesion at the cuff site after the use of an endotracheal tube. **B.** Potential lesions after the use of tracheostomy tubes. Anterolateral stenosis can be seen at the stomal level. Circumferential stenosis can be seen at the cuff level (lower than with an endotracheal tube). The segment in between is often inflamed and malacotic. **C.** Damage to the tracheoesophageal fistula occurring at the level of the tracheostomy cuff; circumferential damage is usual at this level. **E.** Tracheoinnominate artery fistula. (Adapted with permission from Grillo H. *Surgical treatment of postintubation tracheal injuries.* J Thorac Cardiovasc Surg. 1979 Dec;78(6):860-875.)

Acute Management. A comprehensive bronchoscopic evaluation is critical in the initial phase of evaluation. Stenosis length, location, distance between the vocal cords and proximal stenosis, and distance from the distal aspect to the major carina must be documented. In patients with severe stenosis and respiratory compromise, rigid bronchoscopy can be used to dilate the stenosis; this provides immediate relief of the airway obstruction and facilitates thorough evaluation of the stenosis. Rarely, if ever, is tracheostomy necessary.

Most intubation injuries are located in the upper third of the trachea and can be accessed for resection through a collar incision. Resection typically involves 2 to 4 cm of trachea for benign stenosis. It is critical to fully resect all inflamed and scarred tissue. However, a primary anastomosis can still be performed without undue tension, even if up to one half of the trachea requires resection.² Ideally, the patient is extubated in the operating room or shortly thereafter. For patients in whom tracheal resection is not possible, such as patients with significant comorbidities or with an excessively long stenosis, endotracheal stenting, typically silicone T-tubes, can provide palliation. Wire mesh stents should not be used, given their known propensity to erode through the wall of the airway. Balloon dilation, laser ablation, and tracheoplasty have also been described, although the efficacy is marginal.

Tracheal replacement is evolving as an option for management of tracheal stenosis as bioengineering techniques for decellularizing donor trachea have been developed. This removes all antigens against which the recipient immune system might react and enables use of the donor trachea scaffolding without risk of rejection. Following decellularization, the donor tracheal scaffolding is seeded with recipient chondrocytes, to restore tracheal rigidity, and with recipient epithelial cells, to recreate the inner epithelial lining. Several case reports of successful allogeneic

tracheal transplantation have been published. The technique continues to be limited to a few highly specialized centers, due, in part, to the scarcity of donor trachea and the need for tissue bioengineering expertise as well as the lack of established efficacy for the approach. Current efforts are focused on creation of biosynthetic scaffolding that can be used instead of donor trachea. This would substantially increase the availability of the tracheal replacement material and enable widespread use of the technique, but early results have been contested, including three case reports called into question as containing multiple data fabrications and omissions.

Tracheal Fistulas

Tracheoinnominate Artery Fistula. Tracheoinnominate artery fistula has two main causes: low placement of a tracheostomy and hyperinflation of the tracheal cuff. Tracheostomy placement should be through the second to fourth tracheal rings without reference to the location of the sternal notch. When placed below the fourth tracheal ring, the inner curve of the tracheostomy cannula will be positioned to exert pressure on the posterior aspect of the innominate artery, leading to arterial erosion. Similarly, the tracheal cuff, when hyperinflated, will cause ischemic injury to the anterior airway and subsequent erosion into the artery. Most cuff-induced fistulas will develop within 2 weeks after placement of the tracheostomy.

Clinically, tracheoinnominate artery fistulas present with bleeding. A premonitory hemorrhage often occurs and, although it is usually not massive, must not be ignored or simply attributed to general airway irritation or wound bleeding. With significant bleeding, the tracheostomy cuff can be hyperinflated to temporarily occlude the arterial injury. If such an effort is unsuccessful, the tracheostomy incision should be immediately opened widely and a finger inserted to compress the artery

Figure 19-4. Steps in the emergency management of a tracheoinnominate artery fistula.

against the manubrium (Fig. 19-4). The patient can then be orally intubated, and the airway suctioned free of blood. Emergent surgical resection of the involved segment of artery is performed, usually without reconstruction.

Tracheoesophageal Fistula. Tracheoesophageal fistulas (TEFs) occur primarily in patients receiving prolonged mechanical ventilator support concomitant with an indwelling nasogastric tube.⁴ Cuff compression of the membranous trachea against the nasogastric tube leads to airway and esophageal injury and fistula development. Clinically, airway suctioning reveals saliva, gastric contents, or tube feedings. Gastric insufflation, secondary to positive pressure ventilation, can occur. Bronchoscopy is diagnostic; with the bronchoscope inserted, the endotracheal tube is withdrawn, and the fistula at the cuff site is exposed. Alternatively, esophagoscopy demonstrates the cuff of the endotracheal tube in the esophagus.

Treatment, first and foremost, requires removing tubes from the esophagus and weaning the patient from the ventilator. The cuff of the endotracheal tube should be placed below the fistula, avoiding overinflation. To minimize aspiration, a gastrostomy tube should be placed for gastric decompression (to prevent reflux) and a jejunostomy tube for feeding. If aspiration persists, esophageal diversion with cervical esophagostomy

can be performed. Once weaned from the ventilator, tracheal resection and primary anastomosis, repair of the esophageal defect, and interposition of a muscle flap between the trachea and esophagus can be performed (Fig. 19-5).⁵

Tracheal Neoplasms

Although extremely rare, the most common primary tracheal neoplasms are squamous cell carcinomas (related to smoking) and adenoid cystic carcinomas. Clinically, tracheal tumors present with cough, dyspnea, hemoptysis, stridor, or symptoms of invasion of contiguous structures (such as the recurrent laryngeal nerve or the esophagus). The most common radiologic finding of tracheal malignancy is tracheal stenosis, but it is found in only 50% of cases. With tumors other than squamous cell carcinomas, symptoms may persist for months because of slow tumor growth rates. Stage of presentation is advanced, with approximately 50% of patients presenting with stage IV disease. Five-year survival for all tracheal neoplasms is 40% but falls to 15% for those with stage IV disease.⁶

Squamous cell carcinomas often present with regional lymph node metastases and are frequently unresectable at presentation. Their biologic behavior is similar to that of squamous cell carcinoma of the lung. Adenoid cystic carcinomas, a type of

Figure 19-5. Single-stage operation for closure of a tracheoesophageal fistula and tracheal resection. **A.** The fistula is divided, and the trachea is transected below the level of damage. **B.** The fistula is closed on the tracheal side in a single layer and the esophageal side in a double layer. The damaged trachea segment is resected. **C.** A pedicled muscle flap, such as the sternohyoid muscle, is used to buttress the esophageal repair. **D.** View of completed tracheal anastomosis. m. = muscle.

salivary gland tumor, are generally slow growing, spread submucosally, and tend to infiltrate along nerve sheaths and within the tracheal wall. Although indolent in nature, adenoid cystic carcinomas are malignant and can spread to regional lymph nodes, lung, and bone. Squamous cell carcinoma and adenoid cystic carcinomas represent approximately 65% of all tracheal neoplasms. The remaining 35% is comprised of small cell carcinomas, mucoepidermoid carcinomas, adenocarcinomas, lymphomas, and others.⁷

Therapy. Evaluation and treatment of patients with tracheal tumors should include neck and chest computed tomography (CT) and rigid bronchoscopy. Rigid bronchoscopy permits general assessment of the airway and tumor; it also allows debridement or laser ablation of the tumor to provide relief of dyspnea. If the tumor is judged to be completely resectable, primary resection and anastomosis is the treatment of choice for these tumors (Fig. 19-6). Up to 50% of the length of the trachea can be resected with primary anastomosis. In most tracheal resections,

anterolateral tracheal mobilization and suturing of the chin to the sternum for 7 days are done routinely. Use of laryngeal and hilar release is determined at the time of surgery, based on the surgeon's judgment of the degree of tension present. For longer resections, specialized maneuvers are necessary such as laryngeal release and right hilar release to minimize tension on the anastomosis.

Postoperative mortality, which occurs in up to 10% of patients, is associated with the length of tracheal resection, use of laryngeal release, the type of resection, and the histologic type of the cancer. Factors associated with improved long-term survival include complete resection and use of radiation as adjuvant therapy in the setting of incomplete resection.⁸ Due to their radiosensitivity, radiotherapy is frequently given postoperatively after resection of both adenoid cystic carcinomas and squamous cell carcinomas.⁹ A dose of 50 Gy or greater is usual. Nodal positivity does not seem to be associated with worse survival. Survival at 5 and 10 years is much better for adenoid

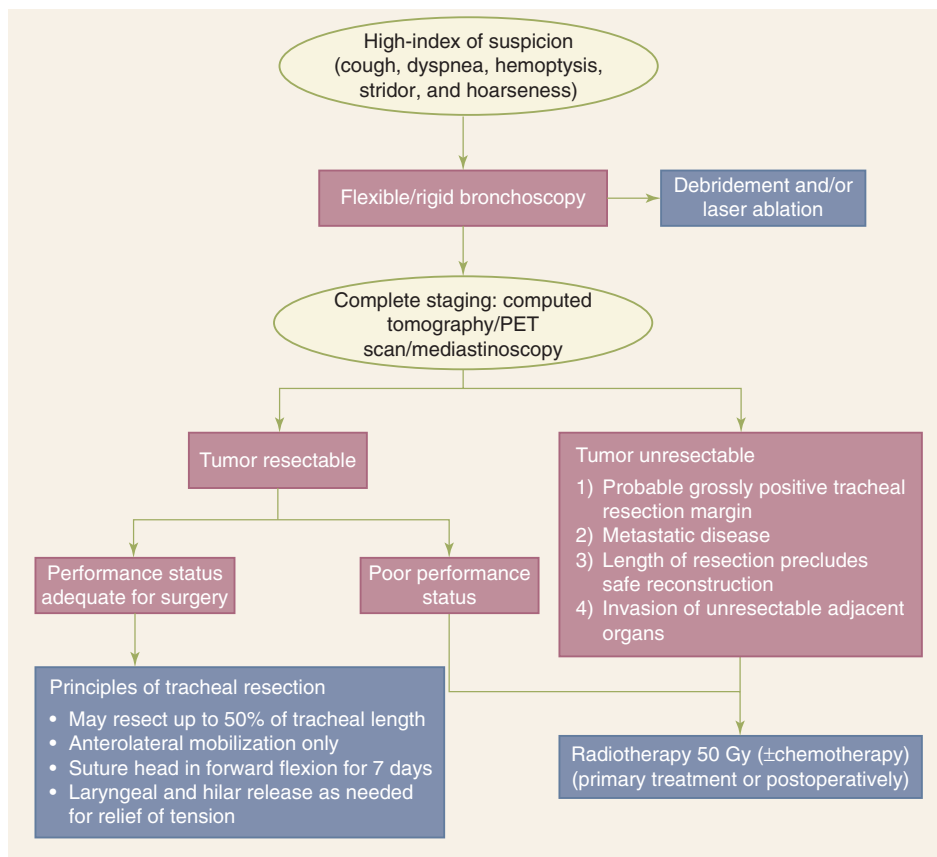

Figure 19-6. Algorithm for evaluation and treatment of tracheal neoplasm. PET = positron emission tomography.

cystic (73% and 57%, respectively) than for tracheal cancers (47% and 36%, respectively; $P < .05$). For patients with unresectable tumors, radiation may be given as the primary therapy to improve local control, but it is rarely curative. For recurrent airway compromise, stenting or laser therapies should be considered as part of the treatment algorithm.

LUNG

Anatomy

Segmental Anatomy. The segmental bronchial and vascular anatomy of the lungs allows subsegmental and segmental resections, if the clinical situation requires or if lung tissue can be preserved¹⁰ (Fig. 19-7). Note the continuity of the pulmonary parenchyma between adjacent segments of each lobe.

Lymphatic Drainage. Lymph nodes that drain the lungs are divided into two groups according to the tumor-node-metastasis (TNM) staging system for lung cancer: the pulmonary lymph nodes (N1) and the mediastinal nodes (N2) (Fig. 19-8).

The N1 lymph nodes constitute the following: (a) intrapulmonary or segmental nodes that lie at points of division of segmental bronchi or in the bifurcations of the pulmonary artery; (b) lobar nodes that lie along the upper, middle, and lower lobe bronchi; (c) interlobar nodes located in the angles formed by the main bronchi bifurcating into the lobar bronchi; and (d) hilar nodes along the main bronchi. The interlobar lymph nodes lie in the depths of the interlobar fissure on each side and constitute a lymphatic sump for each lung, referred to as the *lymphatic sump of Borrie*; all of the pulmonary lobes of the corresponding lung drain into this group of nodes (Fig. 19-9). On the right,

the nodes of the lymphatic sump lie around the bronchus intermedius (bounded above by the right upper lobe bronchus and below by the middle lobe and superior segmental bronchi). On the left, the lymphatic sump is confined to the interlobar fissure, with the lymph nodes in the angle between the lingular and lower lobe bronchi. These nodes are always in close proximity to pulmonary arterial branches and typically must be carefully dissected to identify the pulmonary arterial segments for division during lung resection.

The N2 lymph nodes consist of four main groups. (a) The anterior mediastinal nodes are located in association with the upper surface of the pericardium, the phrenic nerves, the ligamentum arteriosum, and the left aspect of the innominate vein. (b) The posterior mediastinal group includes paraesophageal lymph nodes within the inferior pulmonary ligament and, more superiorly, between the esophagus and trachea near the arch of the azygos vein. (c) The tracheobronchial lymph nodes are made up of three subgroups that are located near the bifurcation of the trachea. These include the subcarinal nodes, which lie in the obtuse angle between the trachea and each main stem bronchus, and the nodes that lay anterior to the lower end of the trachea. (d) Paratracheal lymph nodes are located in proximity to the trachea in the superior mediastinum. Those on the right side form a chain with the tracheobronchial nodes inferiorly and with some of the deep cervical nodes above (scalene lymph nodes).

Lymphatic drainage to the mediastinal lymph nodes from the right lung is ipsilateral, except for occasional bilateral drainage to the superior mediastinum. In contrast, in the left lung, particularly the left lower lobe, lymphatic drainage occurs with equal frequency to ipsilateral and contralateral superior mediastinal nodes.

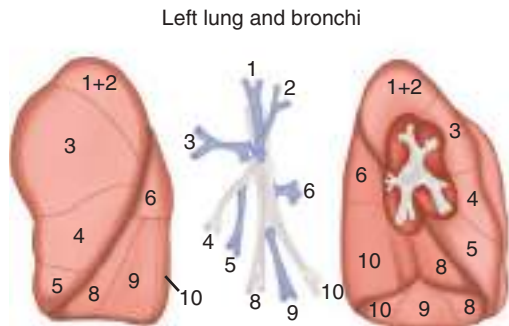

Figure 19-7. Segmental anatomy of the lungs and bronchi.

Figure 19-9. The lymphatic sump of Borrie includes the groups of lymph nodes that receive lymphatic drainage from all pulmonary lobes of the corresponding lung.

Normal Lung Histology

The lung can be conveniently viewed as two linked components: the tracheobronchial tree (or conducting airways component) and the alveolar spaces (or gas exchange component). The tracheobronchial tree consists of approximately 23 airway divisions to the level of the alveoli. It includes the main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and terminal bronchioles (i.e., the smallest airways still lined by bronchial epithelium and without alveoli). The tracheobronchial tree is normally lined by pseudostratified ciliated columnar cells and mucous (or goblet) cells, which both derive from basal cells (Fig. 19-10). Ciliated cells predominate. Goblet cells, which release mucus, can significantly increase in number in acute bronchial injury, such as exposure to cigarette smoke. The normal bronchial epithelium also contains bronchial submucosal glands, which are mixed salivary-type glands

Figure 19-8. The location of regional lymph node stations for lung cancer.

A

B

Figure 19-10. Normal lung histology. **A.** Pseudostratified ciliated columnar cells and mucous cells normally line the tracheobronchial tree. **B.** A Kulchitsky cell is depicted (*arrow*).

containing mucous cells, serous cells, and neuroendocrine cells called Kulchitsky cells, which are also found within the surface epithelium. The bronchial submucosal glands can give rise to salivary gland-type tumors, including mucoepidermoid carcinomas and adenoid cystic carcinomas.

Two cell types, called type I and type II pneumocytes, make up the alveolar epithelium. Type I pneumocytes comprise 40% of the total number of alveolar epithelial cells, but cover 95% of the surface area of the alveolar wall. These cells are not capable of regeneration because they have no mitotic potential. Type II pneumocytes cover only 3% of the alveolar surface, but comprise 60% of the alveolar epithelial cells. In addition, clusters of neuroendocrine cells are seen in the alveolar spaces.

Preinvasive Lesions

The term “precancerous” does not mean that an inevitable progression to invasive carcinoma will occur, but such lesions, particularly those with high-grade dysplasia,^{11,12} do constitute a clear marker for potential development of invasive cancer.

Three precancerous lesions of the respiratory tract are currently recognized.

1. **Squamous dysplasia and carcinoma in situ.** Cigarette smoke can induce a transformation of the tracheobronchial pseudostratified epithelium to metaplastic squamous mucosa, with subsequent evolution to dysplasia as cellular abnormalities accumulate. Dysplastic changes include altered cellular polarity and increased cell size, number of cell layers, nuclear-to-cytoplasmic ratio, and number of mitoses. Gradations are considered mild, moderate, or severe. Carcinoma in situ represents carcinoma still confined by the basement membrane.
2. **Atypical adenomatous hyperplasia (AAH).** AAH is a lesion smaller than 5.0 mm, comprising epithelial cells lining the alveoli that are similar to type II pneumocytes. Histologically, AAH is similar to adenocarcinoma in situ; it represents the beginning stage of a stepwise evolution to adenocarcinoma in situ and then to adenocarcinoma. With the availability of thin-section CT, it is possible to detect

preinvasive adenocarcinoma lesions as early as AAH. These lesions can be multiple, are typically small (5 mm or less), and have a ground-glass appearance.

3. **Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.** This rare lesion represents a diffuse proliferation of neuroendocrine cells, but without invasion of the basement membrane. It can exist as a diffuse increase in the number of single neuroendocrine cells, or as small lesions less than 5.0 mm in diameter. Lesions over 5.0 mm in size or that breach the basement membrane are carcinoid tumors.

Invasive or Malignant Lesions

The pathologic diagnosis of lung cancer is currently based on light microscopic criteria and is broadly divided into two main groups: *non-small cell lung carcinoma* and neuroendocrine tumors.¹³ Immunohistochemical staining and electron microscopy are used as adjuncts in diagnosis, particularly in the assessment of potential neuroendocrine tumors.

Non-Small Cell Lung Carcinoma. The term *non-small cell lung carcinoma (NSCLC)* includes many tumor cell types, including large cell, squamous cell, and adenocarcinoma. Historically, these subtypes were considered to be a uniform group based on limited understanding of the distinct clinical behaviors of the subtypes as well as the fact that there were few treatment options available. With increasing understanding of the molecular biology underlying these tumor subtypes, however, the approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly.

Adenocarcinoma The incidence of adenocarcinoma has increased over the last several decades, and it is now the most common lung cancer, accounting for 30% of lung cancers in

male smokers and 40% of lung cancers in female smokers.

- 1▶ Adenocarcinoma is the histologic subtype for 80% and 60% of lung cancers in nonsmoking females and males, respectively. It occurs more frequently in females than in males. It is the most frequent histologic subtype in women, patients who are under 45 years of age, and Asian populations.¹⁴

Histologic Subtyping of Adenocarcinoma. Increasing understanding of lung adenocarcinoma, such as important clinical, radiologic, pathologic, and genetic differences between mucinous and nonmucinous adenocarcinomas, prompted multiple changes in the classification system in 2011.¹⁵ Based on consensus, the international working group proposed a multidisciplinary approach, with standardized criteria and terminology for diagnosis in cytologic and small biopsy specimens, and routine molecular testing for known mutations, such as *EGFR* and *KRAS* mutations (Table 19-1). The new classification system delineated

- 2▶ a stepwise pathologic progression, from AAH to invasive adenocarcinoma based on the predominant histologic growth patterns; the terms *bronchioloalveolar carcinoma* and
- 3▶ *mixed subtype adenocarcinoma* were eliminated in favor of more biologically driven classification (Table 19-2).

1. **Adenocarcinoma in situ (AIS).** AISs are small (≤ 3 cm) solitary adenocarcinomas that have pure lepidic growth; lepidic growth is characterized by tumor growth within the alveolar spaces. These lesions are not invasive into the stroma, vascular system, or pleura and do not have papillary or micropapillary patterns or intra-alveolar tumor cells. They are very rarely mucinous, consisting of type II pneumocytes or Clara cells. These patients are expected to have 100% disease-specific survival with complete surgical resection. On CT scan, AIS can appear as a pure ground-glass neoplasm,

Table 19-1

Difference between invasive mucinous adenocarcinoma and nonmucinous adenocarcinoma in situ/minimally invasive adenocarcinoma/lepidic predominant adenocarcinoma

	INVASIVE MUCINOUS ADENOCARCINOMA (FORMERLY MUCINOUS BAC)	NONMUCINOUS AIS/MIA/LPA (FORMERLY NONMUCINOUS BAC)
Female	49/84 (58%) ^{52,120-123}	101/140 (72%) ^{52,120-123}
Smoker	39/87 (45%) ^{52,120-122,124}	75/164 (46%) ^{52,120-122,124}
Radiographic appearance	Majority consolidation; air bronchogram ¹²⁵ Frequent multifocal and multilobar presentation ^{56,125-128}	Majority ground-glass attenuation ^{23,56,58,103,129-134}
Cell type	Mucin-filled, columnar, and/or goblet ^{50-52,125,135}	Type II pneumocyte and/or Clara cell ^{50-52,125,135}
Phenotype		
CK7	Mostly positive (~88%) ^{a54,55,136-139}	Positive (~98%) ^{a54,55,136-139}
CK20	Positive (~54%) ^{a54,55,136-139}	Negative (~5%) ^{a54,55,136-139}
TTF-1	Mostly negative (~17%) ^{a54,55,120,137-139}	Positive (~67%) ^{a54,55,120,137-139}
Genotype		
<i>KRAS</i> mutation	Frequent (~76%) ^{a55,94,121,127,140-144}	Some (~13%) ^{a55,121,127,140-144}
<i>EGFR</i> mutation	Almost none (~3%) ^{a55,121,127,140-142}	Frequent (~45%) ^{a55,121,127,140-142}

Note: ^aNumbers represent the percentage of cases that are reported to be positive.

Enteric

Abbreviations: BAC = bronchioloalveolar carcinoma; IASLC = International Association for the Study of Lung Cancer; ATS = American Thoracic Society; ERS = European Respiratory Society. Reproduced with permission from Travis WD, Brambilla E, Noguchi M, et al: International association for the study of lung cancer/american thoracic society/european respiratory society international multidisciplinary classification of lung adenocarcinoma, *J Thorac Oncol*. 2011 Feb;6(2):244-285.

but occasionally it will present as part of a solid or part-solid nodule. Mucinous AIS is more likely to appear solid or to have the appearance of consolidation. As with AAH, the lesions can be single or multiple; the ground-glass changes in AIS, however, tend to have a higher attenuation compared to AAH. The 8th edition American Joint Committee on Cancer (AJCC) staging manual t-stage for AIS is tumor in situ (Tis).

2. **Minimally invasive adenocarcinoma (MIA).** In the same size solitary lesion, if less than 5 mm of invasion are noted within a predominantly lepidic growth pattern, the lesion is termed *minimally invasive adenocarcinoma (MIA)* to indicate a patient group with near 100% survival when the lesion is completely resected. This differentiates patients with AIS, but recognizes the fact that the presence of invasion becomes prognostically significant when the size of the invasive component reaches 5 mm or greater in size.¹⁶ If multiple areas of microscopic invasion are found within the lepidic growth, the size of the largest invasive area, measured in the largest dimension, is used; this area must be ≤ 5 mm to be considered MIA. As with AIS, MIA is very rarely mucinous. The invasive component histologically is acinar, papillary, micropapillary, and/or solid and shows tumor cells infiltrating into the surrounding myofibroblastic stroma. On CT scan, the appearance of MIA is often a part-solid nodule (≤ 5 mm) with a predominant ground-glass component, but can be

highly variable. The 8th edition American Joint Committee on Cancer (AJCC) staging manual t-stage for MIA is T1mi.

3. **Lepidic predominant adenocarcinoma (LPA).** If lymphovascular invasion, pleural invasion, tumor necrosis, or more than 5 mm of invasion are noted in a lesion that has lepidic growth as its predominant component, MIA is excluded, the lesion is called *lepidic predominant adenocarcinoma (LPA)*, and the size of the invasive component is recorded for the T stage.
4. **Invasive adenocarcinoma.** The new classification system now recommends classifying invasive adenocarcinoma by the most predominant subtype after histologic evaluation of the resection specimen. To determine the predominant subtype, histologic sections are evaluated, and the patterns are determined, in 5% increments, throughout the specimen. This semiquantitative method encourages the viewer to identify and quantify all patterns present, rather than focusing on a single pattern. In the pathology report, the tumor is classified by the predominant pattern, with percentages of the subtypes also reported (Fig. 19-11).
Subtypes include:
 - a. Lepidic predominant
 - b. Acinar predominant
 - c. Papillary predominant
 - d. Micropapillary predominant
 - e. Solid predominant

Adenocarcinoma is often peripherally located and frequently discovered incidentally on routine chest radiographs, unlike squamous cell cancers. When symptoms occur, they are due to pleural or chest wall invasion (pleuritic or chest wall pain) or pleural seeding with malignant pleural effusion. Invasive adenocarcinoma is usually solid by CT scan, but can also be part-solid and even a ground-glass nodule. Occasionally, a lobar ground-glass opacification may be present, which is often associated with significant respiratory compromise and can be mistaken for lobar pneumonia. Bubble-like or cystic lucency on CT scan in small (≤ 2 cm) adenocarcinomas or extensive associated ground-glass components correlate with slow growth and well-differentiated tumors and a more favorable prognosis. Intratumoral air bronchograms are usually indicative of well-differentiated tumor, whereas spiculations that are coarse and thick (≥ 2 mm) portend vascular invasion and nodal metastasis and are associated with decreased survival following complete surgical resection. Pleural retraction is also a poor prognostic indicator.

5. Additional histologic variants include colloid adenocarcinoma (formerly mucinous cystadenocarcinoma), fetal adenocarcinoma, and enteric adenocarcinoma. Clear cell and signet ring cell types are no longer considered to be distinct subtypes as they are found in association with most of the five dominant histologic patterns (lepidic, acinar, papillary, micropapillary, and solid). However, they are still notable, as they can signal clinically relevant molecular changes, such as the presence of the *EML4-ALK* fusion gene in solid tumors with signet ring features.

Squamous Cell Carcinoma Representing 30% to 40% of lung cancers, squamous cell carcinoma is the most frequent cancer in men and highly correlated with cigarette smoking. They arise primarily in the main, lobar, or first segmental bronchi, which are collectively referred to as the central airways. Symptoms of airway irritation or obstruction are common, and include cough,

Figure 19-11. Major histologic patterns of invasive adenocarcinoma. **A.** Lepidic predominant pattern with mostly lepidic growth (*right*) and a smaller area of invasive acinar adenocarcinoma (*left*). **B.** Lepidic pattern consists of a proliferation type II pneumocytes and Clara cells along the surface alveolar walls. **C.** Area of invasive acinar adenocarcinoma (same tumor as in **A** and **B**). **D.** Acinar adenocarcinoma consists of round to oval-shaped malignant glands invading a fibrous stroma. **E.** Papillary adenocarcinoma consists of malignant cuboidal to columnar tumor cells growing on the surface of fibrovascular cores. **F.** Micropapillary adenocarcinoma consists of small papillary clusters of glandular cells growing within this airspace, most of which do not show fibrovascular cores. **G.** Solid adenocarcinoma with mucin consisting of sheets of tumor cells with abundant cytoplasm and mostly vesicular nuclei with several conspicuous nucleoli. No acinar, papillary, or lepidic patterns are seen, but multiple cells have intracytoplasmic basophilic globules that suggest intracytoplasmic mucin. **H.** Solid adenocarcinoma with mucin. Numerous intracytoplasmic droplets of mucin are highlighted with this diastase-periodic acid Schiff stain. (*Reproduced with permission from Travis WD, Brambilla E, Noguchi M, et al: International association for the study of lung cancer/american thoracic society/european respiratory society international multidisciplinary classification of lung adenocarcinoma, J Thorac Oncol. 2011 Feb;6(2):244-285.*)

hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis).

Occasionally a more peripherally based squamous cell carcinoma will develop in a tuberculosis scar or in the wall of a bronchiectatic cavity. Histologically, cells develop a pattern of clusters with intracellular bridges and keratin pearls. Central necrosis is frequent and may lead to the radiographic findings of a cavity (possibly with an air-fluid level). Such cavities may become infected, with resultant abscess formation.

Large Cell Carcinoma Large cell carcinoma accounts for 10% to 20% of lung cancers and may be located centrally or peripherally. These tumors have cell diameters of 30 to 50 μm , which are often admixed with various other malignant cell types. Large cell carcinoma can be confused with a large cell variant of neuroendocrine carcinoma, but can be differentiated by special immunohistochemical stains.

Salivary Gland-Type Neoplasms. Salivary-type submucosal bronchial glands throughout the tracheobronchial tree can give

rise to tumors that are histologically identical to those seen in the salivary glands. The two most common are adenoid cystic carcinoma and mucoepidermoid carcinoma. Both occur centrally due to their site of origin. Adenoid cystic carcinoma is a slow-growing tumor that is locally and systemically invasive, growing submucosally and infiltrating along perineural sheaths. Mucoepidermoid carcinoma consists of squamous and mucous cells and is graded as low or high grade, depending on mitotic rate and degree of necrosis.

Neuroendocrine Neoplasms. Neuroendocrine lung tumors are classified into neuroendocrine hyperplasia and three grades of neuroendocrine carcinoma (NEC). Immunohistochemical staining for neuroendocrine markers (including chromogranins, synaptophysin, CD57, and neuron-specific enolase) is essential to accurate diagnosis.¹⁷

Grade I NEC (classic or typical carcinoid) is a low-grade NEC; 80% arise in the central airway epithelium and occur primarily in younger patients. Because it is a central lesion, hemoptysis, with or without airway obstruction and pneumonia is the most common presentation. Histologically, tumor cells

are arranged in cords and clusters with a rich vascular stroma, which can lead to life-threatening hemorrhage with even simple bronchoscopic biopsy maneuvers. Regional lymph node metastases are seen in 15% of patients, but systemic spread and death from Grade I NEC is rare.

Grade II NECs (atypical carcinoid) have a much higher malignant potential and, unlike grade I NEC, are etiologically linked to cigarette smoking and more likely to be peripherally located. Histologic findings may include areas of necrosis, nuclear pleomorphism, and higher mitotic rates. Lymph node metastases are found in 30% to 50% of patients. At diagnosis, 25% of patients already have remote metastases.

Grade III NEC large cell–type tumors occur primarily in heavy smokers and in the mid to peripheral lung fields. Often large with central necrosis and a high mitotic rate, their neuroendocrine nature is revealed by positive immunohistochemical staining for at least one neuroendocrine marker.

Grade IV NEC (small cell lung carcinoma [SCLC]) is the most malignant NEC and accounts for 25% of all lung cancers; these NECs often have early, widespread metastases. These cancers also arise primarily in the central airways. As with squamous cell cancers, symptoms include cough, hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis). Evaluation includes expert pathology review and comprehensive evaluation for metastatic

disease. Three groups of grade IV NEC are recognized: pure small cell carcinoma (previously referred to as oat cell carcinoma), small cell carcinoma with a large cell component, and combined (mixed) tumors.

Grade IV NECs consist of smaller cells (diameter 10 to 20 μm) with little cytoplasm and very dark nuclei; they can be difficult to distinguish from lymphoproliferative lesions and atypical carcinoid tumors. Histologically, a high mitotic rate with easily visualized multiple mitoses and areas of extensive necrosis are characteristic. Importantly, very small bronchoscopic biopsies can distinguish NSCLC from SCLC, but crush artifact may make NSCLC appear similar to SCLC. If uncertainty exists, special immunohistochemical stains or rebiopsy (or both) will be necessary. These tumors are the leading producer of paraneoplastic syndromes.

Lung Cancer Epidemiology

Lung cancer is the leading cancer killer and second most frequently diagnosed cancer in the United States, accounting for 26% of all cancer deaths in 2017—more than cancers of the breast, prostate, ovary, and colon and rectum combined (Fig. 19-12).¹⁸ Lung cancer incidence continues to decline, though at twice the rate for men compared to women (Fig. 19-13A, B). It is encouraging, however, that the average annual death rate declined by 3.5% per year for men and 2% per year for women from 2010 to 2014, representing a 43% decline in mortality for men and a 17% decline for women from 1990

Figure 19-12. Leading new cancer cases and deaths: 2017 estimates. *Excludes basal and squamous cell skin cancers and in situ carcinomas except urinary bladder. (Reproduced with permission from Siegel RL, Miller KD, Jemal A: *Cancer Statistics, 2017*, CA Cancer J Clin. 2017 Jan;67(1):7-30.)

†Mortality rates for pancreatic and liver cancers are increasing.

Trends in Age-Adjusted Cancer Death Rates* by Site, Females, US, 1930-2014

*Per 100,000, age adjusted to the 2000 US standard population.

†Uterus refers to uterine cervix and uterine corpus combined.

‡Mortality rates for liver cancer are increasing.

Figure 19-13. Trends in death rates by sex for select cancers, United States, 1930 to 2014. **A.** Males. **B.** Female rates are age-adjusted to the 2000 U.S. standard population. Due to improvements in International Classification of Diseases (ICD) coding over time, numerator data for cancers of the lung and bronchus, colon and rectum, liver, and uterus differ from the contemporary time period. For example, rates for lung and bronchus include pleura, trachea, mediastinum, and other respiratory organs. (Adapted with permission from Siegel RL, Miller KD, Jemal A: *Cancer Statistics, 2017*, CA Cancer J Clin. 2017 Jan;67(1):7-30.)

to 2014.¹⁸ Unfortunately, most patients are still diagnosed at an advanced stage of disease (22% with regional metastasis and 57% with distant metastasis), so therapy is rarely curative.¹⁸

Prognostic markers for lung cancer survival include female sex (5-year survival of 18.3% for women vs. 13.8% for men), younger age (5-year survival of 22.8% for those <45 years vs. 13.7% for those >65 years), and white race (5-year survival of 16.1% for whites vs. 12.2% for blacks). When access to advanced medical care is unrestricted, as for the military population, the racial difference in survival disappears, suggesting that, at least in part, differences in survival may be explained by less access to advanced medical care and later diagnosis.¹⁹

Risk Factors for Lung Cancer. Cigarette smoking is the leading preventable cause of cancer death, accounting for 29% of the population attributable fraction in 2010, and is implicated as a causal factor in approximately 90% of lung cancers in men and nearly 80% in women. Two lung cancer types—squamous cell and small cell carcinoma—are extraordinarily rare in the absence of cigarette smoking. The risk of developing lung cancer escalates with the number of cigarettes smoked, the number of years of smoking, and the use of unfiltered cigarettes. Conversely, the risk of lung cancer declines with smoking cessation, but never drops to that of never smokers, regardless of the length of abstinence (Table 19-3).²⁰ Radon exposure accounts for the vast majority of the remaining cancers. Approximately 25% of all lung cancers worldwide and 53% of cancers in women are not related to smoking, and most of them (62%) are adenocarcinomas. Table 19-4 summarizes the existing data regarding the etiology of lung cancer in nonsmokers.²¹

Nearly 3500 deaths from lung cancer each year are attributable to secondhand (environmental) smoke exposure, which confers an excess risk for lung cancer of 24% when a nonsmoker lives with a smoker.²² Risk is conferred by exposure to any burning tobacco, including cigars. The amount of secondhand exposure from one large cigar is equivalent to the exposure from 21 cigarettes. As with active smoking, risk of developing lung cancer increases with longer duration and higher level of exposure to environmental tobacco.

Over 7000 chemicals have been identified in tobacco smoke, and more than 70 of the compounds are known to be carcinogens. The main chemical carcinogens are polycyclic aromatic hydrocarbons, which are actively or passively inhaled in the tobacco smoke and absorbed; these compounds are activated by specific enzymes and become mutagenic, bind to macromolecules such as deoxyribonucleic acid (DNA), and induce

genetic mutations. In treating any patient with a previous smoking history, it is important to remember that there has been field cancerization of the entire aerodigestive tract. The patient's risk is increased for cancers of the oral cavity, pharynx, larynx, tracheobronchial tree and lung, and esophagus. In examining such patients, a detailed history and physical examination of these organ systems must be performed.

Other causes of lung cancer include exposure to a number of industrial compounds, including asbestos, arsenic, and chromium compounds. In fact, the combination of asbestos and cigarette smoke exposure has a multiplicative effect on risk. Pre-existing lung disease confers an increased risk of lung cancer—up to 13%—for individuals who have never smoked. Patients with chronic obstructive pulmonary disease are at higher risk for lung cancer than would be predicted based on smoking risk alone. Patients with secondary scar formation related to a history of tuberculosis or other lung infections also have a higher risk of primary lung carcinoma. This increase is thought to be related to poor clearance of inhaled carcinogens and/or to the effects of chronic inflammation.

Screening for Lung Cancer in High-Risk Populations

In 2002, the National Lung Screening Trial (NLST) was launched to determine whether screening with CT in high-risk populations would reduce mortality from lung cancer. The study randomized 53,353 eligible patients age 55 to 74 years to either three annual low-dose helical CT scans (LDCT; aka spiral CT) or posteroanterior view chest radiograph. Patients were eligible for the trial if they had a greater than 30 pack-year history of cigarette smoking; had smoked within the past 15 years if a former smoker; had no prior history of lung cancer; had no history of other life-threatening cancers in the prior 5 years; did not have symptoms suggestive of an undiagnosed lung cancer (such as hemoptysis or weight loss); and had not had a chest CT scan in the prior 18 months. Accrual to the study was excellent, and the primary endpoint of a 20% relative reduction in mortality was achieved in 2010. An absolute risk reduction of lung cancer death of four per 1000 individuals screened by LDCT was realized. Interestingly, all-cause mortality was also reduced by nearly 7% in the LDCT group, further emphasizing the impact of lung cancer on the mortality of smokers and former smokers.²³ The U.S. Preventive Services Task Force (USPSTF) now recommends annual screening for lung cancer with low-dose computed tomography screening in high risk patients. Annual screening averted 14% of lung cancer deaths

4▶ when applied to a population of asymptomatic adults age 55 to 80 years who have a 30 pack-year smoking history and are either currently smoking or have quit within the past 15 years. Patients should be healthy enough to tolerate curative treatment, specifically surgery per guidelines, and screening should be discontinued once the patient has not smoked for 15 years or develops a life-limiting health condition, becomes unable to tolerate lung surgery or is unwilling to undergo curative lung resection. Requirements for coverage differ between Medicare and private insurers, with private insurers following the USPSTF guidelines, while Medicare uses age 55 to 77 years with the same smoking history but does not define comorbid conditions. Use of standardized reporting with criteria for lung nodule identification and classification is required by the Center for Medicaid & Medicare Services (CMS) but is only recommended by private insurers. Shared decision-making is also required by Medicare, but it is only recommended by private insurers. Medicare also differs from private

Table 19-3

Relative risk of lung cancer in smokers

SMOKING CATEGORY	RELATIVE RISK
Never smoked	1.0
Currently smoke	15.8–16.3
Formerly smoked	
Years of abstinence	
1–9	5.9–19.5
10–19	2.0–6.1
>20	1.9–3.7

Data from Samet JM. Health benefits of smoking cessation, *Clin Chest Med.* 1991;12(4):669-679.

Table 19-4

Summary of selected studies of risk factors for lung cancer in individuals who never smoked

RISK FACTOR	RISK ESTIMATE (95% CI)	COMMENTS	REFERENCE
Environmental tobacco smoke	1.19 (90% CI: 1.04–1.35)	Meta-analysis of 11 U.S. studies of spousal exposure (females only)	225
	1.21 (1.13–1.30)	Meta-analysis of 44 case-control studies worldwide of spousal exposure	226
	1.22 (1.13–1.33)	Meta-analysis of 25 studies worldwide of workplace exposure	226
	1.24 (1.18–1.29)	Meta-analysis of 22 studies worldwide of workplace exposure	227
Residential radon	8.4% (3.0%–15.8%) per 100 Bq m ³ increase in measured radon	Meta-analysis of 13 European studies	228
	11% (0%–28%) per 100 Bq m ³	Meta-analysis of 7 North American studies	229
Cooking oil vapors	2.12 (1.81–2.47)	Meta-analysis of 7 studies from China and Taiwan (females who never smoked)	230
Indoor coal and wood burning	2.66 (1.39–5.07)	Meta-analysis of 7 studies from China and Taiwan (both sexes)	230
	1.22 (1.04–1.44)	Large case-control study (2861 cases and 3118 controls) from Eastern and Central Europe (both sexes)	231
	2.5 (1.5–3.6)	Large case-control study (1205 cases and 1541 controls) from Canada (significant for women only)	232
Genetic factors: family history, CYP1A1 Ile462Val polymorphism, XRCC1 variants	1.51 (1.11–2.06)	Meta-analysis of 28 case-control, 17 cohort, and 7 twin studies	233
	2.99 (1.51–5.91)	Meta-analysis of 14 case-control studies of Caucasian never smokers	234
	2.04 (1.17–3.54)	Meta-analysis of 21 case-control studies of Caucasian and Asian never smokers (significant for Caucasians only)	235
	No association	Meta-analysis of 13 case-control studies	236
	No association overall; reduced risk 0.65 (0.46–0.83) with Arg194Trp polymorphism and 0.56 (0.36–0.86) with Arg280His for heavy smokers	Large case-control study from Europe (2188 cases and 2198 controls)	237
	Increased risk for never smokers 1.3 (1.0–1.8) and decreased risk for heavy smokers 0.5 (0.3–1.0) with Arg299Gln	Large case-control study from the United States (1091 cases and 1240 controls)	238
Viral factors: HPV 16 and 18	10.12 (3.88–26.4) for never smoking women >60 y	Case-control study (141 cases, 60 controls) from Taiwan of never smoking women	239

insurers in that it requires accreditation of the imaging center and submission of all low-dose CT data to a CMS-approved national registry, among other specifications. With this approach, it is expected that 50% of diagnosed cancers will be early stage. Screening of patients age 50 years or older with a 20 pack-year or greater history and additional risk factors (as determined by the Tammemagi lung cancer risk calculator or other validated risk scores) that increase the risk of lung cancer to 1.3% or greater should also be considered as part of lung cancer screening programs. In all cases, patient-physician shared decision-making should be undertaken, with a discussion of the risks and benefits of screening. It is important to note that there was a 7%

false-positive rate in NLST trial, which can lead to patient anxiety, invasive testing, and potentially morbid procedures to further evaluate the finding. The impact of these issues on patient quality of life and cost-effectiveness requires further study, particularly as screening programs are implemented outside of the controlled setting of a clinical trial. It is also critical that regulatory guidelines for patient eligibility, frequency of screening, interpretation of the scans, processes for further evaluation and management of positive findings, and dose of radiation are well established and well accepted to ensure the generalizability of the results for patients who will be screened in the general medical community rather than in the specialized centers that performed the trial.

Solitary Pulmonary Nodule

A solitary pulmonary nodule is typically described as a single, well-circumscribed, spherical lesion that is 3 cm or less in diameter and completely surrounded by normal aerated lung parenchyma.²⁴ Lung atelectasis, hilar enlargement, and pleural effusion are absent. The majority are detected incidentally on chest radiographs (CXR) or CT scans obtained for some other purpose. About 150,000 solitary nodules are found incidentally each year, with increasing numbers as low-dose computed tomography screening in high-risk populations is adopted. The clinical significance of such a lesion depends on whether or not it represents a malignancy.

The differential diagnosis of a solitary pulmonary nodule should include a broad variety of congenital, neoplastic, inflammatory, vascular, and traumatic disorders. The probability of cancer in a solitary pulmonary nodule increases if the patient has a history of smoking (50% or higher for smokers compared to 20% to 40% in never smokers). It is also more likely to be malignant if it is symptomatic or the patient is older, male, or has had occupational exposures.

Solitary pulmonary nodules were defined by findings on CXR, but with the increased sensitivity of low-dose screening CT, up to 50% of solitary lesions are found to be associated with multiple (one to six) other, usually subcentimeter, nodules. In the Early Lung Cancer Action project, almost 7% of healthy

volunteers were found to have between one and three nodules, and 25% had up to six nodules. CT scanning is necessary to characterize nodule number, location, size, margin morphology, calcification pattern, and growth rate.²⁵ Spiral (helical) CT allows continuous scanning as the patient is moved through a scanning gantry, allowing the entire thorax to be imaged during a single breath hold (Fig. 19-14). Compared to conventional CT, this provides a superior image quality, because motion artifacts are eliminated, and improves detection of pulmonary nodules and central airway abnormalities.²⁶ The shorter acquisition time of spiral CT also allows for consistent contrast filling of the great vessels, resulting in markedly improved visualization of pathologic states and anatomic variation contiguous to vascular structures. In addition, three-dimensional spiral CT images can be reconstructed for enhanced visualization of spatial anatomic relationships.²⁷ Thin sections (1 to 2 mm collimation) at 1-cm intervals should be used to evaluate pulmonary parenchyma and peripheral bronchi. If the goal is to find any pulmonary metastases, thin sections at intervals of 5 to 7 mm collimation are recommended. For assessing the trachea and central bronchi, collimation of 3 to 5 mm is recommended. Providing accurate clinical history and data is of paramount importance to obtaining appropriate imaging.

CT findings characteristic of benign lesions include small size, calcification within the nodule, and stability over time.

Figure 19-14. Spiral computed tomography scan showing normal transverse chest anatomy at four levels. **A.** At the level of the tracheal bifurcation, the aorticopulmonary window can be seen. **B.** The origin of the left pulmonary artery can be seen at a level 1 cm inferior to **A.** **C.** The origin and course of the right pulmonary artery can be seen at this next most cephalad level. The left upper lobe bronchus can be seen at its origin from the left main bronchus. **D.** Cardiac chambers and pulmonary veins are seen in the lower thorax. AA = ascending aorta; APW = aorticopulmonary window; DA = descending aorta; LA = left ventricle; LMB = left main bronchus; LPA = left pulmonary artery; MPA = main pulmonary artery; RA = right atrium; RPA = right pulmonary artery; RV = right ventricle; SVC = superior vena cava; T = trachea.

Four patterns of benign calcification are common: diffuse, solid, central, and laminated or “popcorn.” Granulomatous infections such as tuberculosis can demonstrate the first three patterns, whereas the popcorn pattern is most common in hamartomas. In areas of endemic granulomatous disease, differentiating benign versus malignant can be challenging. Infectious granulomas arising from a variety of organisms account for 70% to 80% of this type of benign solitary nodules; hamartomas are the next most common single cause, accounting for about 10%.

CT findings characteristic of malignancy include growth over time; increasing density on CT scan (40% to 50% of partial solid lesions are malignant compared to only 15% of subcentimeter solid or nonsolid nodules); size >3 cm; irregular, lobulated, or spiculated edges; and the finding of the corona radiata sign (consisting of fine linear strands extending 4 to 5 mm outward and appearing spiculated on radiographs) (Fig. 19-15). Calcification that is stippled, amorphous, or eccentric is usually associated with cancer.

Growth over time is an important characteristic for differentiating benign and malignant lesions. Lung cancers have volume-doubling times from 20 to 400 days; lesions with shorter doubling times are likely due to infection, and longer doubling times suggest benign tumors, but can represent slower-growing lung cancer. Positron emission tomography (PET) scanning can differentiate benign from malignant nodules²⁸; most lung tumors have increased signatures of glucose uptake, as compared with healthy tissues, and thus glucose metabolism can be measured using radio-labeled ¹⁸F-fluorodeoxyglucose (FDG). Meta-analysis estimates 97% sensitivity and 78% specificity for predicting malignancy in a nodule. False-negative results can occur (especially in patients who have AIS, MIA, or LPA, carcinoids, and tumors <1 cm in diameter), as well as false-positive results (because of confusion with other infectious or inflammatory processes).

Metastatic Lesions to the Lung

The cause of a new pulmonary nodule(s) in a patient with a previous malignancy can be difficult to discern.²⁹ Features suggestive of metastatic disease are multiplicity; smooth, round borders on CT scan; and temporal proximity to the original primary lesion. One must always entertain the possibility that a single new lesion is a primary lung cancer. The probability of a new primary cancer vs. metastasis in patients presenting with solitary lesions depends on the type of initial neoplasm. The highest likelihood of a new primary lung cancer is in patients with a history of uterine (74%), bladder (89%), lung (92%), and head and neck (94%) carcinomas.

Surgical resection of pulmonary metastases has a role in properly selected patients.³⁰ The best data regarding outcomes of resection of pulmonary metastases come from the International Registry of Lung Metastases (IRLM). The registry was established in 1991 by 18 thoracic surgery departments in Europe, the United States, and Canada and included data on 5206 patients. About 88% of patients underwent complete resection. Survival analysis at 5, 10, and 15 years (grouping all primary tumor types) was performed (Table 19-5). Multivariate analysis showed a better prognosis for patients with germ cell tumors, osteosarcomas, a disease-free interval over 36 months, and a single metastasis.³¹ Depicted in Fig. 19-16, survival after metastasectomy in a variety of cancers is optimal when metastatic disease is resectable, solitary, and identified 36 or more months after initial treatment. When any or all of these optimal characteristics are absent, survival progressively declines.

Actuarial survival data from the International Registry of Lung Metastases

SURVIVAL	COMPLETE RESECTION (%)	INCOMPLETE RESECTION (%)
5 years	36	13
10 years	26	7
15 years	22	—

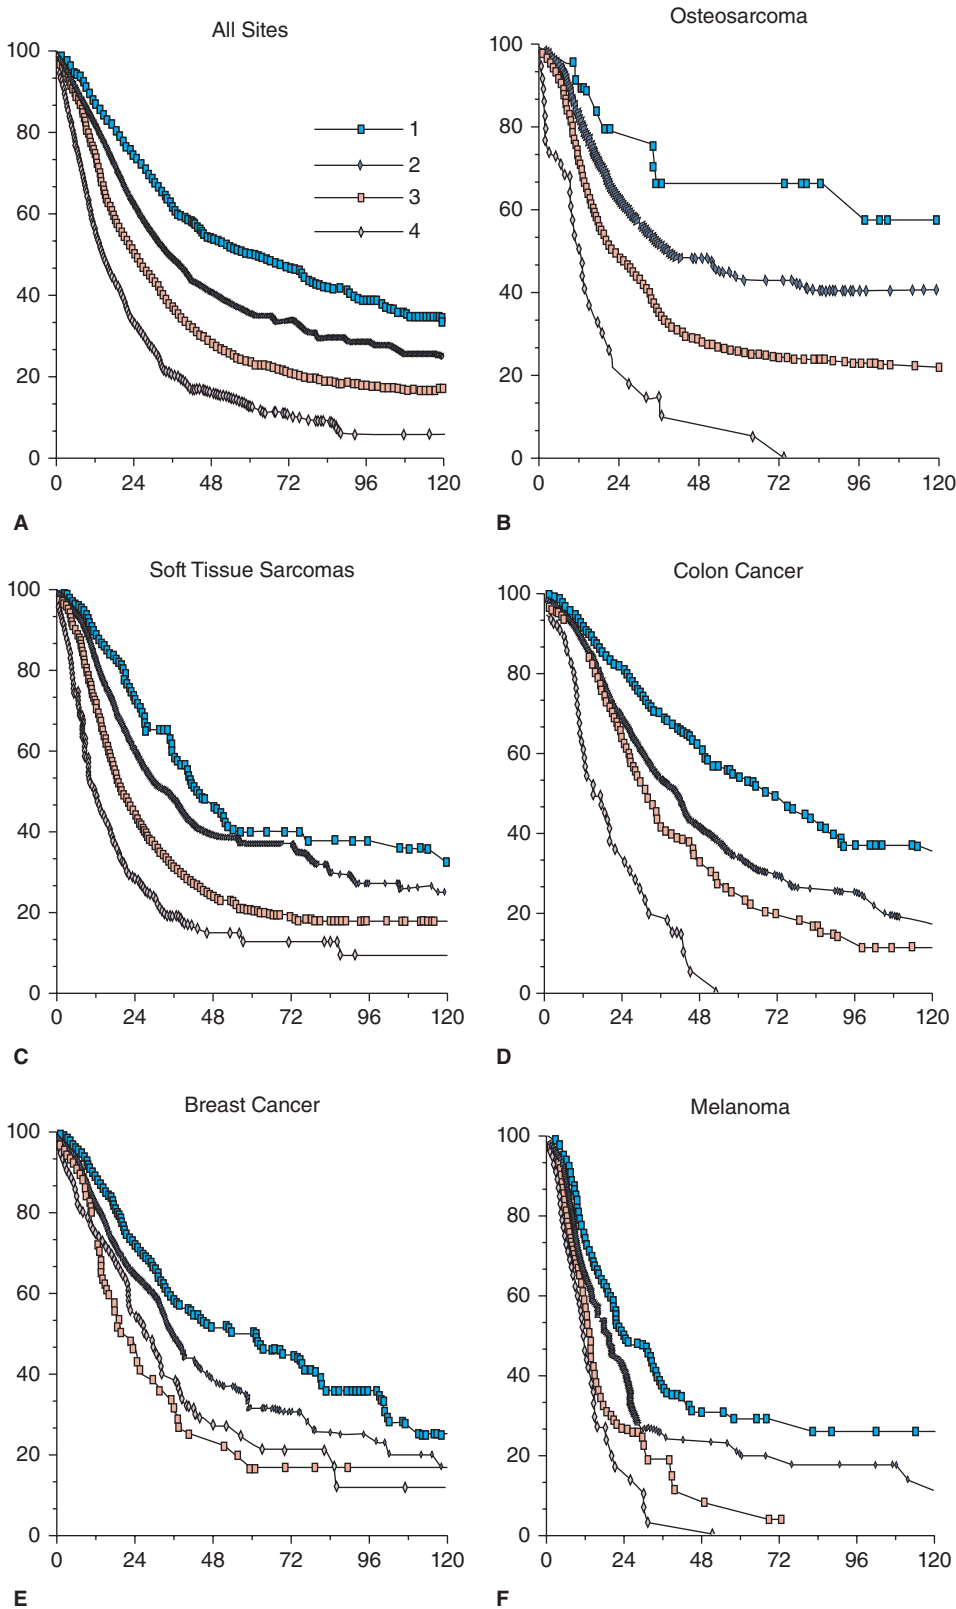

Figure 19-16. The actuarial survival after metastasectomy is depicted for patients with various tumor types (A-F) further categorized into four groups according to resectability, solitary or multiple, the interval between primary resection and metastasectomy, and a combination of factors known in our work and in others, as follows: (1) resectable, solitary, and disease-free interval (DFI) greater than or equal to 36 months; (2) resectable, solitary, and DFI 36+ months; (3) resectable, multiple metastases, and DFI <36 months; and (4) unresectable. (Reproduced with permission from Pastorino U: *The development of an international registry*, J Thorac Oncol. 2010 Jun; 5(6 Suppl 2):S196-S197.)

The general principles of patient selection for metastasectomy are listed in Table 19-6. The technical aim of pulmonary metastasectomy is complete resection of all macroscopic tumors. In addition, any involved adjacent structures should be resected en bloc (i.e., chest wall, diaphragm, and pericardium). Multiple lesions and/or hilar lesions may require lobectomy. Pneumonectomy is rarely justified or employed.

Pulmonary metastasectomy can be approached through a thoracotomy or via video-assisted thoracic surgery (VATS) techniques. McCormack and colleagues reported their experience at Memorial Sloan-Kettering in a prospective study of 18 patients who presented with no more than two pulmonary metastatic lesions and underwent VATS resection.³² A thoracotomy was performed during the same operation; if palpation

Table 19-6

General principles governing appropriate selection of patients for pulmonary metastasectomy

1. Primary tumor must already be controlled.
2. Patient must be able to tolerate general anesthesia, potential single-lung ventilation, and the planned pulmonary resection.
3. Metastases must be completely resectable based on computed tomographic imaging.
4. There is no evidence of extrapulmonary tumor burden.
5. Alternative superior therapy must not be available.

identified any additional lesions, they were resected. The study concluded that the probability that a metastatic lesion will be missed by VATS excision is 56%. Patients in the Memorial study were evaluated before the advent of spiral CT scanning, however, and it remains controversial whether metastasis resection should be performed via VATS. Proponents of VATS argue that the resolution of spiral CT scanning is so superior that prior studies using standard CT scanners are no longer relevant. Indeed, a recent study suggested that only 18% of malignant nodules would be missed using a VATS approach in the current era while another study from the United Kingdom found equivalent outcomes with regard to missed lesions and pulmonary progression comparing open and VATS approaches. To date, no prospective study using spiral CT scan has been performed to resolve this clinical dilemma.

Primary Lung Cancer-Associated Signs and Symptoms

Lung cancer displays one of the most diverse presentation patterns of all human maladies (Table 19-7). The wide range of symptoms and signs is related to (a) histologic features, which often help determine the anatomic site of origin in the lung; (b) the specific tumor location in the lung and its relationship to surrounding structures; (c) biologic features and the production of a variety of paraneoplastic syndromes; and (d) the presence or absence of metastatic disease. Symptoms related to the local intrathoracic effect of the primary tumor can be conveniently divided into two groups: pulmonary and nonpulmonary thoracic.

Pulmonary Symptoms. Pulmonary symptoms result from the direct effect of the tumor on the bronchus or lung tissue. Symptoms (in order of frequency) include cough (secondary to irritation or compression of a bronchus), dyspnea (usually due to central airway obstruction or compression, with or without atelectasis), wheezing (with narrowing of a central airway of >50%), hemoptysis (typically, blood streaking of mucus that is rarely massive; indicates a central airway location), pneumonia (usually due to airway obstruction by the tumor), and lung abscess (due to necrosis and cavitation, with subsequent infection).

Nonpulmonary Thoracic Symptoms. Nonpulmonary thoracic symptoms result from invasion of the primary tumor directly into a contiguous structure (e.g., chest wall, diaphragm, pericardium, phrenic nerve, recurrent laryngeal nerve, superior vena cava, and esophagus), or from mechanical compression of a structure (e.g., esophagus or superior vena cava) by enlarged tumor-bearing lymph nodes.

Table 19-7

Clinical presentation of lung cancer

CATEGORY	SYMPTOM	CAUSE
Pulmonary symptoms	Cough	Bronchus irritation or compression
	Dyspnea	Airway obstruction or compression
	Wheezing	>50% airway obstruction
	Hemoptysis	Tumor erosion or irritation
	Pneumonia	Airway obstruction
Nonpulmonary thoracic symptoms	Pleuritic pain	Parietal pleural irritation or invasion
	Local chest wall pain	Rib and/or muscle involvement
	Radicular chest pain	Intercostal nerve involvement
	Pancoast's syndrome	Stellate ganglion, chest wall, brachial plexus involvement
	Hoarseness	Recurrent laryngeal nerve involvement
	Swelling of head and arms	Bulky involved mediastinal lymph nodes
		Medially based right upper lobe tumor

Peripherally located tumors (often adenocarcinomas) extending through the visceral pleura lead to irritation or growth into the parietal pleura and potentially to continued growth into the chest wall structures. Three types of symptoms, depending on the extent of chest wall involvement, are possible: (a) **pleuritic pain**, from noninvasive contact of the parietal pleura with inflammatory irritation or direct parietal pleural invasion; (b) **localized chest wall pain**, from deeper invasion and involvement of the rib and/or intercostal muscles; and (c) **radicular pain**, from involvement of the intercostal nerve(s). Radicular pain may be mistaken for renal colic in the case of tumors invading the inferoposterior chest wall.

Other specific nonpulmonary thoracic symptoms include:

1. **Pancoast's syndrome.** Tumors originating in the superior sulcus (posterior apex) elicit: apical chest wall and/or shoulder pain (from involvement of the first rib and chest wall); Horner's syndrome (unilateral enophthalmos, ptosis, miosis, and facial anhidrosis from invasion of the stellate sympathetic ganglion); and radicular arm pain (from invasion of T1, and occasionally C8, brachial plexus nerve roots).
2. **Phrenic nerve palsy.** The phrenic nerve traverses the hemithorax along the mediastinum, parallel and posterior to the superior vena cava and anterior to the pulmonary hilum. Tumors at the medial lung surface or anterior hilum can directly invade the nerve; symptoms include shoulder pain (referred), hiccups, and dyspnea with exertion because of

diaphragm paralysis. Radiographically, unilateral diaphragm elevation on chest radiograph is present; the diagnosis is confirmed by fluoroscopic examination of the diaphragm with paradoxical motion with breathing and sniffing (the “sniff” test).

3. **Recurrent laryngeal nerve palsy.** Recurrent laryngeal nerve (RLN) involvement most commonly occurs on the left side, given the hilar location of the left RLN as it passes under the aortic arch. Paralysis results from: (a) invasion of the vagus nerve above the aortic arch by a medially based left upper lobe tumor; or (b) direct invasion of the RLN by hilar tumor and/or hilar or aortopulmonary lymph node metastases. Symptoms include voice change, often referred to as hoarseness, but more typically a loss of tone associated with a breathy quality, and coughing, particularly when drinking liquids.
4. **Superior vena cava (SVC) syndrome.** As a result of bulky enlargement of involved mediastinal lymph nodes compressing or a medially based right upper lobe tumor invading the SVC, SVC syndrome symptoms include variable degrees of swelling of the head, neck, and arms; headache; and conjunctival edema. It is seen most commonly with NEC grade IV (small cell) lung cancer.
5. **Pericardial tamponade.** Pericardial effusions (benign or malignant), associated with increasing levels of dyspnea and/or arrhythmias, and pericardial tamponade occur with direct pericardial invasion. Diagnosis requires a high index of suspicion in the setting of a medially based tumor with symptoms of dyspnea and is confirmed by CT scan or echocardiography.
6. **Back pain.** Results from direct invasion of a vertebral body and is often localized and severe. If the neural foramina are involved, radicular pain may also be present.
7. **Other local symptoms.** Dysphagia is usually secondary to external esophageal compression by enlarged lymph nodes involved with metastatic disease, usually with lower lobe tumors. Finally, dyspnea, pleural effusion, or referred shoulder pain can result from invasion of the diaphragm by a tumor at the base of a lower lobe.

Associated Paraneoplastic Syndromes. All lung cancer histologies are capable of producing a variety of paraneoplastic syndromes, most often from systemic release of tumor-derived biologically active materials (Table 19-8). Paraneoplastic syndromes may produce symptoms even before any local symptoms are produced by the primary tumor, thereby aiding in early diagnosis. Their presence does not influence resectability or treatment options. Symptoms often abate with successful treatment; paraneoplastic symptom recurrence may herald tumor recurrence. The majority of such syndromes are associated with grade IV NEC (small cell carcinoma), including many endocrinopathies.

1. **Hypertrophic pulmonary osteoarthropathy (HPO).** Often severely debilitating, symptoms of HPO may antedate the diagnosis of cancer by months. Clinically, ankle, feet, forearm, and hand tenderness and swelling are characteristic, resulting from periostitis of the fibula, tibia, radius, metacarpals, and metatarsals. Clubbing of the digits may occur in up to 30% of patients with grade IV NEC (Fig. 19-17). Plain radiographs show periosteal inflammation and elevation, while bone scans demonstrate intense but

symmetric uptake in the long bones. Aspirin or nonsteroidal anti-inflammatory agents provide temporary relief; treatment requires successful tumor eradication.

2. **Hypercalcemia.** Up to 10% of patients with lung cancer will have hypercalcemia, most often due to metastatic disease. Ectopic parathyroid hormone secretion by the tumor, most often squamous cell carcinoma, is causative in up to 15%, however, and should be suspected if metastatic bone disease is not present. Symptoms of hypercalcemia include lethargy, depressed level of consciousness, nausea, vomiting,

and dehydration. Following complete tumor eradication, the calcium level will normalize. Unfortunately, tumor recurrence is extremely common and may manifest as recurrent hypercalcemia.

3. **Hyponatremia.** Characterized by confusion, lethargy, and possible seizures, hyponatremia can result from the inappropriate secretion of antidiuretic hormone from the tumor into the systemic circulation (syndrome of inappropriate secretion of antidiuretic hormone [SIADH]) in 10% to 45% of patients with grade IV NEC (small cell). It is diagnosed by the presence of hyponatremia, low serum osmolality, and high urinary sodium and osmolality. Another cause of hyponatremia can be the ectopic secretion of atrial natriuretic peptide (ANP).
4. **Cushing's syndrome.** Autonomous tumor production of an adrenocorticotropic hormone (ACTH)-like molecule leads to rapid serum elevation of ACTH and subsequent severe hypokalemia, metabolic alkalosis, and hyperglycemia. Symptoms are primarily related to the metabolic changes while the physical signs of Cushing's syndrome (e.g., truncal obesity, buffalo hump, striae) are unusual due to the rapidity of ACTH elevation. Diagnosis is made by demonstrating hypokalemia (<3.0 mmol/L); nonsuppressible elevated plasma cortisol levels that lack the normal diurnal variation; elevated blood ACTH levels; or elevated urinary 17-hydroxycorticosteroids, all of which are not suppressible by administration of exogenous dexamethasone. Immunoreactive ACTH is present in nearly all extracts of SCLC, and a high percentage of patients with SCLC have elevated

ACTH levels by radioimmunoassay, yet fewer than 5% have symptoms of Cushing's syndrome.

5. **Peripheral and central neuropathies.** Unlike other paraneoplastic syndromes, which are usually due to ectopic secretion of an active substance, these syndromes are felt to be immune mediated. Cancer cells are thought to secrete antigens normally expressed only by the nervous system, generating antibodies leading either to interference with neurologic function or to immune neurologic destruction. Up to 16% of lung cancer patients have neuromuscular disability, and, of these, half have grade IV NEC (small cell) and 25% have squamous cell carcinomas. In patients with neurologic or muscular symptoms, central nervous system (CNS) metastases must be ruled out with CT or magnetic resonance imaging (MRI) of the head. Other metastatic disease leading to disability must also be excluded.
6. **Lambert-Eaton syndrome.** This myasthenia-like syndrome is caused by tumor secretion of immunoglobulin G (IgG) antibodies targeting voltage-gated calcium channels, which causes a neuromuscular conduction defect by decreasing the amount of acetylcholine released from presynaptic sites at the motor end plate. Symptoms, including gait abnormalities from proximal muscle weakness and impaired coordination, may actually precede radiographic evidence of the tumor. Therapy is directed at the primary tumor with resection, radiation, and/or chemotherapy. Many patients have dramatic improvement after successful therapy. For patients with refractory symptoms, treatment consists of guanidine

hydrochloride, immunosuppressive agents such as prednisone and azathioprine, and occasionally plasma exchange. Unlike with myasthenia gravis patients, neostigmine is usually ineffective.

Symptoms Associated with Metastatic Lung Cancer. Lung cancer metastasizes most commonly to the CNS, vertebral bodies, bone, liver, adrenal glands, lungs, skin, and soft tissues. CNS metastases are present at diagnosis in 10% of patients; another 10% to 15% will develop CNS metastases following diagnosis. Focal symptoms, including headache, nausea, vomiting, seizures, hemiplegia, and dysarthria, are common. Lung cancer is the most common cause of spinal cord compression, either by primary tumor invasion of an intervertebral foramen or direct extension of vertebral metastases. Bony metastases are identified in 25% of lung cancer patients. They are primarily lytic and produce pain locally; thus, any new and localized skeletal symptoms must be evaluated radiographically. Liver metastases and adrenal metastases are typically asymptomatic and usually discovered by routine CT scan. Adrenal metastasis may lead to adrenal hypofunction. Skin and soft tissue metastases occur in 8% of patients dying of lung cancer and generally present as painless subcutaneous or intramuscular masses. Occasionally, tumor erodes through overlying skin; excision may then be necessary for both mental and physical palliation.

Nonspecific Cancer-Related Symptoms. Lung cancer often produces a variety of nonspecific symptoms such as anorexia, weight loss, fatigue, and malaise and their presence raises concern for metastatic disease.

Lung Cancer Management

Role of Histologic Diagnosis and Molecular Testing.

Establishing a clear histologic diagnosis early in the evaluation and management of lung cancer is critical to effective treatment. Molecular signatures are also key determinants of treatment algorithms for adenocarcinoma and will likely become important for squamous cell carcinoma as well. Currently, differentiation between adenocarcinoma and squamous cell carcinoma in cytologic specimens or small biopsy specimens is imperative in patients with advanced stage disease, as treatment with pemetrexed or bevacizumab-based chemotherapy is associated with improved progression-free survival in patients with adenocarcinoma but not squamous cell cancer. Furthermore, life-threatening hemorrhage has occurred in patients with squamous cell carcinoma who were treated with bevacizumab. Finally, *EGFR* mutation predicts response to *EGFR* tumor kinase inhibitors and is now recommended as first-line therapy in advanced adenocarcinoma. Because adequate tissue is required for histologic assessment and molecular testing, each institution should have a clear, multidisciplinary approach to patient evaluation, tissue acquisition, tissue handling/processing, and tissue analysis (Fig. 19-18). In many cases, tumor morphology differentiates adenocarcinoma from the other histologic subtypes. If no clear morphology can be identified, then additional testing for one immunohistochemistry marker for adenocarcinoma and one for squamous cell carcinoma will usually enable differentiation. Immunohistochemistry for neuroendocrine markers is reserved for lesions exhibiting neuroendocrine morphology. Additional molecular testing should be performed on all adenocarcinoma specimens for known predictive and prognostic tumor markers (e.g., *EGFR*, *KRAS*, and *EML4-ALK* fusion gene). Ideally,

use of tissue sections and cell block material is limited to the minimum necessary at each decision point. This emphasizes the importance of a multidisciplinary approach; surgeons and radiologists must work in direct cooperation with the cytopathologist to ensure that tissue samples are adequate for morphologic diagnosis as well as providing sufficient cellular material to enable molecular testing. With adoption of endobronchial and endoscopic ultrasound, electromagnetic navigational bronchoscopy, VATS, and even transthoracic image-guided fine-needle and core-needle biopsy, surgeons are increasingly involved in the acquisition of diagnostic tissue for primary, metastatic, and recurrent intrathoracic disease, and a thorough understanding of key issues is necessary to ensure optimal treatment and patient outcomes.

Patient Evaluation. Pretreatment evaluation encompasses three areas: diagnosis and assessment of the primary tumor, assessment for metastatic disease, and determination of functional status (the patient's ability to tolerate the prescribed treatment regimen). A discrete approach to each area allows the surgeon to systematically evaluate the patient, perform accurate clinical staging, and determine the patient's functional suitability for therapy (Table 19-9).

Assessment of the Primary Tumor Primary tumor assessment begins with directed history questions regarding the presence or absence of pulmonary, nonpulmonary, thoracic, and paraneoplastic symptoms. Because patients often present to the surgeon with a CXR or CT scan demonstrating the lesion, tumor location can guide the history and physical examination.

A routine chest CT scan should be performed; this should include intravenous contrast to enable assessment of the primary tumor, delineation of mediastinal lymph nodes relative to normal mediastinal structures, and the tumor's relationship to surrounding and contiguous structures. Recommendations for treatment and options for obtaining tissue diagnosis require a thorough understanding and assessment of CT findings.

Concern for contiguous invasion of adjacent structures is often raised in response to a combination of symptom history, location of the primary tumor, and CT imaging. It is common to see the primary tumor abutting the chest wall without clear radiographic evidence of rib destruction. In this circumstance, localized pain can indicate parietal pleural, rib, or intercostal nerve involvement. Similar observations apply to tumors abutting the recurrent laryngeal nerve, phrenic nerve, diaphragm, vertebral bodies, and chest apex. Thoracotomy should not be denied because of presumptive evidence of invasion of the chest wall, vertebral body, or mediastinal structures; proof of invasion may require thoracoscopy or even thoracotomy.

MRI of pulmonary lesions and mediastinal nodes, overall, offers no real advantages over CT scanning. It is an excellent modality, however, for defining a tumor's relationship to a major vessel, given its excellent imaging of vascular structures. This is especially true if the use of iodine contrast material is contraindicated. Thus, use of MRI in lung cancer patients is reserved for those with contrast allergies or suspected mediastinal, vascular, or vertebral body invasion.

Options for Tissue Acquisition The surgeon must have an evidence-based algorithm for diagnosis and treatment of a pulmonary nodule and masses (Fig. 19-19).²⁴ Depending on nodule size, bronchial tree proximity, and the population prevalence of lung cancer, bronchoscopy has a 20% to 80% sensitivity for detecting neoplastic processes within a pulmonary lesion.

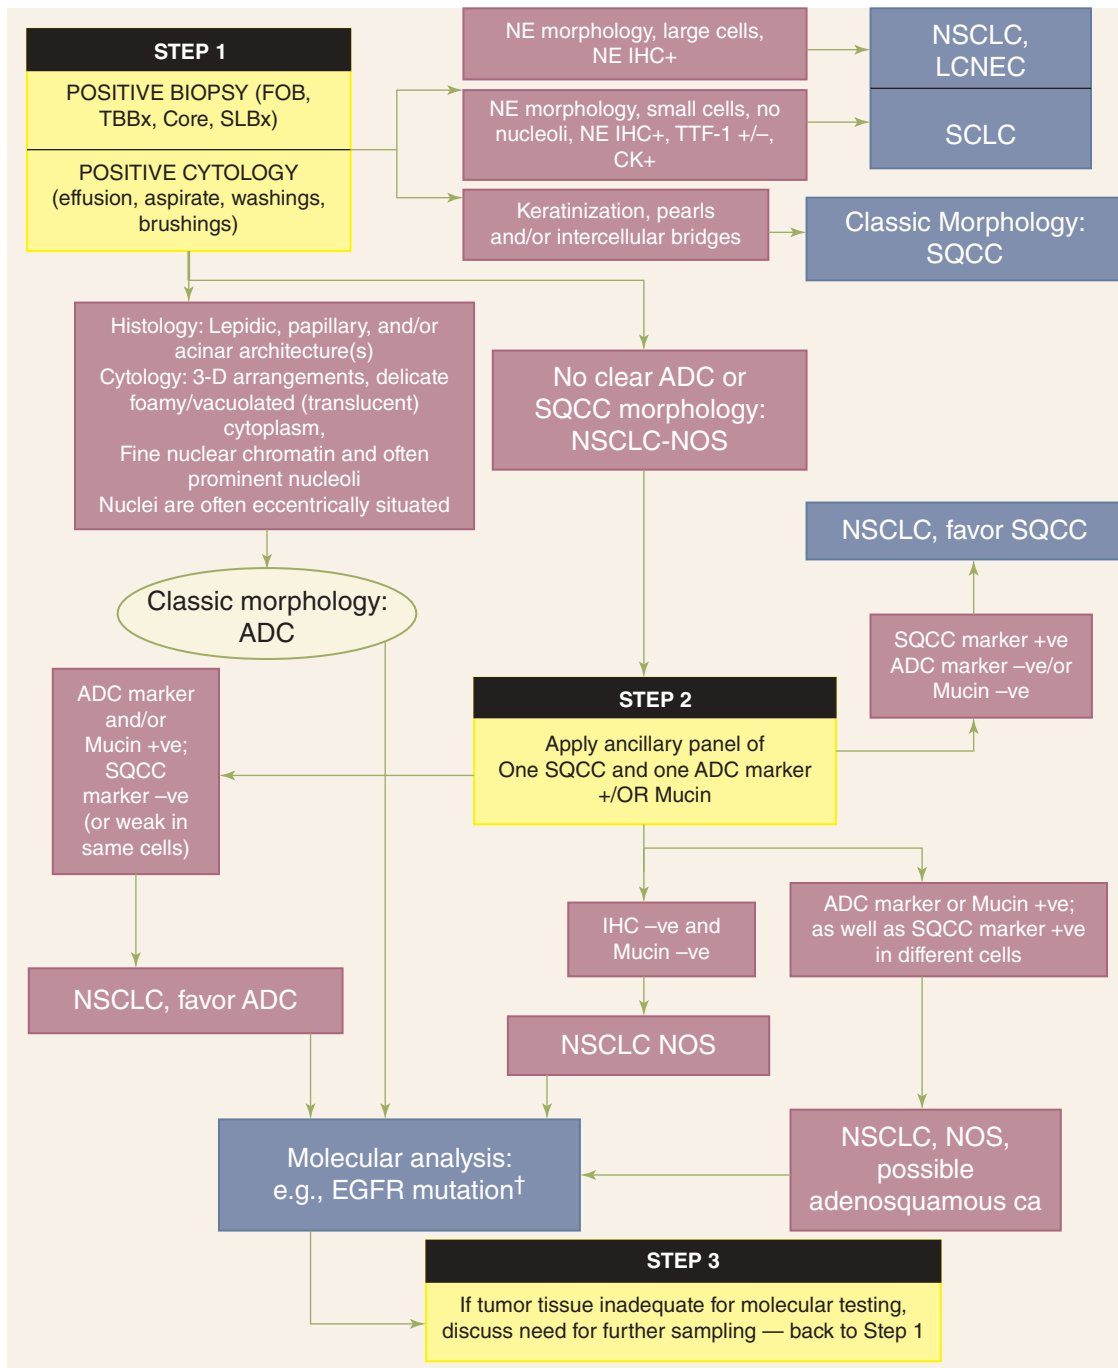

Figure 19-18. Algorithm for adenocarcinoma diagnosis in small biopsies and/or cytology. Step 1: When positive biopsies (fiberoptic bronchoscopy [FOB], transbronchial [TBBx], core, or surgical lung biopsy [SLBx]) or cytology (effusion, aspirate, washings, and brushings) show clear adenocarcinoma (ADC) or squamous cell carcinoma (SQCC) morphology, the diagnosis can be firmly established. If there is neuroendocrine (NE) morphology, the tumor may be classified as small cell carcinoma (SCLC) or non-small cell lung carcinoma (NSCLC), probably large cell neuroendocrine carcinoma (LCNEC) according to standard criteria (+ = positive, - = negative, and ± = positive or negative). If there is no clear ADC or SQCC morphology, the tumor is regarded as NSCLC—not otherwise specified (NOS). Step 2: NSCLC-NOS can be further classified based on (a) immunohistochemical stains, (b) mucin (DPAS or mucicarmine) stains, or (c) molecular data. If the stains all favor ADC-positive ADC marker(s) (i.e., TTF-1 and/or mucin positive) with negative SQCC markers, then the tumor is classified as NSCLC, favor ADC. If SQCC markers (i.e., p63 and/or CK5/6) are positive with negative ADC markers, the tumor is classified as NSCLC, favor SQCC. If the ADC and SQCC markers are both strongly positive in different populations of tumor cells, the tumor is classified as NSCLC-NOS, with a comment it may represent adenosquamous carcinoma. If all markers are negative, the tumor is classified as NSCLC-NOS. †EGFR mutation testing should be performed in (1) classic ADC, (2) NSCLC, favor ADC, (3) NSCLC-NOS, and (4) NSCLC-NOS, possible adenosquamous carcinoma. In NSCLC-NOS, if EGFR mutation is positive, the tumor is more likely to be ADC than SQCC. Step 3: If clinical management requires a more specific diagnosis than NSCLC-NOS, additional biopsies may be indicated. CD = cluster designation; CK = cytokeratin; DPAS = diastase-periodic acid Schiff; DPAS +ve = periodic-acid Schiff with diastase; EGFR = epidermal growth factor receptor; IHC = immunohistochemistry; NB = of note; TTF-1 = thyroid transcription factor-1; -ve = negative; +ve = positive. (Reproduced with permission from Travis WD, Brambilla E, Noguchi M, et al: *Diagnosis of lung cancer in small biopsies and cytology: implications of the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society classification*, Arch Pathol Lab Med. 2013 May;137(5):668-684.)

Table 19-9

Evaluation of patients with lung cancer

	PRIMARY TUMOR	METASTATIC DISEASE	FUNCTIONAL ASSESSMENT
History	Pulmonary	Weight loss	Ability to walk up two flights of stairs
	Nonpulmonary thoracic	Malaise	Ability to walk on a flat surface indefinitely
	Paraneoplastic	New bone pain Neurologic signs or symptoms Skin lesions	
Physical examination	Voice	Supraclavicular node palpation	Accessory muscle usage
		Skin examination	Air flow by auscultation
		Neurologic examination	Force of cough
Radiographic examination	Chest CT	Chest CT, PET	Chest CT: tumor anatomy, atelectasis
Tissue analysis	Bronchoscopy	Bone scan, head MRI, abdominal CT	Quantitative perfusion scan
	Transthoracic needle aspiration and biopsy	Bronchoscopic lymph node FNA Endoscopic ultrasound Mediastinoscopy Biopsy of suspected metastasis	
Other	Thoracoscopy	—	Pulmonary function tests (FEV ₁ , DLCO, O ₂ consumption)

Abbreviations: CT = computed tomography; DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 second; FNA = fine-needle aspiration; MRI = magnetic resonance imaging; O₂ = oxygen; PET = positron emission tomography.

Diagnostic tissue from bronchoscopy can be obtained by one of four methods:

1. Brushings and washings for cytology
2. Direct forceps biopsy of a visualized lesion
3. Endobronchial ultrasound-guided fine-needle aspiration (FNA) of an externally compressing lesion without visualized endobronchial tumor
4. Transbronchial biopsy with fluoroscopy to guide forceps to the lesion or electromagnetic navigational bronchoscopy

Electromagnetic navigation bronchoscopy is a recent addition to the surgeon's armamentarium for transbronchial biopsy of peripheral lung lesions. Using electromagnetic markers that create a three-dimensional image and align the recorded CT images to the patient's true anatomy, a transbronchial catheter is advanced, and brushings, FNA, cup biopsy, and washings can be performed. Diagnostic yield using electromagnetic navigation bronchoscopy as an adjunct to standard bronchoscopy is reported as high as 80%. The approach can also be used for placement of fiducial markers for subsequent stereotactic body radiation therapy and for tattooing the perilesional region to guide subsequent video-assisted thoracoscopic resection.

Pneumothorax rates are approximately 1% to 3.5%.

For peripheral lesions (roughly the outer half of the lung), transbronchial biopsy is performed first, followed by brushings and washings. This improves diagnostic yield by disrupting the lesion with the biopsy forceps and mobilizing additional cells. For central lesions, direct forceps biopsy is often possible. For central lesions with external airway compression but no visible endobronchial lesions, endobronchial ultrasound (EBUS) is highly accurate and safe for transbronchial biopsies of both the

primary tumor (when it abuts the central airways) as well as the mediastinal lymph nodes.³³

Image-guided transthoracic FNA (ultrasound or CT FNA) biopsy can accurately diagnose appropriately selected peripheral pulmonary lesions in up to 95% of patients. Three biopsy results are possible after image-guided biopsy procedures: malignant, a specific benign process, or indeterminate. Because false-negative rates range from 3% to 29%, further diagnostic efforts are warranted in the absence of a specific benign diagnosis (such as granulomatous inflammation or hamartoma) because malignancy is not ruled out.³⁴ The primary complication is pneumothorax in as many as 30% of cases. Intrapulmonary bleeding occurs, but it rarely causes clinically significant hemoptysis or respiratory compromise.

Some groups advocate use of video-assisted thoracoscopic biopsy as the first option for diagnosis, citing superior diagnostic accuracy and low surgical risk. With VATS, the nodule can be excised with a wedge or segmental resection, if less than 3 cm, or a core-needle biopsy can be performed under direct vision for larger lesions. VATS can also provide valuable staging information, including sampling/dissection of mediastinal lymph nodes and assessing whether the primary tumor has invaded a contiguous structure (such as the chest wall or mediastinum).

Lesions most suitable for VATS are those that are located in the outer one-third of the lung. The surgeon should avoid direct manipulation of the nodule or violation of the visceral pleura overlying the nodule. In addition, the excised nodule must be extracted from the chest within a bag to prevent seeding of the chest wall. If the patient's pulmonary reserve is adequate, the surgeon can proceed to lobectomy (either VATS or open) after frozen section diagnosis.

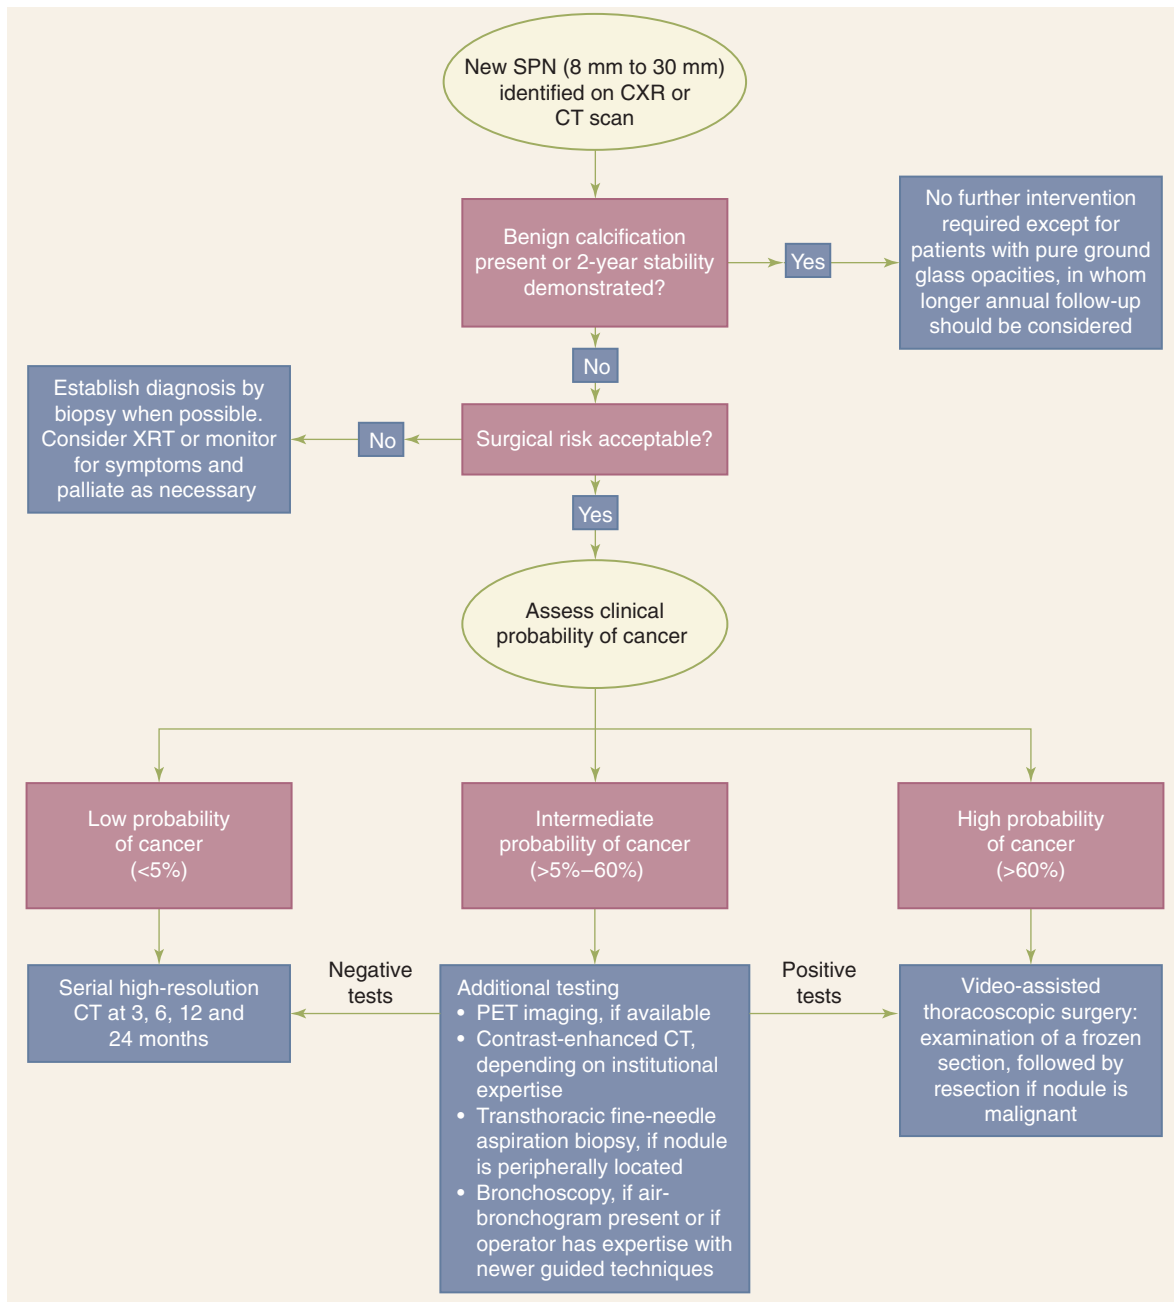

Figure 19-19. Recommended management algorithm for patients with solitary pulmonary nodules (SPNs) measuring 8 mm to 30 mm in diameter. CT = computed tomography; CXR = chest radiograph; PET = positron emission tomography; XRT = radiotherapy. (Adapted with permission from Gould MK, Fletcher J, Iannettoni MD, et al: *Evaluation of patients with pulmonary nodules: when is it lung cancer?* ACCP evidence-based clinical practice guidelines (2nd edition), Chest. 2007 Sep;132(3 Suppl):108S-130S.²⁴)

A thoracotomy is occasionally necessary to diagnose and stage a primary tumor. Although this occurs rarely, two circumstances may require such an approach: (a) a deep-seated lesion that yielded an indeterminate needle biopsy result or that could not be biopsied for technical reasons; or (b) inability to determine invasion of a mediastinal structure by any method short of palpation. In the circumstance of a deep-seated lesion without a diagnosis, tissue can be obtained via thoracotomy using FNA, core-needle biopsy, or excisional biopsy. Intraoperative frozen-section analysis is required; if the open biopsy frozen-section result is indeterminate, a lobectomy may be necessary in extremely rare situations. If a pneumonectomy is required to remove the lesion, a tissue diagnosis of cancer *must* be made before proceeding.

Assessment for Metastatic Disease Approximately 40% of patients with newly diagnosed lung cancer present with distant metastasis. The presence of lymph node or systemic metastases may imply inoperability. As with the primary tumor, assessment for the presence of metastatic disease should begin with the history and physical examination, focusing on new bone pain, neurologic symptoms, and new skin lesions. In addition, constitutional symptoms (e.g., anorexia, malaise, and unintentional weight loss of >5% of body weight) suggest either a large tumor burden or the presence of metastases. Physical examination focuses on overall appearance, noting any evidence of weight loss such as redundant skin or muscle wasting, and a complete examination of the head and neck, including

evaluation of cervical and supraclavicular lymph nodes and the oropharynx. This is particularly true for patients with a significant tobacco history. The skin should be thoroughly examined. Routine laboratory studies include serum levels of hepatic enzymes (e.g., serum glutamic oxaloacetic transaminase and alkaline phosphatase), and serum calcium (to detect bone metastases or the ectopic parathyroid syndrome). Elevation of either hepatic enzymes or serum calcium levels typically occurs with extensive metastases.

Mediastinal Lymph Nodes. Chest CT scanning facilitates assessment of mediastinal and hilar nodes for enlargement. However, a positive CT result (i.e., nodal diameter >1.0 cm) predicts actual metastatic involvement in only about 70% of lung cancer patients. Thus, up to 30% of such nodes are enlarged from non-cancerous reactive causes (e.g., inflammation due to atelectasis or pneumonia secondary to the tumor). Patients should not be denied an attempt at curative resection just because of a positive CT result for mediastinal lymph node enlargement; any CT finding of metastatic nodal involvement must be confirmed histologically. The negative predictive value of normal-appearing lymph nodes by CT (lymph nodes <1.0 cm) is better than the positive predictive value of a suspicious-appearing lymph node, particularly with small squamous cell tumors. With normal-size lymph nodes and a T1 tumor, the false-negative rate is less than 10%, leading many surgeons to omit mediastinoscopy. However, the false-negative rate increases to nearly 30% with centrally located and T3 tumors. It has also been demonstrated that T1 adenocarcinomas or large cell carcinomas have a higher rate of early micrometastasis. Therefore, all such patients should undergo mediastinoscopy.

Mediastinal lymph node staging by PET scanning appears to have greater accuracy than CT scanning. PET staging of mediastinal lymph nodes has been evaluated in two meta-analyses. The overall sensitivity for mediastinal lymph node metastasis was 79% (95% confidence interval [CI] 76%–82%), with a specificity of 91% (95% CI 89%–93%) and an accuracy of 92% (95% CI 90%–94%).³⁵

In comparing PET with CT scans in patients who also underwent lymph node biopsies, PET had a sensitivity of 88% and a specificity of 91%, whereas CT scanning had a sensitivity of 63% and a specificity of 76%. Combining CT and PET scanning may lead to even greater accuracy.³⁶ In one study of CT, PET, and mediastinoscopy in 68 patients with potentially operable NSCLC, CT correctly identified the nodal stage in 40 patients (59%). It understaged the tumor in 12 patients and overstaged it in 16 patients. PET correctly identified the nodal stage in 59 patients (87%). It understaged the tumor in five patients and overstaged it in four. For detecting N2 and N3 disease, the combination of PET and CT scanning yielded a sensitivity, specificity, and accuracy of 93%, 95%, and 94%, respectively. CT scan alone yielded 75%, 63%, and 68%, respectively. Studies examining combined PET-CT consistently show improved accuracy compared to PET or CT alone; accuracy for PET-CT nodal positivity confirmed by mediastinoscopy is approximately 75%, with a negative predictive value of approximately 90%. Right upper lobe lesions were more likely to have occult N2 disease than other lobes of the lung.^{37–40} PET-positive mediastinal lymph nodes require histologic verification of node positivity, either by EBUS-guided FNA or mediastinoscopy, to minimize the risk of undertreatment, assuming node positivity without histologic confirmation relegates the patient to, at a minimum, induction chemotherapy. If there is a suggestion of

N3 disease, the patient would be incorrectly staged as having IIIB disease and would not be considered a candidate for potentially curative surgical resection.

It is important for surgeons who are managing patients with lung cancer to have a clear algorithm for invasive mediastinal staging. In general, invasive staging is underutilized, placing many patients at risk for over- or understaging and, thus, inappropriate treatment. An absolute indication for obtaining a tissue diagnosis is mediastinal lymph node enlargement greater than 1.0 cm by CT scan. There are several options for invasive mediastinal staging (Table 19-10):

1. **Endobronchial Ultrasound (EBUS)-guided transbronchial needle aspiration.** Less invasive than mediastinoscopy, EBUS enables image-guided transtracheal and transbronchial FNA cytologic samples from hilar masses and lymph nodes from level 4R and 4L, level 7, level 10, and level 11. Rapid onsite pathologic evaluation with expert cytopathology evaluation greatly increases the diagnostic accuracy of the procedure; importantly, the intraoperative evaluation will confirm whether the target lesion is being sampled and greatly facilitates acquisition of satisfactory samples for determining the morphologic diagnosis as well as sufficient material for cell block for immunohistochemistry

TABLE 19-10

Techniques for invasive mediastinal staging

Endoscopic

- Endobronchial ultrasound with transbronchial needle aspiration
- Endoscopic ultrasound with needle aspiration
- Transbronchial needle aspiration
- Computed tomography–guided transthoracic needle aspiration

Surgical

- Video-assisted mediastinoscopy
- Transcervical extended mediastinal lymphadenectomy (TEMLA)
- Video-assisted mediastinal lymphadenectomy (VAMLA)
- Thoracoscopic transthoracic lymphadenectomy

Indications for invasive mediastinal staging in lung cancer

1. Radiographically enlarged mediastinal lymph nodes
2. Centrally located tumors
3. N1 nodal enlargement
4. Tumor size >3 cm
5. Peripheral clinical stage I tumor with nonenlarged but FDG-avid mediastinal lymph nodes

Indications for prethoracotomy/thoracoscopy biopsy of stations 5 and 6 lymph nodes

1. Criteria for invasive staging met and other mediastinal lymph node stations are negative (assuming patient would have induction therapy if any nodal station positive)
2. Enrollment criteria for induction therapy protocol require pathologic confirmation of N2 disease
3. Computed tomography scan shows evidence of bulky nodal metastasis or extracapsular spread that could prevent complete resection
4. Tissue diagnosis of a hilar mass or of lymph nodes causing recurrent laryngeal nerve paralysis is needed

and molecular testing. EBUS does not allow assessment of level 3, 5, or 6 nodal stations.

2. **Endoscopic ultrasound (EUS).** EUS can accurately visualize mediastinal paratracheal lymph nodes (stations 4R, 7, and 4L), paraesophageal (station 8) and inferior pulmonary ligament (station 9) lymph nodes and visualize primary lung lesions contiguous with or near the esophagus (see Fig. 19-8). Using FNA or core-needle biopsy, samples of lymph nodes or primary lesions can be obtained. Diagnostic yield is improved with intraoperative cytologic evaluation, which can be performed with the cytopathologist in the operating room. Limitations of EUS include the inability to visualize the anterior (pretracheal) mediastinum; thus, EUS does not replace mediastinoscopy/EBUS for complete mediastinal nodal staging. However, it may not be necessary to perform mediastinoscopy if findings on EUS are positive for N2 nodal disease, particularly if more than one station is found to harbor metastases.
3. **Cervical video-assisted mediastinoscopy.** Mediastinoscopy provides tissue sampling of all paratracheal and subcarinal lymph nodes and permits visual determination of the presence of extracapsular extension of nodal metastasis (Fig. 19-20). With complex hilar or right paratracheal primary tumors, it allows direct biopsies and assessment of invasion into the mediastinum. Mediastinoscopy is recommended for centrally located tumors, T2 and T3 primary tumors, and occasionally for T1 adenocarcinomas or large cell carcinomas (due to their higher rate of metastatic spread). Some surgeons perform mediastinoscopy in all lung cancer patients because of the poor survival associated with surgical resection of N2 disease.
4. It is important to note that EBUS or EUS can be used for initial diagnosis in enlarged lymph nodes, but the predictive value of a negative EBUS in a patient with radiographically suspicious mediastinal disease is not sufficient to accurately guide treatment. At the authors' institutions, it is standard to begin mediastinal lymph node staging with EBUS-guided FNA of clinically suspicious mediastinal lymphadenopathy.

Figure 19-20. Cervical mediastinoscopy. Paratracheal and subcarinal lymph node tissues (within the pretracheal space) can be sampled using a mediastinoscope introduced through a suprasternal skin incision.

If intraoperative rapid onsite cytologic evaluation is negative, mediastinoscopy is performed in the same operative setting to ensure accurate mediastinal staging. However, if the FNA is positive, mediastinoscopy is not performed, and the patient is referred to medical oncology for induction therapy; avoiding a pretreatment mediastinoscopy in this manner facilitates the safe performance of a postinduction mediastinoscopy for restaging of the mediastinum in patients who respond favorably to induction therapy.

5. Left video-assisted thoracoscopic lymph node sampling may be needed for patients with left upper lobe tumors who have localized regional spread to stations 5 and 6 lymph nodes, without mediastinal paratracheal involvement (see Fig. 19-8). If there is a low index of suspicion for nodal metastasis, the patient can be scheduled for VATS biopsy and lobectomy under the same anesthesia; the procedure begins by sampling the level 5 and 6 nodes for frozen section, and if the nodes are negative, the anatomic lung resection is performed. If the index of suspicion is high, the VATS biopsy is performed as a separate procedure. Cervical mediastinoscopy should precede VATS biopsy, even if patients have normal paratracheal lymph nodes. Additional diagnostic evaluation of the lymph nodes in stations 5 and 6 may be unnecessary if the mediastinal lymph nodes are proven to be benign with biopsy during cervical mediastinoscopy and the preoperative CT scan suggests complete respectability of the tumor. There are, however, several indications for prethoracotomy biopsy of stations 5 and 6 lymph nodes, which are listed in Table 19-10. It is particularly important to prove that mediastinal lymph nodes are pathologically involved and not just radiographically suspicious for nodal metastasis prior to deciding that the patient is *not* a candidate for resection.

Pleural Effusion. The presence of pleural effusion on radiographic imaging should not be assumed to be malignant. Pleural effusion may be secondary to atelectasis or consolidation (seen with central tumors), cardiac dysfunction, or may be a reactive effusion. When associated with a peripherally based tumor abutting the visceral or parietal pleural surface, probability of being malignant is higher. If this is the only site concerning for metastatic disease, pathologic confirmation is mandatory. It is reasonable to start with thoracentesis, but cytology reveals malignant cells in only 50% of malignant effusions on initial thoracentesis; negative cytology 5 times is needed to have 95% certainty of a benign process. Thoracoscopy may be needed to rule out pleural metastases in select patients and is usually performed as a separate staging procedure, often with subsequent mediastinoscopy if thoracoscopy is negative for metastasis.

Distant Metastases. Currently, chest CT and PET are routine in the evaluation of patients with lung cancer. Integrated PET-CT scanners have become standard and have substantially improved accuracy of detection and localization of lymph node and distant metastases, as compared with independently performed PET and CT scans (Fig. 19-21). This technology overcomes the imprecise information on the exact location of focal abnormalities seen on PET and has become the standard imaging modality for lung cancer. Compared to routine chest or abdominal CT and bone scans, PET scanning detects 10% to 15% more distant metastases, but should be confirmed with MRI and/or biopsies if the patient otherwise has early-stage disease. Brain MRI should be performed when the suspicion or risk of brain metastases is increased, such as in patients with

A

B

C

Figure 19-21. Imaging of non-small cell lung cancer by integrated positron emission tomography (PET)-computed tomography (CT) scan. **A.** CT of the chest showing a tumor in the left upper lobe. **B.** PET scan of the chest at the identical cross-sectional level. **C.** Coregistered PET-CT scan clearly showing tumor invasion (confirmed intraoperatively). (Adapted with permission from Lardinois D, Weder W, Hany TF, et al. Staging of non-small-cell lung cancer with integrated positron-emission tomography and computed tomography, *N Engl J Med.* 2003 Jun 19;348(25):2500-2507.)

clinical stage III disease. In the absence of neurologic symptoms or signs, the probability of a negative head CT scan is 95%. Liver abnormalities that are not clearly simple cysts or hemangiomas and adrenal enlargement, nodules, or masses are further evaluated by MRI scanning and, occasionally, by needle

biopsy. Adrenal adenomas have a high lipid content (secondary to steroid production), but metastases and most primary adrenal malignancies contain little if any lipid; thus, MRI is usually able to distinguish the two.

Tumor, Node, and Metastasis: Lung Cancer Staging The staging of any tumor is an attempt to estimate the extent of disease and determine the patient's prognosis; in a given patient, tumors are typically classified into a clinical stage and a pathologic stage. Clinical staging includes history and physical examination, radiographic test results, and diagnostic biopsy information. Therapeutic plans are generated based on clinical stage. After surgical resection of tumor and lymph nodes, postoperative pathologic stage (pTNM) is determined, providing further prognostic information.

The staging of solid epithelial tumors is based on the TNM staging system. The primary tumor "T" status provides information about tumor size and relationship to surrounding structures; the "N" status provides information about regional lymph nodes; and the "M" status provides information about the presence or absence of metastatic disease. The designation of lymph nodes as N1, N2, or N3 requires familiarity with the lymph node mapping system⁴¹ (see Fig. 19-8). Based on clearly delineated anatomic boundaries, accurate and reproducible localization of thoracic lymph nodes is possible, facilitating detailed nodal staging for individual patients and standardization of nodal assessment between surgeons.

Pathologic staging criteria are based on the predicted survival relative to each combination of tumor, node, and metastasis status. In 2018, the AJCC eighth edition incorporated multiple changes into the staging system for NSCLC based on analysis of survival predictors from 77,156 lung cancer patients worldwide. Table 19-11a shows the clinical and pathologic criteria changes implemented and each of the TNM descriptors currently used in staging NSCLC (Table 19-11b) and the overall stage classifications (Table 19-11c). T-staging is markedly changed, including T category designation for each centimeter in size up to 5 cm, as well as size of the invasive component in lepidic growth tumors. Visceral pleural invasion increases T-stage to T2 for patients with tumors ≤ 3 cm in size, and synchronous primary tumors have an added T suffix (m) in tumor staging. Metastatic disease has also been subdivided into intrathoracic, single-site extrathoracic, and multiple extrathoracic metastasis. In addition to the TNM stage, it is recommended that histologic grade, lymphovascular invasion, adequacy of resection margins and mediastinal dissection, tumor mutation status, treatment, and residual tumor after treatment also be recorded into cancer registries to facilitate evaluation of these potential predictors in future analysis of staging criteria.

Staging for small cell lung cancer (SCLC) is typically based on the extent of disease. SCLC presenting with bulky locoregional disease confined to the ipsilateral hemithorax, with no evidence for distant metastatic disease, is termed "limited" SCLC. Limited disease must be treatable within a tolerable field of radiation. Using AJCC descriptors, this includes any T stage, any N stage, without metastatic disease (M0). The only exception is when multiple lung nodules are widely spread throughout the ipsilateral lung in the same hemithorax; in these patients, the size of the involved area would preclude a "safe" radiation field. In contrast, in "disseminated" disease, tumor is beyond the ipsilateral hemithorax or widely spread within the ipsilateral lung and to distant sites. Metastases to the pleura and pericardium, with resultant effusions, are considered disseminated disease.

Table 19-11a

Changes in Descriptors for non-small cell lung cancer comparing the 7th and 8th editions of the American Joint Committee on Cancer Staging Manual

DESCRIPTOR	SEVENTH EDITION	EIGHTH EDITION
T component		
0 cm (pure lepidic adenocarcinoma ≤ 3 cm total size)	T1a if ≤ 2 cm; T1b if $>2-3$ cm	Tis (AIS)
≤ 0.5 cm invasive size (lepidic predominant adenocarcinoma ≤ 3 cm total size)	T1a if ≤ 2 cm; T1b if $>2-3$ cm	T1mi
≤ 1 cm	T1a	T1a
$>1-2$ cm	T1a	T1b
$>2-3$ cm	T1b	T1c
$>3-4$ cm	T2a	T2a
$>4-5$ cm	T2a	T2b
$>5-7$ cm	T2b	T3
>7 cm	T3	T4
Bronchus <2 cm from carina	T3	T2
Total atelectasis/pneumonitis	T3	T2
Invasion of diaphragm	T3	T4
Invasion of mediastinal pleura	T3	-
N component		
No assessment, no involvement, or involvement of regional lymph nodes	NX, N0, N1, N2, N3	No change
M component		
Metastases within the thoracic cavity	M1a	M1a
Single extrathoracic metastasis	M1b	M1b
Multiple extrathoracic metastases	M1b	M1c

Abbreviations: AIS, adenocarcinoma in situ; mi, minimally invasive adenocarcinoma; Tis, tumor in situ.

Table 19-11b

American Joint Committee on Cancer Lung Cancer Staging Eighth Edition

T	PRIMARY TUMOR
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i> Squamous cell carcinoma <i>in situ</i> (SCIS) Adenocarcinoma <i>in situ</i> (AIS); adenocarcinoma with pure lepidic pattern, ≤ 3 cm in greatest dimension
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1mi	Minimally invasive adenocarcinoma: adenocarcinoma (≤ 3 cm in greatest dimension) with a predominantly lepidic pattern and ≤ 5 mm invasion in greatest dimension
T1a	Tumor ≤ 1 cm in greatest dimension. A superficial, spreading tumor of any size whose invasive component is limited to the bronchial wall and may extend proximal to the main bronchus also is classified as T1a, but these tumors are uncommon.
T1b	Tumor >1 cm but ≤ 2 cm in greatest dimension
T1c	Tumor >2 cm but ≤ 3 cm in greatest dimension
T2	Tumor >3 cm but ≤ 5 cm or having any of the following features: <ul style="list-style-type: none"> • Involves the main bronchus regardless of distance to the carina, but without involvement of the carina • Invades visceral pleura (PL1 or PL2) • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung T2 tumors with these features are classified as T2a if ≤ 4 cm or if the size cannot be determined and T2b if >4 cm but ≤ 5 cm.

(Continued)

Table 19-11b

American Joint Committee on Cancer Lung Cancer Staging Eight Edition (*Continued*)

T2a	Tumor >3 cm but ≤4 cm in greatest dimension
T2b	Tumor >4 cm but ≤5 cm in greatest dimension
T3	Tumor >5 cm but ≤7 cm in greatest dimension or directly invading any of the following: parietal pleura (PL3), chest wall (including superior sulcus tumors), phrenic nerve, parietal pericardium; or separate tumor nodule(s) in the same lobe as the primary
T4	Tumor >7 cm or tumor of any size invading one or more of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; separate tumor nodule(s) in an ipsilateral lobe different from that of the primary
N	REGIONAL LYMPH NODE
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M	DISTANT METASTASIS
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodules or malignant pleural or pericardial effusion. Most pleural (pericardial) effusions with lung cancer are a result of the tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and not an exudate. If these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging descriptor.
M1b	Single extrathoracic metastasis in a single organ (including involvement of a single nonregional node)
M1c	Multiple extrathoracic metastases in a single organ or in multiple organs

Metastases to brain, bone, bone marrow, and the pleural and pericardial spaces are common.

Assessment of Functional Status Patients with potentially resectable tumors require careful assessment of their functional status and ability to tolerate either lobectomy or pneumonectomy. The surgeon should first estimate the likelihood of pneumonectomy, lobectomy, or possibly sleeve resection, based on the 5▶ CT images. A sequential process of evaluation then unfolds.

A patient's history is the most important tool for gauging risk. Specific questions regarding performance status should be routinely asked. If the patient can walk on a flat surface indefinitely, without oxygen and without having to stop and rest secondary to dyspnea, he will be very likely to tolerate lobectomy. If the patient can walk up two flights of stairs (up two standard levels), without having to stop and rest secondary to dyspnea, she will likely tolerate pneumonectomy. Finally, nearly

all patients, except those with carbon dioxide (CO₂) retention on arterial blood gas analysis, will be able to tolerate periods of single-lung ventilation and wedge resection. Formal assessment of cardiac fitness is mandatory; use of risk scores such as the Thoracic Revised Cardiac Risk Index developed by Dr. Brunelli and colleagues provides useful prognostic information for postresection survival from early-stage lung cancer.

Current smoking status and sputum production are also pertinent. Current smokers and patients with a greater than 60 pack-year history of smoking have a significantly increased risk of postoperative pulmonary complications; heavy smokers are 2.5 times more likely to develop pulmonary complications and three times more likely to develop pneumonia compared to patients with a ≤60 pack-year history (odds ratio [OR] 2.54; 95% CI 1.28–5.04; $P = .0008$). Impaired exchange of CO₂ is also predictive of increased risk, independent of the smoking history. For every 10% decline in percent carbon monoxide diffusion capacity (%DLCO), the risk of any pulmonary complication increased by 42% (OR 1.42; 95% CI 1.16–1.75; $P = .008$).⁴² Risk reduction requires smoking cessation at least 8 weeks preoperatively, a requirement that is often not feasible in a cancer patient. Nevertheless, abstinence for at least 2 weeks before surgery should be encouraged. Smoking cessation on the day of surgery leads to increased sputum production and potential secretion retention postoperatively, and some authors have reported increased rates of pulmonary complications in this group.⁴³ Patients with chronic daily sputum production will have more problems postoperatively with retention and atelectasis; they are also at higher risk for pneumonia. Sputum culture, antibiotic administration, and bronchodilators may be warranted preoperatively.

Pulmonary function studies are routinely performed when any resection greater than a wedge resection will be performed. Of all the measurements available, the two most valuable are forced expiratory volume in 1 second (FEV₁) and carbon monoxide diffusion capacity (DLCO). General guidelines for the use of FEV₁ in assessing the patient's ability to tolerate pulmonary resection are as follows: greater than 2.0 L can tolerate pneumonectomy, and greater than 1.5 L can tolerate lobectomy. It must be emphasized that these are guidelines only. It is also important to note that the raw value is often imprecise because normal values are reported as "percent predicted" based on corrections made for age, height, and gender. For example, a raw FEV₁ value of 1.3 L in a 62-year-old, 75-inch (190-cm) male has a percent predicted value of 30% (because the normal expected value is 4.31 L); in a 62-year-old, 62-inch female, the predicted value is 59% (normal expected value 2.21 L). The male patient is at high risk for lobectomy, while the female could potentially tolerate pneumonectomy.

To calculate the predicted postoperative value for FEV₁ or DLCO, the percent predicted value of FEV₁ or DLCO is multiplied by the fraction of remaining lung after the proposed surgery. For example, with a planned right upper lobectomy, a total of three segments will be removed. Therefore, three of a total 20 segments will leave the patient with $(20 - 3/20) \times 100 = 85\%$ of their original lung capacity. In the two patients mentioned earlier, the man will have a predicted postoperative FEV₁ of $30\% \times 0.85 = 25\%$, whereas the woman will have a predicted postoperative FEV₁ of 50%. Percent predicted value of less than 50% for either FEV₁ or DLCO correlates with risk for postoperative complications, particularly pulmonary complications; the risk of complications increases in a stepwise fashion for each 10% decline. Figure 19-22 shows the relationship between predicted postoperative DLCO and estimated operative mortality.

Figure 19-22. Operative mortality after major pulmonary resection for non-small cell lung cancer (334 patients) as a function of percent predicted postoperative carbon monoxide diffusion capacity (ppoDLCO%). *Solid line* indicates logistic regression model; *dashed lines* indicate 95% confidence limits. (Reproduced with permission from Wang J, Olak J, Ferguson MK: *Diffusing capacity predicts operative mortality but not long-term survival after resection for lung cancer*, J Thorac Cardiovasc Surg. 1999 Mar;117(3):581-586.)

Quantitative perfusion scanning is used in select circumstances to help estimate the functional contribution of a lobe or whole lung. Such perfusion scanning is most useful when the impact of a tumor on pulmonary physiology is difficult to discern. With complete collapse of a lobe or whole lung, the impact is apparent, and perfusion scanning is usually unnecessary. Figure 19-23 shows a tumor with significant right main stem airway obstruction with associated atelectasis and volume loss of the right lung. At presentation, the patient was dyspneic with ambulation, and the FEV₁ was 1.38 L. Six months prior, this patient could walk up two flights of stairs without dyspnea. The surgeon can anticipate that the patient will tolerate pneumonectomy because the lung is already not functioning due to main stem airway obstruction, and may, in fact, be contributing to a shunt. However, with centrally located tumors associated with partial obstruction of a lobar or main bronchus or of the pulmonary artery, perfusion scanning may be valuable in predicting the postoperative result of resection. For example, if the quantitative perfusion to the right lung is measured to be 21% (normal is 55%) and the patient's percent predicted FEV₁ is 60%, the predicted postoperative FEV₁ after a right pneumonectomy would be $60\% \times 0.79 = 47\%$, indicating the ability to tolerate pneumonectomy. If the perfusion value is 55%, the predicted postoperative value would be 27%, and pneumonectomy would pose a significantly higher risk.

It is not uncommon to encounter patients with significant reductions in their percent predicted FEV₁ and DLCO whose history shows a functional status that is inconsistent with the pulmonary function tests. In these circumstances, exercise testing that yields maximal oxygen consumption ($\dot{V}O_{2max}$) has emerged as a valuable decision-making technique to help patients with abnormal FEV₁ and DLCO (Table 19-12). Values <10 mL/kg/min are associated with a 26% mortality after major pulmonary

Figure 19-23. Chest computed tomography scan of an obstructing right main stem lung tumor. *Arrow* indicates location of right main bronchus. The right lung volume is much less than the left lung volume.

resection compared to only 8.3% with $\dot{V}_{O_{2max}} \geq 10$ mL/kg/min.

6▶ Values >15 mL/kg/min generally indicate the patient's ability to tolerate pneumonectomy.

The risk assessment of a patient is an amalgam of clinical judgment and data that must be integrated with the experienced clinician's sense of the patient and with the patient's attitude

toward the disease and toward life. Figure 19-24 provides a useful algorithm for determining suitability for lung resection.⁴⁴

Lung Cancer Treatment

Grade IV NEC (Small Cell) Lung Carcinoma. In rare circumstances where SCLC presents as an isolated lung lesion, lobectomy followed by chemotherapy is warranted after surgical mediastinal staging has confirmed the absence of N2 disease. Often, ultrasound-guided FNA provides a definitive positive diagnosis and more invasive approaches are not needed. However, less than 5% are stage I, and there is no benefit from surgical resection for more advanced-stage disease; treatment is chemotherapy with or without radiation therapy depending on the extent of disease and the patient performance status.

Early-Stage Non-Small Cell Lung Cancer. Early-stage disease includes T1 and T2 tumors (with or without N1 nodal involvement) and T3 tumors (without N1 nodal involvement). This group represents a small but increasing proportion of the total number of patients diagnosed with lung cancer each year (approximately 16% of an estimated 222,500 patients in 2017).¹⁸ Surgical resection is the current standard, ideally accomplished by video-assisted lobectomy or pneumonectomy, depending on the tumor location.

Despite the term "early-stage," the overall 5-year survival rate for all localized lung cancer is 55% and only 26% when regional metastasis was present between 2004 and 2009.⁴⁵ Median survival for untreated patients with stage IA NSCLC is 14 months, and 5-year survival rate is 22%.⁴⁶ After surgical resection of postoperative pathologic stage IA disease, 5-year survival is better than with no treatment, but still only 67%.⁴¹ Survival declines with higher stages. Advanced age at diagnosis, male sex, low socioeconomic status, nonsurgical treatment, and poor histologic grade are associated with increased mortality risk on multivariate analysis.⁴⁵

Depending on tumor size and location, lobectomy, sleeve lobectomy, and occasionally pneumonectomy, with mediastinal lymph node dissection or sampling, are appropriate for patients with clinical early-stage disease. Sleeve resection is performed for tumors located at airway bifurcations when an adequate bronchial

(Modified with permission from Colice GL, Shafazand S, Griffin JP: *Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: ACCP evidenced-based clinical practice guidelines (2nd edition)*, Chest. 2007 Sep;132(3 Suppl):161S-177S.⁴⁴)

margin cannot be obtained by standard lobectomy. Pneumonectomy is rarely performed; primary indications for pneumonectomy in early-stage disease include large central tumors involving the distal main stem bronchus and inability to completely resect involved N1 lymph nodes. The latter circumstance occurs with bulky adenopathy or with extracapsular nodal spread.

Management of Early-Stage Lung Cancer in the High-Risk Patient Lobectomy may not be an option for some patients with early-stage disease, due to poor cardiopulmonary function or other comorbid illnesses. The ultimate decision that a patient is inoperable, both with regard to the patient's ability to tolerate surgery and the likelihood of successful resection, should be accepted only after evaluation by an expert surgeon. Surgeons with limited expertise, when faced with a complicated patient, should refer the patient to a high-volume center for further evaluation if they are unable to offer the patient surgical resection in their own center.

Rationale for Limited Resection in Early-Stage Lung Cancer.

Limited resection, defined as segmentectomy or wedge resection, is a viable option for achieving local control in high-risk patients. Historically, limited resection with wedge or segmentectomy has been considered a compromise operation due to unacceptably high rates of local recurrence and concerns for worse survival.^{47,48} Subsequent meta-analysis of the literature shows that the difference in death rate is likely negligible⁴⁹ (Table 19-13). The high rates of local recurrence demonstrated by Ginsberg and others, however, remain a significant concern and continue to restrict the use of limited resection for early-stage lung cancer to the high-risk patient.

With the recent publication of a 20% reduction in lung cancer mortality with screening CT scans in high-risk populations, the topic of limited resection is again the subject of intensive review. Studies investigating anatomic segmentectomy (or extended wedge resection) with hilar and mediastinal lymph node dissection suggest that close attention to the ratio of surgical margin to tumor diameter and a careful assessment of the lymph nodes substantially reduce local recurrence.⁵⁰⁻⁵² Recurrence rates were 6.2%, comparable to rates associated with lobectomy, when the margin-to-tumor diameter ratio exceeded 1, compared to 25% if the margin-to-tumor diameter ratio was less than 1.⁵⁰ In most centers, this requires use of a thoracotomy, although increasing experience with VATS in high-volume centers shows that limited resection is safe and feasible, with perioperative adverse outcomes that are comparable to lobectomy.⁵²⁻⁵⁵

Rationale for Tumor Ablation in the Management of Primary Lung Cancer. Limited resection, by definition, requires that the patient has sufficient cardiopulmonary reserve to undergo a general anesthesia and loss of at least one pulmonary segment. For the high-risk or nonoperable patient, as determined by experienced pulmonary surgeons, tumor ablation techniques have been developed for treatment of early-stage lung cancers.

Current limitations of this approach include the absence of nodal staging, lack of tissue for molecular profiling, chemoresistance, or sensitivity testing, concerns about definitions of locoregional recurrence, and a lack of uniformity across centers. Surgeons typically define locoregional recurrence as tumor growth within the operative field, including resectable lymph nodes, whereas local recurrence after ablation is most commonly defined as tumor growth within the field of treatment. Despite the fact that in-transit or lymph node metastases are

present in up to 27% of clinically stage I NSCLCs at resection, any tumor growth outside the field of ablative treatment is not be considered treatment failure.⁵⁶

Despite these limitations, tumor ablative strategies are increasingly proposed as viable alternatives to surgical resection, even in potentially operable patients.⁵⁷⁻⁶² While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers. Multidisciplinary collaboration between thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.

The two most commonly applied ablation techniques are radiofrequency ablation and stereotactic body radiotherapy.

1. **Radiofrequency ablation.** Radiofrequency ablation is performed using either monopolar or bipolar delivery of electrical current to electrodes placed within the tumor tissue. In lung tumors, the electrodes are typically inserted into the tumor mass under CT guidance. An electrical current is delivered; the current is converted by means of friction into heat, which quickly leads to immediate and irreparable tissue destruction in the tissue surrounding the electrode. The efficacy of radiofrequency ablation for controlling the primary tumor and improving survival in poor operative candidates (either due to significant comorbid diseases precluding general anesthesia or poor pulmonary function excluding lung resection) is safe and feasible for peripheral lung nodules. In tumors <3.5 cm, the rate of radiographic resolution of tumor is up to 80%, and cancer-specific survival at 2 years was approximately 90%, indicating excellent local control of the primary site.^{57-59,63} It has become the preferred modality for small peripheral tumors over standard external-beam radiation in centers where the technique is available.

Radiofrequency ablation is an excellent modality for the patient at risk for adverse outcomes with pulmonary resection or for patients who refuse surgery, and surgeons should have an algorithm for determining which patients are optimal for this modality⁶⁴⁻⁶⁹ (see Fig. 19-24). Target lesions larger than 5 cm, tumor abutting the hilum, associated malignant pleural or pericardial effusion, greater than three lesions in one lung, and the presence of pulmonary hypertension are all contraindications to radiofrequency ablation.⁶⁴ Proximity to a large vessel is a contraindication not only due to the risk of massive bleeding, but also because large blood vessels act as a heat sink and lethal cellular temperatures are less likely to be achieved. For these patients, stereotactic body radiotherapy may provide local tumor control with less risk of major complications. Combination therapy with either external-beam radiation or stereotactic body radiotherapy is also under investigation.

2. **Stereotactic body radiotherapy.** Stereotactic body radiotherapy applies highly focused, high-intensity, three-dimensional conformal radiation to the target lesion over a few sessions. Tumor motion quantification and image guidance technologies have significantly improved the delivery of radiation with high levels of precision

to the target lesion. This accuracy is important because the lung is extremely sensitive to radiation injury and the majority of patients with early-stage lung cancer who are currently considered candidates for ablative therapy have marginal lung function; excessive injury to normal surrounding lung tissue is not desirable. Importantly, these techniques allow the safe delivery of up to 66 Gy of radiation to the target tumors without exceeding the maximum-tolerated dose.⁶²⁻⁷⁰ A phase II North American multicenter study recently demonstrated the safety and efficacy of this approach in 59 nonoperable patients.⁶² Patients with biopsy-proven, node-negative peripheral NSCLCs less than 5 cm in diameter (T1 or T2) were treated with stereotactic body radiotherapy after they were deemed inoperable, based on coexisting medical conditions, by a thoracic surgeon and/or pulmonologist. Primary tumor control was excellent; at 3 years, 97.6% were deemed to have primary tumor control by the authors, and 90.6% had local control. However, it is important to note that primary tumor failure was defined specifically as at least a 20% increase in the longest diameter of the gross tumor volume by CT scan and evidence of tumor viability either by biopsy confirming carcinoma or by demonstration of FDG avidity on PET scan. For viability to be confirmed with PET scan, the uptake was required to be of similar intensity to the pretreatment staging PET scan. Failure beyond a 1.5- to 2-cm margin around the primary tumor volume was considered local failure. Failure in regional node basins was seen in two patients. When compared to locoregional control rates of approximately 6.5% with limited resection, the 3-year locoregional recurrence was higher at 12.8%.

3. Patient selection for stereotactic body radiotherapy, as with limited resection and radiofrequency ablation, is important. Because the radiation field is so precise, patients with severe emphysema and chronic obstructive pulmonary disease can be safely treated without significant concern for worsening lung function. However, patients with central tumors near the mediastinum and hilum have increased incidence of significant hypoxia, hemoptysis, atelectasis, pneumonitis, and reduced pulmonary function.⁷⁰ In the multicenter trial detailed earlier, treated tumors were required to be greater than 2 cm from the proximal bronchial tree in all directions (which they defined as the distal 2 cm of the trachea, carina, and named major lobar bronchi up to their first bifurcation).⁶²

Rationale for Chemotherapy in the Management of Early-Stage NSCLC. The role of chemotherapy in early-stage (stages I and II) NSCLC is evolving, with several prospective phase 2 studies having shown a potential benefit.^{71,72} Initial concerns that induction chemotherapy may result in increased perioperative morbidity or mortality appear to be unwarranted, as the incidence of perioperative morbidity and mortality is not different between the two groups, except in patients undergoing right-sided pneumonectomy after induction chemotherapy.⁷³ As shown in Table 19-14, an absolute survival benefit of 4% to 7% can be realized using induction for all stages of lung cancer, and in situations where use of adjuvant chemotherapy is anticipated, induction chemotherapy is an acceptable alternative.

Table 19-14

Five-year stage-specific survival after induction chemotherapy followed by surgery

National Comprehensive Cancer Network guidelines currently recommend observation for T1a (≤ 1 cm), T1b (>1 –2 cm), and T1c (>2 –3 cm), node-negative, completely resected NSCLCs (T1abcN0M0). For patients with larger tumors (T2a tumor >3 –4 cm; T2b tumor >4 –5 cm) that are node-negative, it is recommended that chemotherapy be considered in high-risk patients, ideally in the setting of a clinical trial. High-risk tumor characteristics include poorly differentiated tumors, moderately to poorly differentiated lung neuroendocrine tumors, vascular invasion, resection limited to wedge resection only, tumors >4 cm in size, visceral pleural involvement, and when lymph node sampling at the time of resection was incomplete (Nx).

Evaluation and Management of Locally Advanced NSCLC. Five-year relative survival in patients with locoregional disease is 28%, but there is significant heterogeneity within the group. Stage III disease includes patients with small tumors that have metastasized to the mediastinal lymph nodes as well as large tumors (>7 cm), and tumor invading unresectable structures or the major carina with no nodal metastasis at all. Patients with clinically evident N2 disease (i.e., bulky adenopathy present on CT scan or mediastinoscopy, with lymph nodes often replaced by tumor) have a 5-year survival rate of 5% to 10% with surgery alone. In contrast, patients with microscopic N2 disease discovered incidentally in one lymph node station after surgical resection have a 5-year survival rate that may be as high as 30%. As a result, many surgeons and oncologists differentiate between microscopic and bulky N2 lymphadenopathy and the number of involved N2 nodal stations in determining whether to proceed with resection following induction therapy. It is generally accepted that surgical resection is appropriate for patients with a single-station metastasis with a single lymph node smaller than 3 cm, although randomized trials specifically investigating resection following induction therapy for patients with single-station microscopic disease have not yet been performed.

Histologic confirmation of N2 nodal metastases is imperative; false-positive findings on PET scan are unacceptably high, and reliance on this modality will lead to significant undertreatment of patients with earlier stage cancers. This is particularly true in regions with high incidence of granulomatous diseases.

When N2 nodes are found, incidentally, to harbor metastasis at the time of planned anatomic lung resection, the decision to proceed with resection varies depending on surgeon preference; it is acceptable to either proceed with anatomic resection and mediastinal lymph node sampling/dissection or to stop the procedure, refer the patient for induction therapy, and reevaluate for resection after induction therapy is completed.

When histologically confirmed metastases are found during preoperative staging evaluation, patients should be referred for induction chemotherapy; patients in whom the mediastinal nodes are sterilized by induction therapy have a better prognosis, and surgical resection is generally warranted as part of a multimodal approach. As with preinduction evaluation, histologic confirmation of persistent N2 disease after induction therapy is imperative; patients should not be denied surgical resection following induction chemotherapy based on radiographic evidence for N2 disease because the survival for resected NSCLC is significantly better than with definitive chemotherapy.

Surgery in T4 and Stage IV Disease Surgery is occasionally appropriate for highly selected patients with tumors invading the SVC, carinal or vertebral body involvement, or satellite nodules in the same lobe (T3, N0-1, M0) or in T4, N0-1 tumors with limited invasion into the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, diaphragm or carina through direct extension. Surgery generally does *not* have a role in the care of patients with any tumor with N3 disease or T4 tumors with N2 disease. Survival rates remain extremely low for these patients. Similarly, the treatment of patients with stage IV disease is chemotherapy. However, on occasion, patients with a single site of metastasis are encountered, particularly with adenocarcinomas presenting with a solitary brain metastasis. In this highly select group, 5-year survival rates of 10% to 15% can be achieved with surgical excision of the brain metastasis and the primary tumor, assuming it is early stage.

Surgery for Management of Pancoast's Tumor Carcinoma arising in the extreme apex of the chest with associated arm and shoulder pain, atrophy of the muscles of the hand, and Horner's syndrome presents a unique challenge to the surgeon. Any tumor of the superior sulcus, including tumors without evidence for involvement of the neurovascular bundle, is now commonly known as Pancoast's tumors, after Henry Pancoast who described the syndrome in 1932. The designation is reserved for tumors involving the parietal pleura or deeper structures overlying the first rib. Chest wall involvement at or below the second rib is not a Pancoast's tumor.⁷⁴ Treatment is multidisciplinary; due to the location of the tumor and involvement of the neurovascular bundle that supplies the ipsilateral extremity, preserving postoperative function of the extremity is critical. For this reason, resection should only be performed in patients who are proven negative for mediastinal lymph node involvement. Survival with N2 positive nodes is poor, and the morbidity and mortality associated with surgical resection are high. If bulky lymphadenopathy is present, EBUS- or EUS-guided FNA may prove nodal involvement. However, a negative FNA is not sufficient for proving the absence of mediastinal involvement and should be followed by mediastinoscopy to ensure accurate and complete evaluation of the mediastinum.

Because Pancoast's tumors have high rates of local recurrence and incomplete resection, induction chemoradiotherapy followed by surgery is recommended. This treatment regimen was well tolerated in a study performed by the Southwest Oncology

Group, with 95% of patients completing induction treatment. Complete resection was achieved in 76%. Five-year survival was 44% overall and 54% when complete resection was achieved. Disease progression with this regimen was predominantly at distant sites, with the brain being the most common.⁷⁵ The current treatment algorithm for Pancoast's tumors is presented in Fig. 19-25.

Surgical excision is performed via thoracotomy with en bloc resection of the chest wall and vascular structures and anatomic lobectomy. A portion of the lower trunk of the brachial plexus and the stellate ganglion are also typically resected. With chest wall involvement, en bloc chest wall resection, along with lobectomy, is performed, with or without chest wall reconstruction.

For small rib resections or those posterior to the scapula, chest wall reconstruction is usually unnecessary. Larger defects (two rib segments or more) are usually reconstructed with Gore-Tex to provide chest wall contour and stability. En bloc resection is also used for other locally advanced tumors (T3) with direct invasion of the adjacent chest wall, diaphragm, or pericardium. If a large portion of the pericardium is removed, reconstruction with thin Gore-Tex membrane will be required to prevent cardiac herniation and venous obstruction.

Preoperative (Induction) Chemotherapy for NSCLC The use of chemotherapy before anatomic surgical resection has a number of potential advantages:

1. The tumor's blood supply is still intact, allowing better chemotherapy delivery and avoiding tumor cell hypoxia (in any residual microscopic tumor remaining postoperatively), which would increase radioresistance.
2. The primary tumor may be downstaged, enhancing resectability.
3. Patients are better able to tolerate chemotherapy before surgery and are more likely to complete the prescribed regimen than after surgery.
4. It functions as an in vivo test of the primary tumor's sensitivity to chemotherapy.
5. Response to chemotherapy can be monitored and used to guide decisions about additional therapy.
6. Systemic micrometastases are treated.
7. It identifies patients with progressive disease/nonresponders and spares them a pulmonary resection.

Potential disadvantages include:

1. There is a possible increase in the perioperative complication rate in patients requiring right pneumonectomy after induction chemotherapy.
2. While the patient is receiving chemotherapy, potentially curative resection is delayed; if the patient does not respond, this delay could result in tumor spread.

In stage IIIA N2 disease, the response rates to induction chemotherapy are high, in the range of 70%. The treatment is generally safe, as it does not cause a significant increase in perioperative morbidity. Two randomized trials have now compared surgery alone for patients with N2 disease to preoperative chemotherapy followed by surgery. Both trials were stopped before complete accrual because of a significant increase in survival for the chemotherapy arm.

The initially observed survival differences have been maintained for up to 3 years and beyond (5-year data not shown). Given these results, induction chemotherapy with

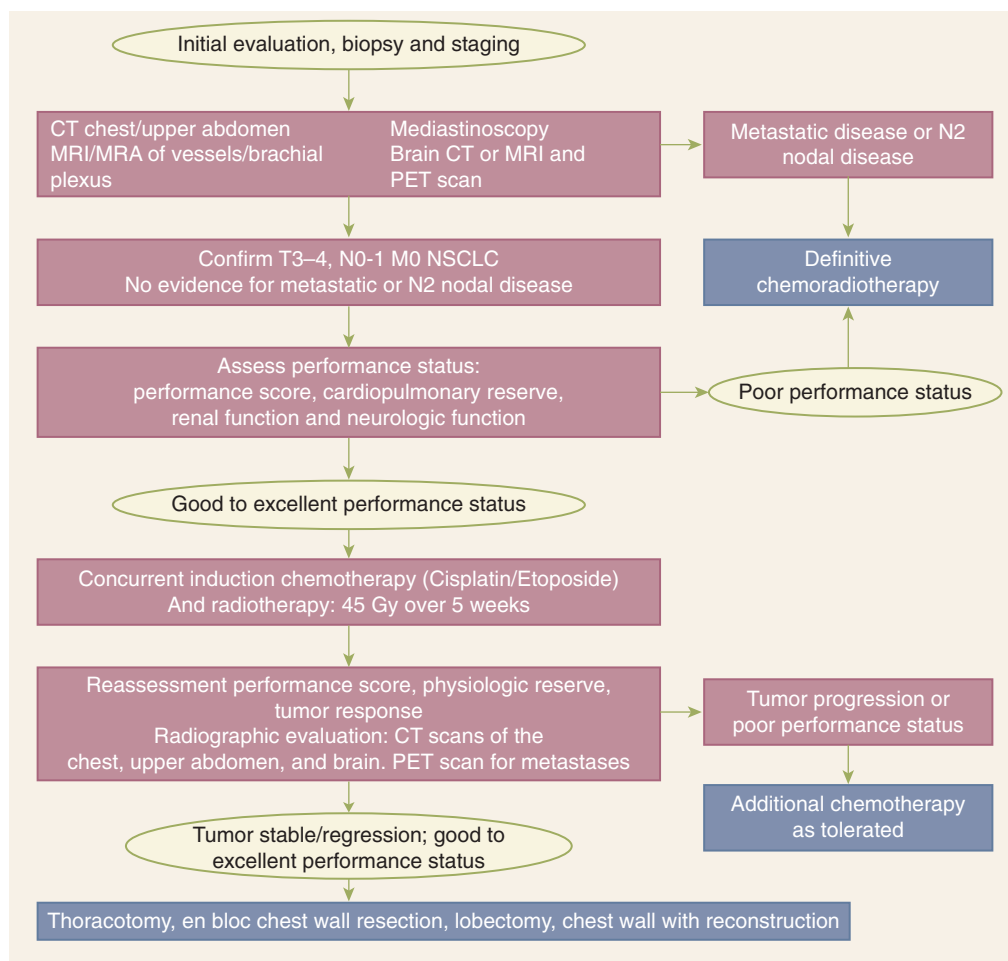

Figure 19-25. Treatment algorithm for Pancoast's tumors. CT = computed tomography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; NSCLC = non-small cell lung cancer; PET = positron emission tomography.

cisplatin-based regimen (two to three cycles) has become standard for patients with N2 disease. Table 19-15 summarizes the findings of a systematic review and meta-analysis reporting response rates, progression-free survival, and overall survival after induction chemotherapy followed by surgical resection.

Postoperative (Adjuvant) Chemotherapy for NSCLC Postoperative adjuvant chemotherapy was previously thought to confer no benefit based on multiple prospective randomized trials, in part because patients who had undergone thoracotomy and lung resection had difficulty tolerating the adjuvant regimens. More recently, however, newer, more effective agents have shown promise, and adjuvant therapy is better tolerated after minimally invasive lung resection (i.e., VATS or robotic anatomic resection). Targeted therapies, which have been shown to be beneficial in advanced-stage lung cancer, are of particular interest.

Any patient with nodal metastasis (N1 or N2) or with T3 tumors (defined as tumors >5 to ≤ 7 cm or separate tumor in same lobe or direct invasion of chest wall [includes parietal pleura and superior sulcus]/parietal pericardium/phrenic nerve) should receive adjuvant chemotherapy if they are able to tolerate the regimen. In the situation where the margins of resection are positive, re-resection is recommended. If not possible, concurrent chemoradiation is recommended for macroscopic residual tumor and sequential chemoradiation for microscopic residual tumor.

Definitive Nonsurgical Treatment for NSCLC. Recent advances in targeted therapies have changed the management of

advanced NSCLC from a generalized, platinum-based approach to one in which molecular analysis and targeted, personalized therapies are now standard of care. It is now mandatory that the pathologist clearly differentiate between squamous cell carcinoma and adenocarcinoma because the therapeutic options are different and use of bevacizumab, while beneficial in patients with adenocarcinoma, has been found to cause excessive pulmonary hemorrhage in patients with squamous histology. For the surgeon, this requirement translates into a much more aggressive approach to tissue diagnosis. At our institution, the cytopathologist provides onsite rapid assessment of the fine-needle aspirate to determine whether tumor cells are present and confirm that sufficient tumor cells are present to enable molecular testing. This has increased the number of passes performed during an EBUS-guided FNA or during CT-guided aspiration of a pulmonary or intrathoracic lesion; typically, an additional two to three passes are made for cell block material after confirming the presence of tumor cells in the target area. When insufficient cells are obtained for molecular testing, despite having a diagnosis, additional sampling is warranted; this is mandatory in patients with adenocarcinoma and likely to become necessary for other non-small cell histologic types as advances in targeted therapies become available for clinical use. Acquiring adequate tissue for diagnosis may require mediastinoscopy or VATS; close communication between the oncologist, surgeon, pathologist, and patient is needed to ensure that the benefits to the patient clearly outweigh the risks and that results obtained through more aggressive diagnostic measures are needed to direct subsequent care.

Randomized trials of neoadjuvant chemotherapy for stage III non-small cell lung cancer

Study	NO. OF PATIENTS (STAGE III)	CHEMOTHERAPY	RESPONSE RATE (%)	PCR (%)	COMPLETE RESECTION	PFS	OS	5-YEAR SURVIVAL (%)

Once a treatment plan has been devised, two strategies for delivery are available. “Sequential” chemoradiation involves full-dose systemic chemotherapy (i.e., cisplatin combined with a second agent) followed by standard radiotherapy (approximately 60 Gy). The combination of chemotherapy followed by radiation has improved 5-year survival from 6% with radiotherapy alone to 17%.⁷⁶ An alternative approach, referred to as “concurrent chemoradiation,” administers chemotherapy and radiation at the same time. Certain chemotherapeutic agents sensitize tumor cells to radiation and, thus, enhance the radiation effect. The advantages of this approach are improved primary tumor and locoregional lymph node control and elimination of the delay in administering radiotherapy that occurs with sequential treatment. A disadvantage, however, is the necessary reduction in chemotherapy dosage in order to diminish overlapping toxicities; this can potentially lead to undertreatment of systemic micrometastases. Randomized trials have shown a modest 5-year survival benefit as compared with chemotherapy. In a systematic review of 47 trials and six meta-analyses, an absolute survival benefit of 4% at 2 years was seen when concurrent platinum-based chemoradiation was given compared to sequential radiation.⁷⁷

Definitive radiotherapy is predominantly used for palliation of symptoms in patients with poor performance status; cure rates with radiation as a single modality in patients with N2 or N3 disease is less than 7%. Recent improvement has been seen with three-dimensional conformal radiotherapy and altered fractionation. Such poor results for patients with stage III lung cancer reflect the limitations of locoregional treatment in a disease where death results from systemic metastatic spread.

Options for Thoracic Surgical Approaches

Thoracic surgical approaches have changed over recent years with advancements in minimally invasive surgery. A surgeon trained in advanced minimally invasive techniques can now perform pleural-based, pulmonary and mediastinal procedures through multiple thoracoscopic ports without the need for a substantial, rib-spreading incision. Subjective measures of quality of life after VATS, such as pain (Fig. 19-26) and perceived functional recovery, consistently and reproducibly favor VATS

Figure 19-26. Pie chart comparison of pain control at 3 weeks after lobectomy by standard thoracotomy or video-assisted thoracic surgery (VATS). The pie charts show that patients undergoing VATS had significantly less pain ($P < .01$) as measured by the most potent analgesic still required: severe—schedule II narcotic; moderate—schedule III or lower narcotic; mild—nonsteroidal anti-inflammatory drug (NSAID) or acetaminophen. (Reproduced with permission from Demmy TL, Nwoque C. Is video-assisted thoracic surgery lobectomy better? Quality of life considerations, *Ann Thorac Surg*. 2008 Feb;85(2):S719-S728.)

over thoracotomy. Objective measures such as functional status as measured by 6-minute walk, return to work, and ability to tolerate chemotherapy also favor VATS over thoracotomy. Finally, recovery of respiratory function occurs earlier in VATS patients. These findings are pronounced in patients with chronic obstructive pulmonary disease and in the elderly—populations whose quality of life can be dramatically impacted by changes in their respiratory symptoms and function, thoracic pain, and physical performance. Table 19-16 provides a summary of populations that may benefit from VATS approaches.

Video-Assisted (VATS)/Robotic-Assisted Thoracoscopic Surgery (RATS). VATS/RATS has become the recommended approach to diagnosis and treatment of pleural effusions, recurrent pneumothoraces, lung biopsies, lobectomy or segmental resection, resection of bronchogenic and mediastinal cysts, and intrathoracic esophageal mobilization for esophagectomy.⁷⁸ These approaches are also utilized for pneumonectomy in some centers of excellence with very high

Table 19-16

Special circumstances under which lobectomy by video-assisted thoracic surgery may be preferable

CONDITION	EXAMPLES
Pulmonary compromise	Poor FEV ₁ /DLCO, heavy smoking, sleep apnea, recent pneumonia
Cardiac dysfunction	Congestive heart failure, severe coronary artery disease, recent myocardial infarction, valvular disease
Extrathoracic malignancy	Solitary brain metastasis from lung cancer, deep pulmonary metastases requiring lobectomy
Poor physical performance	Performance status equivalent to a Zubrod score of 2 or 3, morbid obesity
Rheumatologic/orthopedic condition	Spinal disease, severe rheumatoid arthritis, severe kyphosis, lupus erythematosus, osteomyelitis
Advanced age	Age >70 years
Vascular problems	Aneurysm, severe peripheral vascular disease
Recent or impending major operation	Urgent abdominal operation, joint replacement requiring use of crutches, need for contralateral thoracotomy
Psychological/neurologic conditions	Substance abuse, poor command following, pain syndromes
Immunosuppression/impaired wound healing	Recent transplantation, diabetes

Abbreviations: DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 second.

volumes of VATS lung resection. VATS is performed via two to four incisions measuring 0.5 to 1.2 cm in length to allow insertion of the thoracoscope and instruments. An access incision, typically in the fourth or fifth intercostal space in the anterior axillary line, is used for dissection of the hilum during lung resection. The incision location varies according to the procedure. With respect to VATS lobectomy, port

placement varies according to the lobe being resected and is highly variable among surgeons.⁷⁹ The basic principle is to position the ports high enough on the thoracic cage to have access to the hilar structures. Endoscopic staplers are used to divide the major vascular structures and bronchus (Fig. 19-27). Robotic approaches are similarly tailored to the side and lobe undergoing resection, with the entire operation performed using

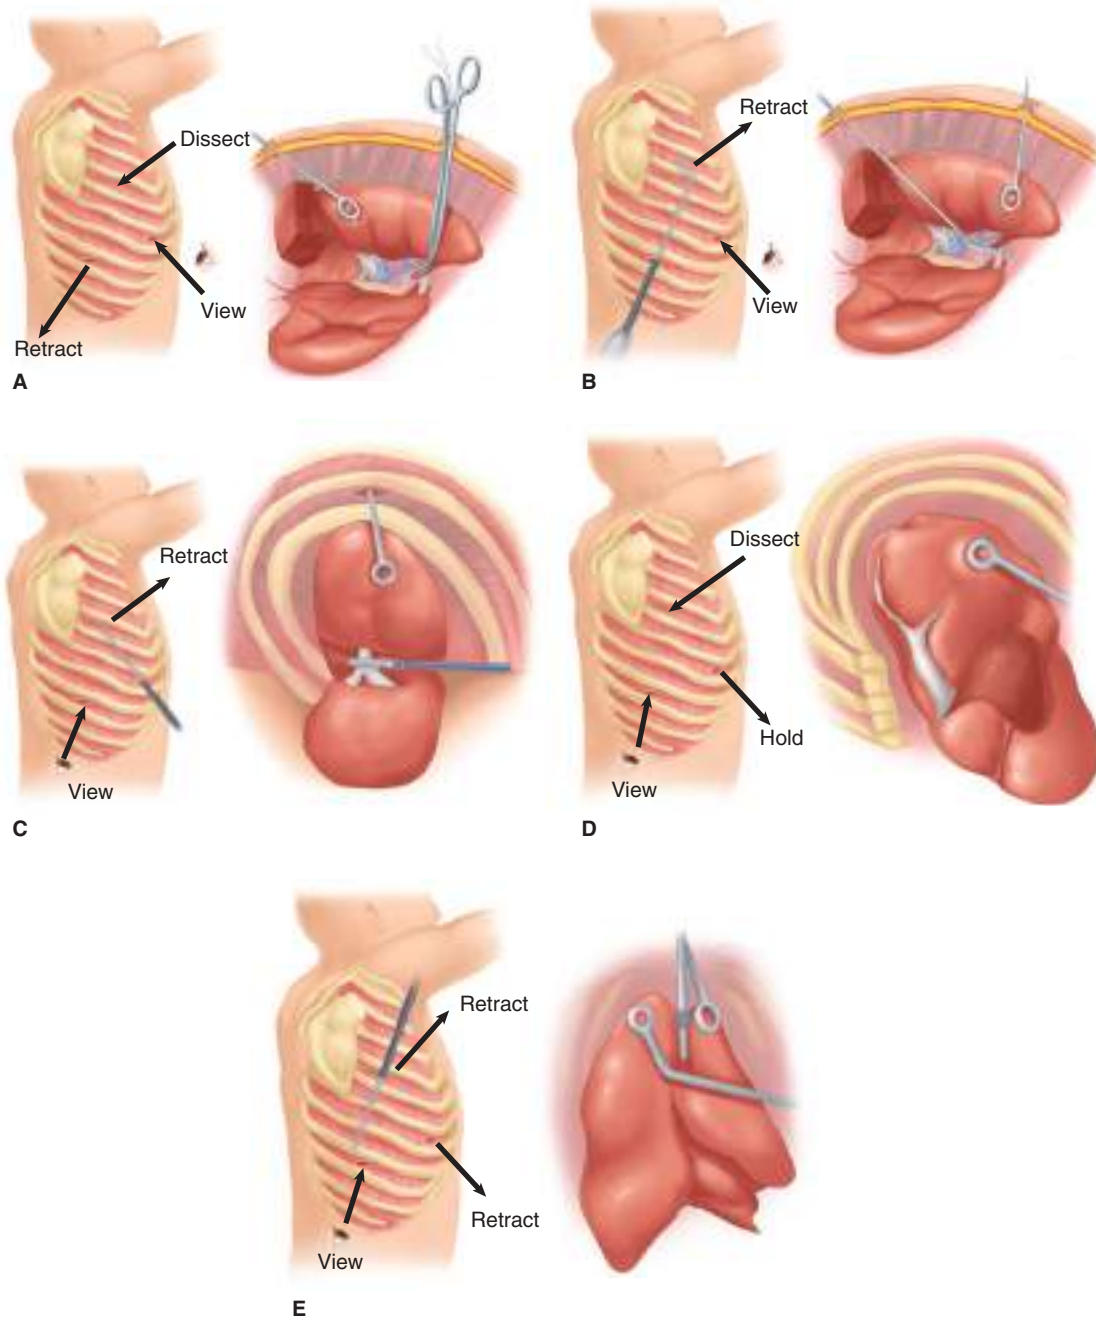

Figure 19-27. Selected video-assisted thoracic surgery lobectomy maneuvers. All the maneuvers are shown with the patient positioned in the left lateral decubitus position. The same maneuvers can be performed in mirror image for left-sided work. **A.** Medial viewing and inferior holding of lung to allow dissection through the access incision. Example shows dissection of the apical hilum. **B.** Medial viewing and access holding of lung to allow stapling of hilar structures from below. Example shows division of the apical pulmonary artery trunk to the right upper lobe (upper lobe branch of vein divided and reflected away). **C.** Standard viewing and use of working port to dissect and divide structures while lung is retracted through access incision. Example shows use of stapler to divide pulmonary artery to right lower lobe. **D.** Standard viewing and use of working port to retract lung and access incision to dissect structures. This method is commonly used to dissect the pulmonary artery in the major fissure. Example shows inferior pulmonary vein after the pulmonary ligament was divided using this maneuver. **E.** Standard viewing and use of access incision to deliver stapler to divide fissures. Example shows division of the posterior fissure between the right lower lobe and the upper lobe.

Figure 19-28. The posterolateral thoracotomy incision. **A.** Skin incision from the anterior axillary line to the lower extent of the scapula tip. **B** and **C.** Division of the latissimus dorsi and shoulder girdle musculature. **D.** The pleural cavity is entered after dividing the intercostal muscles along the lower margin of the interspace, taking care not to injure the neurovascular bundle lying below each rib.

robotic arms, except for one assistant port through which specimens can be removed and suctioning and stapling performed (in early models; the newest robotic models have robotic staplers, allowing the surgeon to have complete control of the entire operation).

Open Approaches to Thoracic Surgery. When a thoracoscopic approach is not possible, an open approach, most frequently the posterolateral thoracotomy, is used to gain access to the intrathoracic space.^{80,81} The posterolateral thoracotomy incision can be used for most pulmonary resections, esophageal operations, and operations in the posterior mediastinum and vertebral column (Fig. 19-28). The anterolateral thoracotomy has traditionally been used in trauma victims. This approach allows quick entry into the chest with the patient supine. In the face of hemodynamic instability, the lateral decubitus position significantly compromises control over the patient's cardiopulmonary system and resuscitation efforts, whereas the supine position allows the anesthesiologist full

access to the patient. A bilateral anterior thoracotomy incision with a transverse sternotomy ("clamshell" thoracotomy) is a standard operative approach to the heart and mediastinum in certain elective circumstances. It is the preferred incision for double-lung transplantation in many centers. A partial median sternotomy can also be added to an anterior thoracotomy ("trap-door" or "hemiclamsell" thoracotomy) for access to mediastinal structures. A hypesthetic nipple is a frequent complication of this approach. The median sternotomy incision allows exposure of anterior mediastinal structures and is principally used for cardiac operations. Although the surgeon has access to both pleural cavities, incision into the pleural cavity can be avoided if entry is unnecessary (Fig. 19-29).

Postoperative Care

Chest Tube Management. At the conclusion of most thoracic operations, the pleural cavity is drained with a chest tube(s). If the visceral pleura has not been violated and there is no concern

Figure 19-29. The median sternotomy incision. **A.** Skin incision from the suprasternal notch to the xiphoid process. **B.** Exposure of the pleural space. a. = artery; v. = vein.

for pneumo- or hemothorax (e.g., after VATS sympathectomy), a chest tube is unnecessary. After chest tube placement, the lung is reexpanded with positive-pressure ventilation. There are two reasons for the use of pleural tubes in this setting: first, the tube allows evacuation of air if an air leak is present; second, blood and pleural fluid can be drained, thereby preventing accumulation within the pleural space that would compromise the patient's respiratory status. The tube is removed when the air leak is resolved and when the volume of drainage decreases below an acceptable level over 24 hours.

Historically, many surgeons have somewhat arbitrarily required less than 150 mL of drainage volume over 24 hours prior to removing a chest tube to minimize risk of reaccumulation. The pleural lymphatics, however, can absorb up to 0.40 mL/kg per hour in a healthy individual, which may be as much as 500 mL over a 24-hour period. In fact, studies have shown that pleural tubes can be removed after VATS lobectomy or thoracotomy with 24-hour drainage volumes as high as 400 mL, without subsequent development of pleural effusions.⁸² It is our current practice to remove chest tubes with 24-hour outputs of 400 mL or less after lobectomy or lesser pulmonary resections. In settings where normal pleural fluid dynamics have been altered, such as malignant pleural effusion, pleural space infections or inflammation, and pleurodesis, strict adherence to

a volume requirement before tube removal is appropriate (typically 100 to 150 mL over 24 hours).

For operations involving lung resection or parenchymal injury, suction levels of -20 cm H₂O are routinely used to eradicate residual air spaces and to control postoperative parenchymal air leaks for the first 12 to 24 hours. The following day, however, the decision to continue suction or place the patient to water seal (off suction) must be made. Applying suction to an air leak has been shown to prolong the duration of the air leak and extend the time frame during which tube thoracostomy is needed.⁸³ The main guidelines for the continued use of suction if an air leak is present depend on the expansion of the remaining lung as determined by CXR. If the lung is well expanded, the chest tube can remain to water seal drainage. If an undrained pneumothorax is present on CXR, the chest tube and its attached tubing should be examined to ensure that the chest tube is patent and the attached tubing is not kinked or mechanically obstructed, such as occurs when the patient is lying on the tube. If the tube is a small caliber tube (pigtail catheter), it should be flushed with sterile saline through a three-way stopcock that has been cleaned with alcohol because these tubes tend to become clogged with fibrin. These catheters are also prone to kinking at the insertion site into the skin. Once the surgeon has confirmed that the chest tube is patent, the patient is asked to voluntarily cough or perform the Valsalva maneuver. This maneuver increases the intrathoracic pressure and will push air that is contained within the hemithorax out of the chest tube. During the voluntary cough, the fluid level in the water seal chamber should move up and down with the cough and with deep respiration, reflecting the pleural pressure changes occurring with these maneuvers. A stationary fluid level implies either a mechanical blockage (e.g., due to external tube compression or to a clot/debris within the tube) or pleurodesis. If bubbles pass through the water seal chamber, an air leak is presumed. If the leak is significant enough to induce atelectasis or collapse of the lung during use of water seal, suction should be used to achieve lung reexpansion.

Pain Control. Good pain control after intrathoracic procedures is critical; it permits the patient to actively clear and manage secretions and promotes ambulation and a feeling of well-being. The most common techniques of pain management are epidural, paravertebral, and intravenous. Epidural catheters are commonly used, although we prefer to use paravertebral catheters in our center. Epidural catheters should be inserted at about the T6 level, roughly at the level of the scapular tip. Lower placement risks inadequate pain control, and higher placement may provoke hand and arm numbness. Typically, combinations of fentanyl at 0.3 μ g/mL with either bupivacaine (0.125%) or ropivacaine (0.1%) are used. Ropivacaine has less cardiotoxicity than bupivacaine; thus, in the case of inadvertent intravenous injection, the potential for refractory complete heart block is significantly less with ropivacaine. Paravertebral blocks can be placed using the same epidural catheter kit 2.5 cm lateral to the spinous process at T4 to T6. Combinations of narcotic and topical analgesia are then infused as with the epidural catheter.

When properly placed, a well-managed epidural can provide outstanding pain control without significant systemic sedation.⁸⁴ Thoracic epidurals do not commonly cause urinary retention, although a low thoracic epidural may block the sensory fibers to the bladder. Motor function, however, remains intact. In some patients who are having difficulty voiding, it

may be possible to avoid Foley catheterization by simply reminding the patient to void on a regular basis. In male patients with voiding difficulty prior to surgery, urinary catheterization may be required. In addition, the use of local anesthetics may cause sympathetic outflow blockade, leading to vasodilation and hypotension often requiring intravenous vasoconstrictors (an α -agonist such as phenylephrine) and/or fluid administration. In such circumstances, fluid administration for hypotension may be undesirable in pulmonary surgery patients, particularly after pneumonectomy. Paravertebral catheters provide equivalent pain control with less effect on hemodynamics.⁸⁵ Recently, liposomal bupivacaine was introduced and has become the standard approach to pain management after thoracic surgery in several centers. The formulation allows for slow-release of bupivacaine for up to 72 hours after injection. Injected directly into the intercostal spaces immediately prior to chest closure, the formulation has shown great promise in several retrospective reports, with randomized trials not yet completed. One limiting factor in use of the formulation is the cost; future trials are needed, with cost-analysis, to determine whether the benefits in pain, reduction in narcotic use, shorter hospital stay and possibly decreased pulmonary complications justify the cost.

Alternatively, intravenous narcotics via patient-controlled analgesia can be used, often in conjunction with ketorolac, gabapentin, and intravenous Tylenol. Dosing must be titrated to balance the degree of pain relief with the degree of sedation. Oversedated patients are as ominous as patients without adequate pain control because of the significant risk of secretion retention, atelectasis/pneumonia, and pulmonary aspiration, especially in elderly patients who should be carefully assessed for aspiration risk when ordered for dietary advancement. Proper pain control with intravenous narcotics requires a carefully regulated balance of pain relief and sedation to maximize the benefits of pain control while minimizing these very real and potentially life-threatening complications.

Whether on epidural, paravertebral, or intravenous pain control, the patient is typically transitioned to oral pain medication on the third or fourth postoperative day. During both the parenteral and oral phase of pain management, a standardized regimen of stool softeners and laxatives is advisable in order to prevent severe constipation.

Respiratory Care. The best respiratory care is achieved when the patient is able to deliver an effective cough to clear secretions and results from the commitment and proper training of all involved healthcare providers. The process begins preoperatively, with clear instructions on using pillows (or other support techniques) over the wound and then applying pressure.

Postoperatively, proper pain control without oversedation (as outlined earlier) is essential. Daily morning rounds should include a careful assessment of the patient's pulmonary status, reminders to the patient and family about the importance of coughing and deep breathing, including use of adjunctive respiratory equipment if ordered, and mobilization of the patient. Early transition to a chair and to ambulation is the best respiratory therapy and should be strongly encouraged. When available, physical and/or cardiopulmonary rehabilitation services are vital additional members of the care team.

Postoperative Complications

Postoperative complications after pulmonary resection range from minor to life-threatening. Strict attention to volume status, early and aggressive pulmonary toilet, and good pain

control can reduce the risk of most complications, but does not completely eliminate them, even in centers of excellence. The most devastating complication after pulmonary resection is postpneumonectomy pulmonary edema, which occurs in 1% to 5% of patients undergoing pneumonectomy and more often after right compared to left pneumonectomy. Clinically, symptoms of respiratory distress manifest hours to days after surgery. Radiographically, diffuse interstitial infiltration or frank alveolar edema is seen. The pathophysiologic causes are related increased permeability and filtration pressure and decreased lymphatic drainage from the affected lung. Judicious use of intravenous fluids perioperatively, including use of vasopressors rather than fluid boluses for hypotension intra- and postoperatively, is critical to minimizing the risk of this syndrome. Treatment consists of ventilatory support, fluid restriction, and diuretics. Extracorporeal membrane oxygenation may be life-saving in centers where this option is available. The syndrome reportedly has a nearly 100% mortality rate despite aggressive therapy.

Other postoperative complications include air leak and bronchopleural fistula. Although these are two very different problems, distinguishing between them may be difficult. Postoperative air leaks are common after pulmonary resection, particularly in patients with emphysematous lung, because the fibrosis and destroyed blood supply impairs healing of surface injuries. Prolonged air leaks (i.e., those lasting >5 days) may be treated by diminishing or discontinuing suction (if used), by continuing chest drainage, or by instilling a pleurodesis agent, usually doxycycline or talcum powder, which will cause pleurodesis of the lung within the chest cavity and minimize the possible collapse of the lung due to persistent air leak. This is useful only in patients in whom full lung expansion is achieved, either with suction or on water seal, as patients with a persistent pneumothorax on CXR will not have adequate lung-to-parietal pleural apposition to achieve adequate pleurodesis.

If the leak is moderate to large, a high index of suspicion for bronchopleural fistula from the resected bronchial stump should be maintained, particularly if the patient is immunocompromised or had induction chemo- and/or radiation therapy. If suspected, flexible bronchoscopy is performed to evaluate the bronchial stump. Management options include continued prolonged chest tube drainage, reoperation, and reclosure (with stump reinforcement with intercostal or pedicled serratus muscle flap). If the fistula is very small (<4 mm), bronchoscopic fibrin glue application has been used successfully to seal the hole in some patients. Patients often have concomitant empyema, and open drainage may be necessary.

Spontaneous Pneumothorax

Spontaneous pneumothorax is secondary to intrinsic abnormalities of the lung and can be classified as primary and secondary. Primary spontaneous pneumothorax is defined as a spontaneous pneumothorax without underlying lung disease. The most common cause is rupture of an apical subpleural bleb. The cause of these blebs is unknown, but they occur more frequently in smokers and males, and they tend to predominate in young postadolescent males with a tall thin body habitus. Treatment is generally chest tube insertion with water seal. If a leak is present and persists for greater than 3 days, thorascopic management (i.e., bleb resection with pleurodesis by talc or pleural abrasion) is performed. Recurrences or complete lung collapse with the first episode are generally indications for thorascopic

intervention.⁸⁶ Additional indications for intervention on the first episode include occupational hazards such as air travel, deep-sea diving, or travel to remote locations. CT findings of multiple small bullae or a large bleb are associated with an increased risk of recurrent pneumothorax.⁸⁷ Many surgeons are now using screening CT scan to recommend VATS bleb resection with pleurodesis for first-episode spontaneous pneumothorax.

Secondary spontaneous pneumothorax occurs in the setting of underlying lung disease, such as emphysema (rupture of a bleb or bulla), cystic fibrosis, acquired immunodeficiency syndrome (AIDS), metastatic cancer (especially sarcoma), asthma, lung abscess, and occasionally lung cancer. Catamenial pneumothorax, a rare but interesting cause of spontaneous pneumothorax in women in their second and third decades, occurs within 72 hours of the onset of menses and is possibility related to endometriosis. Management of pneumothorax in these circumstances is similar to that of primary spontaneous pneumothorax in that drainage and lung reexpansion are required. Additional therapy, however, is often tied to therapy of the specific disease process and may involve lung resection, thoroscopic pleurectomy, or talc pleurodesis.

Pulmonary Infections

Lung Abscess. A *lung abscess* is a localized area of pulmonary parenchymal necrosis caused by an infectious organism; tissue destruction results in a solitary or dominant cavity measuring at least 2 cm in diameter. Less often, there may be multiple, smaller cavities (<2 cm). In that case, the infection is typically referred to as a necrotizing pneumonia. An abscess that is present for more than 6 weeks is considered chronic.

Based on the etiology (Table 19-17), lung abscesses are further classified as primary or secondary. A primary lung abscess occurs, for example, in immunocompromised patients, as a result of highly virulent organisms inciting a necrotizing pulmonary infection, or in patients who have a predisposition to aspirate oropharyngeal or gastrointestinal secretions. A secondary lung abscess occurs in patients with an underlying condition such as a partial bronchial obstruction, a lung infarct, or adjacent suppurative infections (subphrenic or hepatic abscesses).⁸⁸

Pathogenesis Lung abscesses result when necrotizing microorganisms infect the lower respiratory tract via inhalation of aerosolized particles, aspiration of oropharyngeal secretions, or hematogenous spread from distant sites. Direct extension from a contiguous site is less frequent. Most primary lung abscesses are suppurative bacterial infections secondary to aspiration. Risk factors for pulmonary aspiration include advanced age, conditions of impaired consciousness, suppressed cough reflex, dysfunctional esophageal motility, laryngopharyngeal reflux disease, and centrally acting neurologic diseases (e.g., stroke). At the time of aspiration, the composition of the oropharyngeal flora determines the etiologic organisms. With increasing use of proton pump inhibitors to suppress acid secretion in the stomach, the oropharyngeal flora has shifted, and the risk of developing bacterial lung infections after an aspiration event has increased.⁸⁹ Secondary lung abscesses occur most often distal to an obstructing bronchial carcinoma. Infected cysts or bullae are not considered true abscesses.

Microbiology Normal oropharyngeal secretions contain many more *Streptococcus* species and more anaerobes (approximately 1×10^8 organisms/mL) than aerobes (approximately 1×10^7 organisms/mL). Pneumonia that follows from

Table 19-17

Causes of lung abscess

- I. Primary
 - A. Necrotizing pneumonia
 1. *Staphylococcus aureus*, *Klebsiella*, *Pseudomonas*, *Mycobacterium*
 2. *Bacteroides*, *Fusobacterium*, *Actinomyces*
 3. *Entamoeba*, *Echinococcus*
 - B. Aspiration pneumonia
 1. Anesthesia
 2. Stroke
 3. Drugs or alcohol
 - C. Esophageal disease
 1. Achalasia, Zenker's diverticulum, gastroesophageal reflux
 - D. Immunodeficiency
 1. Cancer (and chemotherapy)
 2. Diabetes
 3. Organ transplantation
 4. Steroid therapy
 5. Malnutrition
- II. Secondary
 - A. Bronchial obstruction
 1. Neoplasm
 2. Foreign body
 - B. Systemic sepsis
 1. Septic pulmonary emboli
 2. Seeding of pulmonary infarct
 - C. Complication of pulmonary trauma
 1. Infection of hematoma or contusion
 2. Contaminated foreign body or penetrating injury
 - D. Direct extension from extraparenchymal infection
 1. Pleural empyema
 2. Mediastinal, hepatic, subphrenic abscess

aspiration, with or without abscess development, is typically polymicrobial. An average of two to four isolates present in large numbers have been cultured from lung abscesses sampled percutaneously. Overall, at least 50% of these infections are caused by purely anaerobic bacteria, 25% are caused by mixed aerobes and anaerobes, and 25% or fewer are caused by aerobes only. In nosocomial pneumonia, 60% to 70% of the organisms are gram-negative bacteria. Immunosuppressed patients may develop abscesses because of the usual pathogens as well as less virulent and opportunistic organisms such as *Salmonella* species, *Legionella* species, *Pneumocystis carinii*, atypical mycobacteria, and fungi.

Clinical Features and Diagnosis The typical presentation may include productive cough, fever (>38.9°C), chills, leukocytosis (>15,000 cells/mm³), weight loss, fatigue, malaise, pleuritic chest pain, and dyspnea. Lung abscesses may also present in a more indolent fashion, with weeks to months of cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis, and anemia. After aspiration pneumonia, 1 to 2 weeks typically elapse before cavitation occurs; 40% to 75% of such patients produce putrid, foul-smelling sputum. Severe complications

such as massive hemoptysis, endobronchial spread to other portions of the lungs, rupture into the pleural space and development of pyopneumothorax, or septic shock and respiratory failure are rare in the modern antibiotic era. The mortality rate is about 5% to 10%, except in the presence of immunosuppression, where rates range from 9% to 28%.

The CXR is the primary tool for diagnosing a lung abscess (Fig. 19-30). Its distinguishing characteristic is a density or mass with a relatively thin-walled cavity. An air-fluid level observed within the abscess indicates communication with the

tracheobronchial tree. CT scan of the chest clarifies the diagnosis when CXR is equivocal and identifies endobronchial obstruction and/or an associated mass and other pathologic anomalies. A cavitating lung carcinoma is frequently mistaken for a lung abscess. Differential diagnosis also includes loculated or interlobar empyema, infected lung cysts or bullae, tuberculosis, bronchiectasis, fungal infections, and noninfectious inflammatory conditions (e.g., Wegener's granulomatosis).

Ideally, the specific etiologic organism is identified before antibiotic administration. Bronchoscopy, which is essential to

A

B

C

Figure 19-30. Lung abscess resulting from emesis and aspiration after an alcoholic binge. **A.** Chest X-ray showing an abscess cavity in the left upper lobe. **B.** A coronal tomogram highlights the thin wall of the abscess. **C.** Healing of the abscess cavity after 4 weeks of antibiotic therapy and postural drainage.

rule out endobronchial obstruction due to tumor or foreign body, is ideal for obtaining uncontaminated cultures using bronchoalveolar lavage. Culture samples can also be obtained by percutaneous, transthoracic FNA under ultrasound or CT guidance. Routine sputum cultures are often of limited usefulness because of contamination with upper respiratory tract flora.

Actinomycosis and nocardiosis, although rare, are particularly virulent infections associated with lung abscess. Diagnosis can be difficult.⁹⁰ Both frequently masquerade as other clinical syndromes; thus, it is important for the surgeon to keep these bacteria in mind when considering the differential diagnosis for cavitary lung lesions. *Actinomyces*, a normal oropharyngeal bacterium, causes extensive pulmonary damage. Actinomycosis lung infection typically begins as acute pneumonitis after pulmonary aspiration. The symptoms mimic pulmonary tuberculosis, including chronic cough, night sweats, weight loss, and hemoptysis.

Ongoing infection leads to chronic inflammation and fibrosis; cavitation occurs due to destruction of the pulmonary tissues. Without treatment, the infection continues to destroy surrounding structures, resulting in fistula formation to adjacent structures, including the adjacent lung, interlobar fissures, pleural space, chest wall, and mediastinum. *Actinomyces israelii* is the most common of the species to cause disease. Nocardiosis is also a rare opportunistic infection that usually occurs in an immunocompromised host (HIV or cancer patients) and causes both local and systemic suppurative infections. The most common site is pulmonary, caused by *Nocardia asteroides* in 90% of cases. Infection is slowly progressive, with weight loss, fatigue, cough, and hemoptysis. An acute pulmonary infection is common, with necrotizing pneumonia and cavitation or slowly enlarging pulmonary nodule. In some cases, empyema also develops.

Management of Lung Abscess Systemic antibiotics directed against the causative organism represent the mainstay of therapy. The duration of antimicrobial therapy varies from 3 to 12 weeks for necrotizing pneumonia and lung abscess. It is likely best to treat until the cavity is resolved or until serial radiographs show significant improvement. Parenteral therapy is generally used until the patient is afebrile and able to demonstrate consistent enteral intake. Oral therapy can then be used to complete the course of therapy. For community-acquired infections secondary to aspiration, likely pathogens are oropharyngeal streptococci and anaerobes. Penicillin G, ampicillin, and amoxicillin are the main therapeutic agents, but a β -lactamase inhibitor or metronidazole should be added to cover the increasing prevalence of gram-negative anaerobes that produce β -lactamase. Clindamycin is also a primary therapeutic agent. For hospital-acquired infections, *Staphylococcus aureus* and aerobic gram-negative bacilli are common organisms of the oropharyngeal flora. Piperacillin with a β -lactamase inhibitor (or equivalent alternatives) provide better coverage of likely pathogens.

Surgical drainage of lung abscesses is uncommon since drainage usually occurs spontaneously via the tracheobronchial tree. Indications for intervention are listed in Table 19-18. Drainage and resection may be required for actinomycosis and nocardiosis; diagnosis is often delayed because the bacteria are difficult to culture; invasion of the infection into surrounding structures is, therefore, common. Once identified, long-term antibiotics (months to years) are typically required along with drainage, debridement, and resection as needed. While penicillin derivatives are effective against most *Actinomyces* species,

Table 19-18

Indications for surgical drainage procedures for lung abscesses

1. Failure of medical therapy
2. Abscess under tension
3. Abscess increasing in size during appropriate treatment
4. Contralateral lung contamination
5. Abscess >4–6 cm in diameter
6. Necrotizing infection with multiple abscesses, hemoptysis, abscess rupture, or pyopneumothorax
7. Inability to exclude a cavitating carcinoma

the infections are typically polymicrobial, and broad-spectrum parenteral antibiotics may be required. *Nocardia* species, in contrast, are highly variable; specific identification of the infecting species with antibiotic sensitivities is needed to direct appropriate therapy. Evaluation for malignant spread, particularly to the brain, is also required in the management of nocardiosis, as systemic dissemination occurs early and frequently.

External drainage may be accomplished with tube thoracostomy, percutaneous drainage, or surgical cavernostomy. The choice between tube thoracostomy versus radiographically guided catheter placement depends on the treating physician's preference and institutional technical expertise in placing image-guided thoracostomy tubes. Surgical resection is required in fewer than 10% of lung abscess patients. Lobectomy is the preferred intervention for bleeding from a lung abscess or pyopneumothorax. An important intraoperative consideration is to protect the contralateral lung with a double-lumen tube, bronchial blocker, or contralateral main stem intubation. Surgical treatment has a 90% success rate, with associated mortality of 1% to 13%.

Bronchiectasis. Bronchiectasis is defined as a pathologic and permanent dilation of bronchi with bronchial wall thickening. This condition may be localized to certain bronchial segments, or it may be diffuse throughout the bronchial tree, typically affecting the medium-sized airways. Overall, this is a rare clinical entity in the United States with a prevalence of less than 1 in 10,000, although the incidence has increased in recent years and noncystic fibrosis-related bronchiectasis is now thought to affect 27.5 out of every 10,000 persons over age 75.

Pathogenesis Development of bronchiectasis can be attributed to either congenital or acquired causes. The principal congenital diseases that lead to bronchiectasis include cystic fibrosis, primary ciliary dyskinesia, and immunoglobulin deficiencies (e.g., selective IgA deficiency). Congenital causes commonly produce a diffuse pattern of bronchial involvement. Acquired causes are categorized broadly as infectious and inflammatory. Bronchial obstruction from cancer, inhaled objects, extrinsic airway compression, or inspissated sputum promotes localized infection and subsequent medium airway destruction. Diffuse pneumonic processes from pathogens including necrotizing bacterial pneumonia, pertussis and measles pneumonia, severe influenza, or varicella pneumonia can lead to widespread bronchiectasis. Chronic granulomatous disease, immunodeficiency disorders, and hypersensitivity disorders can also lead to diffuse bronchiectasis.

Noninfectious causes of bronchiectasis include inhalation of toxic gases such as ammonia, which results in severe

and destructive airway inflammatory responses. Allergic bronchopulmonary aspergillosis, Sjögren's syndrome, and α 1-antitrypsin deficiency are some additional examples of presumed immunologic disorders that may be accompanied by bronchiectasis.

In addition, recent studies have suggested an association between chronic gastroesophageal reflux disease, acid suppression, and nontuberculous mycobacterial infection with bronchiectasis.^{91,92} This interaction is thought to be related to chronic aspiration of colonized gastric secretions in the setting of acid suppression; while not proven to be causative, these findings suggest a role for gastroesophageal reflux disease in the pathogenesis of bronchiectasis.

The process shared by all causes of bronchiectasis is impairment of airway defenses or deficits in immunologic mechanisms, which permit bacterial colonization and chronic infection. Common organisms include *Haemophilus* species (55%), *Pseudomonas* species (26%), and *Streptococcus pneumoniae* (12%).⁹³ Both the bacterial organisms and the inflammatory cells recruited to thwart the bacteria elaborate proteolytic and oxidative molecules, which progressively destroy the muscular and elastic components of the airway walls; those components are then replaced by fibrous tissue. Thus, chronic airway inflammation is the essential pathologic feature of bronchiectasis. The dilated airways are usually filled with thick purulent material; more distal airways are often occluded by secretions or obliterated by fibrous tissue. Bronchial wall vascularity increases, bronchial arteries become hypertrophied, and abnormal anastomoses form between the bronchial and pulmonary arterial circulation.

There are three principal types of bronchiectasis, based on pathologic morphology: cylindrical—uniformly dilated bronchi; varicose—an irregular or beaded pattern of dilated bronchi; and saccular (cystic)—peripheral balloon-type bronchial dilation. The saccular type is the most common after bronchial obstruction or infection (Fig. 19-31).

Clinical Manifestations and Diagnosis Typical symptoms are a daily persistent cough and purulent sputum production; the quantity of daily sputum production (10 mL to >150 mL) correlates with disease extent and severity. Other patients may appear asymptomatic or have a dry nonproductive cough (“dry bronchiectasis”). These patients are prone to have involvement of the upper lobes. The clinical course is characterized by progressive

symptoms and respiratory impairment. Increasing resting and exertional dyspnea are the result of progressive airway obstruction. Acute exacerbations may be triggered by viral or bacterial pathogens. Bleeding attributable to chronically inflamed, friable airway mucosa causes increasingly more frequent hemoptysis with disease progression. Massive bleeding may result from erosion of the hypertrophied bronchial arteries.

Both mild and severe forms of bronchiectasis are readily demonstrated with chest CT scanning because it provides a highly detailed, cross-sectional view of bronchial architecture. CXRs, although less sensitive, may reveal characteristic signs of bronchiectasis such as lung hyperinflation, bronchiectatic cysts, and dilated, thick-walled bronchi forming train track–like patterns radiating from the lung hila. Sputum culture may identify characteristic pathogens.

Sputum acid-fast bacillus smears/cultures should be performed to evaluate for nontuberculous mycobacteria, which is common in this setting. Spirometry provides assessment of the severity of airway obstruction and can be followed to track the course of disease.

Management of Bronchiectasis Standard therapy includes optimizing airway clearance, use of bronchodilators to reverse any airflow limitation, and correction of reversible underlying causes whenever possible.⁹⁴ Chest physiotherapy based on vibration, percussion, and postural drainage is widely accepted, although randomized trials demonstrating efficacy are lacking. Acute exacerbations should be treated with a 2- to 3-week course of broad-spectrum intravenous antibiotics tailored to culture and sensitivity profiles, followed by an oral regimen; this will result in a longer-lasting remission.

Macrolide antibiotics have been shown to decrease sputum production, inhibit cytokine release, and inhibit neutrophil adhesion and formation of reactive oxygen species. They also inhibit migration of *Pseudomonas*, disrupt biofilm, and prevent release of virulence factors.⁹⁵ While macrolide therapy does appear to be efficacious, it is important to remember that macrolides have significant activity against nontuberculous mycobacteria, and widespread prophylactic use for patients with bronchiectasis may lead to multidrug-resistant nontuberculous mycobacterial species. It has also been suggested that inhaled antibiotics, such as tobramycin and colistin, improve rates of bacterial clearance and slow the decline in pulmonary function associated with bronchiectasis. Meta-analysis of 12 randomized trials involving 1154 patients showed efficacy of inhaled antibiotics compared to controls, but did not reduce risk of acute exacerbation. Quality of life, likewise, was not improved and antibiotic-resistant *Pseudomonas* rates were similar. Importantly, inhaled antibiotics were associated with a statistically significant reduction in forced expiratory volume in 1 second measures over time.^{96,97}

In addition to antibiotics, daily nebulized hypertonic saline appears to be effective. A recent randomized crossover study comparing lung function and quality of life has shown that 7% normal saline, compared to isotonic saline, results in a statistically significant 15% increase in FEV₁ and an 11% increase in forced vital capacity (compared to 1.8% and 0.7%, respectively, with isotonic saline). Antibiotic use and emergency room utilization were significantly decreased; from this, hypertonic saline appears to be a reasonable adjunct to maintaining quality of life and decreasing exacerbations by reducing sputum volume, improving mucociliary clearance, and slowing the decline in lung function.⁹⁸ Studies supporting mucolytics such as DNase and Mucomyst for non-cystic fibrosis bronchiectasis have

Figure 19-31. Multiple cystic-type bronchiectatic cavities can be seen on a cut section of right lower lobe lung.

shown either no change or a worsening of pulmonary status and require further study in the non-cystic fibrosis population.

Surgical resection of a localized bronchiectatic segment or lobe, preserving as much functional lung as possible, may benefit patients with refractory symptoms while on maximal medical therapy. Multifocal disease must be excluded before any attempt at surgery; any uncorrectable predisposing factor (e.g., ciliary dyskinesia) must also be excluded. Patients with end-stage lung disease from bronchiectasis may be potential candidates for a bilateral lung transplant. Surgical resection is also indicated in patients with significant hemoptysis, although bronchial artery embolization is the preferred first option. Antireflux surgery may also prove beneficial in patients with chronic aspiration, but further studies are required. It is particularly important to recognize that antireflux surgery in patients with severe underlying pulmonary dysfunction has higher risk for perioperative adverse outcomes than in the general population. It should be undertaken only by very experienced surgeons with direct involvement of the pulmonary medicine physicians to minimize postoperative pulmonary compromise.

Mycobacterial Infections

Epidemiology Tuberculosis is a widespread problem that affects nearly one-third of the world's population. It is the ninth leading cause of death worldwide and the leading infectious cause of death. The rate of death from tuberculosis has declined, from 1.7 million in 2000 to 1.3 million among HIV-negative people in 2016. There were 6.3 million new cases of tuberculosis worldwide in 2016 according to the World Health Organization (WHO); 56% are in the countries of India, Indonesia, China, the Philippines, and Pakistan. Treatment success rate was 83%. Only 9257 new cases were reported to the WHO in the United States in 2016. HIV infection is the strongest risk factor for developing active tuberculosis. The elderly, minorities, and recent immigrants are the most common populations to have clinical manifestations of infection, yet no age group, sex, or race is exempt from infection. In most large urban centers, reported cases of tuberculosis are more numerous among the homeless, prisoners, and drug-addicted populations. Immunocompromised patients additionally contribute to an increased incidence of tuberculosis infection, often developing unusual systemic as well as pulmonary manifestations.⁹⁹ As compared with past decades, presently surgical intervention is required more frequently in patients with multidrug-resistant or rifampicin-resistant (but isoniazid-susceptible) tuberculosis organisms (MDR/RR-TB) who do not respond to medical treatment and in selected patients with nontuberculous mycobacterial infections (NTM).

Microbiology Mycobacterial species are obligate aerobes. They are primarily intracellular parasites with slow rates of growth. Their defining characteristic is the property of acid-fastness, which is the ability to withstand decolorization by an acid-alcohol mixture after being stained. *Mycobacterium tuberculosis* is the highly virulent bacillus of this species that produces invasive infection among humans, principally pulmonary tuberculosis.¹⁰⁰ Infections with *M tuberculosis* are primary when they are the first infection in a previously unsensitized host and secondary or postprimary when reactivation of a previous infection occurs.

Because of improper application of antimycobacterial drugs and multifactorial interactions, MDR-TB organisms, defined by their resistance to at least two of the first-line antimycobacterial drugs (isoniazid and rifampin), and rifampicin-resistant (but isoniazid-susceptible) (RR-TB), have emerged.

According to the WHO Global Tuberculosis Report 2017, in 2014, there were 108 reported cases of TB from MDR/RR-TB organisms, with 78% of cases successfully treated. In addition, there is another rare variant termed *extensively drug-resistant tuberculosis (XDR-TB)*. These organisms are resistant to isoniazid and rifampin and have also developed resistance to either fluoroquinolones and injectable second-line drugs (e.g., capreomycin, amikacin, kanamycin), the two other classes of medications in the MDR-TB treatment regimen. In 2014, there were 109,680 MDRTB cases globally, with 6777 (6.2%) extensively drug resistant. Successful treatment was achieved in 54% of MDRTB and only 30% of XDR-TB. In 2016, it was estimated that MDR/RR was the responsible organism for more than 4% of new cases and nearly 20% of previously treated cases.

The more important NTM organisms include *Mycobacterium kansasii*, *M avium* and *M intracellulare* complex (MAC), and *M fortuitum*. The highest incidence of *M kansasii* infection is in Midwestern U.S. cities among middle-aged men from good socioeconomic surroundings. MAC organisms are important infections in elderly and immunocompromised patient groups. *M fortuitum* infections are common complications of underlying severe debilitating disease. None of these organisms are as contagious as *M tuberculosis*.

Pathogenesis and Pathology The main route of transmission is via airborne inhalation of viable mycobacteria. Three stages of primary infection have been described. In the first stage, alveolar macrophages become infected through ingesting the bacilli. In the second stage, from days 7 to 21, the patient typically remains asymptomatic while the bacteria multiply within the infected macrophages. The third stage is characterized by the onset of cell-mediated immunity (CD4⁺ helper T cells) and delayed-type hypersensitivity. Activated macrophages acquire an increased capacity for bacterial killing. Macrophage death increases, resulting in the formation of a granuloma, the characteristic lesion found on pathologic examination.

Tuberculous granulomas are composed of blood-derived macrophages, degenerating macrophages or epithelioid cells, and multinucleated giant cells (fused macrophages with nuclei around the periphery; also known as Langerhans cells). The low oxygen content of this environment inhibits macrophage function and bacillary growth, with subsequent central caseation as macrophage death occurs. A Ghon complex is a single, small lung lesion that is often the only remaining trace of a primary infection. The primary infection is usually located in the peripheral portion of the middle zone of the lungs.

Reactivation tuberculosis may occur after hydrolytic enzymes liquefy the caseum. Typically, the apical and posterior segments of the upper lobes and the superior segments of the lower lobes are involved. Edema, hemorrhage, and mononuclear cell infiltration are also present. The tuberculous cavity may become secondarily infected with other bacteria, fungi, or yeasts, all of which may contribute to enhanced tissue destruction.

The pathologic changes caused by NTM organisms are similar to those produced by *M tuberculosis*. *M intracellulare* complex infections commonly occur, not only in immunocompromised patients but also in patients with previously damaged lungs. Caseous necrosis is uncommon and is characterized by clusters of tissue macrophages filled with mycobacteria. It has a poor granulomatous response and confinement of immune cell infiltration to the interstitium and alveolar walls. Cavitory disease is infrequent, although nodules may be noted.

Clinical Presentation and Diagnosis The clinical course of infection and the presentation of symptoms are influenced by many factors, including the site of primary infection, the stage of disease, and the degree of cell-mediated immunity. About 80% to 90% of tuberculosis patients present with clinical disease in the lungs. In 85% to 90% of these patients, involution and healing occur, leading to a dormant phase that may last a lifetime. The only evidence of tuberculosis infection may be a positive skin reaction to tuberculin challenge or a Ghon complex observed on CXR. Within the first 2 years of primary infection, reactivation may occur in up to 10% to 15% of infected patients. In 80%, reactivation occurs in the lungs; other reactivation sites include the lymph nodes, pleura, and the musculoskeletal system.

After primary infection, pulmonary tuberculosis is frequently asymptomatic. Systemic symptoms of low-grade fever, malaise, and weight loss are subtle and may go unnoticed. A productive cough may develop, usually after tubercle cavitation. Many radiographic patterns can be identified at this stage, including local exudative lesions, local fibrotic lesions, cavitation, bronchial wall involvement, acute tuberculous pneumonia, bronchiectasis, bronchostenosis, and tuberculous granulomas. Hemoptysis often develops from complications of disease such as bronchiectasis or erosion into vascular malformations associated with cavitation.

Extrapulmonary involvement is due to hematogenous or lymphatic spread from pulmonary lesions. Virtually any organ can become infected, giving rise to the protean manifestations of tuberculosis. The pleura, chest wall, and mediastinal organs may all be involved. More than one-third of immunocompromised patients have disseminated disease, with hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

The definitive diagnosis of tuberculosis requires identification of the mycobacterium in a patient's bodily fluids or involved tissues. Skin testing using purified protein derivative is important for epidemiologic purposes and can help exclude infection in uncomplicated cases. For pulmonary tuberculosis, sputum examination is inexpensive and has a high diagnostic yield.

Bronchoscopy with alveolar lavage may also be a useful diagnostic adjunct and has high diagnostic accuracy. Chest CT scan can delineate the extent of parenchymal disease.

Management Medical therapy is the primary treatment of pulmonary tuberculosis and is often initiated before a mycobacterial pathogen is definitively identified. Combinations of two or more drugs are routinely used in order to minimize resistance, which inevitably develops with only single-agent therapy. A current treatment algorithm is outlined in Fig. 19-32. Generally, therapy lasts about 26 weeks (2 months intensive therapy followed by 4 months continuation therapy). A 7-month continuation phase should be considered for patients with cavitary pulmonary TB who remain positive on sputum culture after the 2-month intensive therapy, those patients who did not receive pyrazinamide during the intensive phase, HIV-positive patients who did not receive concomitant antiretroviral therapy, and patients treated with INH and rifampentine once weekly (not recommended) who have persistent positive sputum after 2 months of intensive therapy.

In the United States, surgical intervention is most often required in order to treat patients with MDR/RR-TB organisms whose lungs have been destroyed and who have persistent thick-walled cavitation.¹⁰¹ The indications for surgery

related to mycobacterial pulmonary infections are presented in Table 19-19. The governing principle of mycobacterial surgery is to remove all gross disease while preserving any uninvolved lung tissue. Scattered nodular disease may be left intact, given its low mycobacterial burden. Antimycobacterial medications should be given preoperatively (for about 3 months) and continued postoperatively for 12 to 24 months. Overall, more than 90% of patients who were deemed good surgical candidates are cured when appropriate medical and surgical therapy is used.

Pulmonary Fungal Infections. The incidence of fungal infections has increased significantly, with many new opportunistic fungi emerging. This increase is attributed to the growing population of immunocompromised patients (e.g., organ transplant recipients, cancer patients undergoing chemotherapy, HIV patients, and young and elderly patients) who are more likely to become infected with fungi.¹⁰² Clinically significant examples include species of *Aspergillus*, *Cryptococcus*, *Candida*, and *Mucor*. Other at-risk patient populations include those who are malnourished, severely debilitated, or diabetic or who have hematologic disorders.

Patients receiving high-dose, intensive antibiotic therapies are also susceptible. There are, however, some fungi that are primary or true pathogens, able to cause infections in otherwise healthy patients. Some endemic examples in the United States include species of *Histoplasma*, *Coccidioides*, and *Blastomyces*.¹⁰³

Direct identification of the organism in body exudates or tissues, preferably as growth in culture, provides definitive diagnosis. Serologic testing to identify mycotic-specific antibodies may also be useful. Several new classes of antifungal agents have proven effective against many life-threatening fungi and are less toxic than older agents. In addition, thoracic surgery may be a useful therapeutic adjunct for patients with pulmonary mycoses.

Aspergillosis The genus *Aspergillus* comprises over 150 species and is the most common cause of mortality due to invasive mycoses in the United States. It is typically acute in onset and life-threatening and occurs in the setting of neutropenia, chronic steroid therapy, or cytotoxic chemotherapy. It can also occur in the general intensive care unit population of critically ill patients, including patients with underlying chronic obstructive pulmonary disease (COPD), postoperative patients, patients with cirrhosis or alcoholism, and postinfluenza patients, without any of these factors present. The species most commonly responsible for clinical disease include *A fumigatus*, *A flavus*, *A niger*, and *A terreus*. *Aspergillus* is a saprophytic, filamentous fungus with septate hyphae. Spores (2.5 to 3 μm in diameter) are released and easily inhaled by susceptible patients; because the spores are microns in size, they are able to reach the distal bronchi and alveoli.

Diagnosis of aspergillosis requires one or more cavities on lung imaging, with or without fungal ball or nodules, microscopy or culture positive for *Aspergillus*, or antibodies (precipitins) to *Aspergillus* on serum testing. The characteristics must have been present for 3 months. *Aspergillus* can manifest as one of three clinical syndromes: *Aspergillus* hypersensitivity lung disease, aspergilloma, or invasive pulmonary aspergillosis. Overlap occurs between these syndromes, depending on the patient's immune status.¹⁰⁴ *Aspergillus* hypersensitivity manifests as a productive cough, fever, wheezing, pulmonary infiltrates, eosinophilia, and elevation of IgE antibodies

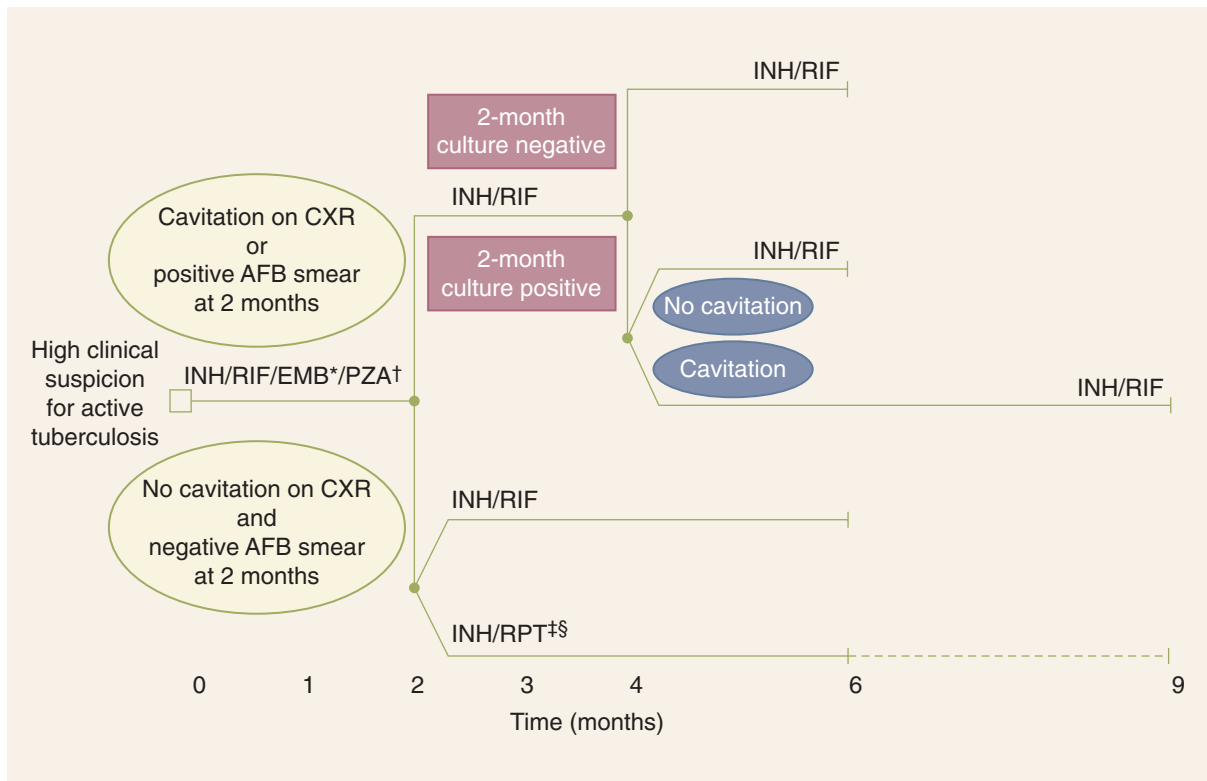

Figure 19-32. Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proven or strongly suspected should have treatment initiated with isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph (CXR) or the acid-fast bacillus (AFB) smear results are positive at completion of 2 months of treatment, the continuation phase of treatment should consist of INH and RIF daily or twice daily for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial CXR and the culture results at the time of completion of 2 months of therapy are positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD4⁺ cell count is <100/ μ L, the continuation phase should consist of daily or three times weekly INH and RIF. In HIV-uninfected patients with no cavitation on CXR and negative results on AFB smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly INH and rifapentine (RPT) or daily or twice weekly INH and RIF to complete a total of 6 months of treatment (*bottom*). For patients receiving INH and RPT whose 2-month culture results are positive, treatment should be extended by an additional 3 months (total of 9 months). *EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses). ‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. §Therapy should be extended to 9 months if results of 2-month culture are positive. (*Reproduced with permission from Blumberg HM, Burman WJ, Chaisson RE, et al. American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis, Am J Respir Crit Care Med. 2003 Feb 15;167(4):603-662.*)

Table 19-19

Indications for surgery to treat mycobacterial pulmonary infections

1. Complications resulting from previous thoracic surgery to treat tuberculosis
2. Failure of optimized medical therapy (e.g., progressive disease, lung gangrene, or intracavitary aspergillosis superinfection)
3. Need for tissue acquisition for definitive diagnosis
4. Complications of pulmonary scarring (e.g., massive hemoptysis, cavernomas, bronchiectasis, or bronchostenosis)
5. Extrapulmonary thoracic involvement
6. Pleural tuberculosis
7. Nontuberculous mycobacterial infection

to *Aspergillus*, whereas aspergilloma (fungal ball) is a matted sphere of hyphae, fibrin, and inflammatory cells that tends to colonize preexisting intrapulmonary cavities. Grossly, aspergilloma appears as a round or oval, friable, gray (or red, brown, or even yellow), necrotic-looking mass (Fig. 19-33). This form is the most common presentation of noninvasive pulmonary aspergillosis. The most common symptoms are hemoptysis, chronic and productive cough, clubbing, malaise, or weight loss. CXR can suggest the diagnosis by the finding of a crescentic radiolucency above a rounded radiopaque lesion (Monad sign).

The natural history varies greatly between patients and, therefore, treatment is individualized. Factors associated with **10** poor prognosis include severe underlying pulmonary disease, growth in the number or size of the aspergilloma(s) during observation, immunosuppression or HIV infection, history of lung transplantation, chronic pulmonary sarcoidosis, and increasing *Aspergillus*-specific IgG titers.

B

Figure 19-33. Pulmonary aspergilloma. **A.** The chest X-ray shows a solid mass within a cavity surrounded by a rim of air between the mass and cavity wall (Monad sign, *arrows*). **B.** A cut section shows the “fungus ball” occupying an old, fibrotic cavity. **C.** Histologic stain reveals characteristic *Aspergillus* hyphae invading the wall of the cavity.

Asymptomatic patients can be observed without any additional therapy. Antifungals have limited utility due to the poor blood supply to the aspergilloma. Oral triazole therapy is now considered the standard of care for chronic, cavitary pulmonary aspergillosis. Hemoptysis is a harbinger of erosion of the disease into adjacent bronchial arteries and typically requires intervention. In the setting of very mild hemoptysis (e.g., blood-streaked sputum), cough suppression is warranted while further therapeutic evaluation is performed.

Bronchial artery embolization is the first-line therapy for massive hemoptysis and may be definitive therapy.¹⁰⁵ This is particularly important to consider for patients with severely impaired pulmonary function who may not have sufficient reserve to tolerate even a very small pulmonary resection. Operative intervention may be required for recurrent hemoptysis, particularly after bronchial artery embolization, chronic cough with systemic symptoms, progressive

infiltrate around the mycetoma, and a pulmonary mass of unknown cause.¹⁰⁶

When operative intervention is indicated, the surgeon must remain cognizant of the goals of the procedure. In the setting of simple aspergilloma, VATs wedge resection is preferred. As this disease typically occurs in patients with significantly impaired pulmonary function, attempts should be made to excise all diseased tissue with as limited a resection as possible. Once resection is completed, the postresection space in the hemithorax should be obliterated with a pleural tent, pneumoperitoneum, decortication of the remaining lung, intrathoracic rotation of a muscle or omental flap, or thoracoplasty. If completely resected for single aspergilloma, antifungal therapy is not needed. If multiple nodules are present or the disease is incompletely resected, however, antifungal therapy should be considered. Long-term follow-up is necessary, given that the recurrence rate after surgery is about 7%.

Invasive pulmonary aspergillosis typically affects immunocompromised patients who have dysfunctional cellular immunity, namely defective polymorphonuclear leukocytes. Invasion of pulmonary parenchyma and blood vessels by a necrotizing bronchopneumonia may be complicated by thrombosis, hemorrhage, and then dissemination. Patients present with fever that is nonresponsive to antibiotic therapy in the setting of neutropenia. They may also have pleuritic chest pain, cough, dyspnea, or hemoptysis. Characteristic signs on CT scan include the halo sign and cavitory lesions. Treatment with voriconazole must be prompt and aggressive, including reversal of neutropenia, if there is to be any chance for recovery. Mortality ranges from 93% to 100% in bone marrow transplant recipients, to approximately 38% in kidney transplant recipients, although this improves to approximately 60% at 12 weeks with antifungal therapy. Several other advances in diagnosis and treatment, including CT scans in high-risk populations and development of additional triazoles and echinocandins, have improved the early identification and response to therapy in this patient population. Additional treatment considerations include the use of hematopoietic growth factors to minimize the neutropenic period, which contributes to uncontrolled disease. Surgical removal of the infectious nidus is advocated by some groups because medical treatment has such poor outcomes. Treatment continues until microbiologic clearance is achieved and clinical signs and radiographic imaging indicate resolution of disease. In addition, the patient should no longer be immunosuppressed. If continuation of immunosuppressive medications is required, antifungal therapy should also continue to prevent recurrence of invasive disease.

Cryptococcosis Cryptococcosis is a subacute or chronic infection caused by *Cryptococcus neoformans*, a round, budding yeast (5 to 20 μm in diameter) that is sometimes surrounded by a characteristic wide gelatinous capsule. Cryptococci are typically present in soil and dust contaminated by pigeon droppings. When inhaled, such droppings can cause a nonfatal disease primarily affecting the pulmonary and central nervous systems. At present, cryptococcosis is one of the most common opportunistic infection in patients with HIV infection, affecting ~3% of that population. Four basic pathologic patterns are seen in the lungs of infected patients: granulomas; granulomatous pneumonia; diffuse alveolar or interstitial involvement; and proliferation of fungi in alveoli and lung vasculature. Symptoms are nonspecific, as are the radiographic findings. *Cryptococcus neoformans* may be isolated from sputum, bronchial washings, percutaneous needle aspiration of the lung, or cerebrospinal fluid. If disease is suspected, serum cryptococcal antigen titers should be obtained; if positive or if the patient has persistent fever, evidence of progression, physiologic compromise, or dissemination, treatment should be promptly initiated. According to the CDC, multiple antifungal agents are effective against *C neoformans*; asymptomatic infections, such as those identified through targeted screening, should be treated with fluconazole while severe lung infections require amphotericin B combined with flucytosine followed by fluconazole for an extended length of time. Duration of therapy is longer in patients who are immunocompromised.

Candidiasis *Candida* organisms are oval, budding cells (with or without mycelial elements) that colonize the oropharynx of many healthy individuals. The fungi of this genus are common hospital and laboratory contaminants. Usually, *Candida*

albicans causes disease in the oral or bronchial mucosa, among other anatomic sites. Approximately 95% of all invasive *Candida* infections are caused by five species: *C albicans*, *C tropicalis*, *C parapsilosis*, *C glabrata*, and *C krusei*. The specific pathogen varies between patient populations and geographic regions. Non-*C albicans* infections now constitute nearly 70% of all cases in the United States, with *C glabrata* leading the list. Resistance to fluconazole is common in the non-*C albicans* species, either natural or developed in response to antifungal therapy, and the shift is likely related to the widespread use of this antifungal agent.¹⁰⁷

The incidence of *Candida* infections has increased and is no longer confined to immunocompromised patients. Increasing incidence of infection has been identified in patients with any of the following risk factors: critical illness of long duration; use of long-term antibiotics, particularly multiple; indwelling urinary or vascular catheter; gastrointestinal perforation; or burn wounds.¹⁰⁸ With respect to the thorax, such patients commonly have candidal pneumonia, pulmonary abscess, esophagitis, and mediastinitis. Pulmonary candidal infections typically result in an acute or chronic granulomatous reaction. Because *Candida* can invade blood vessel walls and a variety of tissues, systemic or disseminated infections can occur, but are less common.

Treatment for candidal infection includes both fungicidal and fungistatic agents. The fungicidal medications include polyenes (amphotericin B deoxycholate [AmB-D] and various lipid-associated amphotericin B preparations) and the echinocandins (casposungin, micafungin, and anidulafungin). Fungistatic drugs include the triazoles (fluconazole, itraconazole, voriconazole, and posaconazole). The availability of multiple effective therapies allows for specific tailoring of treatment, including combination regimens, based on the patient's ability to tolerate associated toxicities, the microbiologic information for the specific candidal species, and the route of administration. While demonstrated efficacy is similar, the triazoles and echinocandins appear to have fewer side effects and are better tolerated than the other classes of antifungal drugs. The current initial recommended regimen for adults with invasive candidiasis is an echinocandin.¹⁰⁷

In addition to prompt institution of antifungal therapy, it is advisable to remove all central venous catheters as soon as can be safely achieved. For fungemia, an eye examination should be performed. Treatment should continue for at least 2 weeks after the last positive blood culture. For patients with *Candida* mediastinitis (which has a mortality rate of >50%), surgical intervention to debride all infected tissues is required, in addition to prolonged administration of antifungal drugs.

Mucormycosis The *Mucor* species, rare members of the class Zygomycetes, are responsible for rapidly fatal disease in immunocompromised patients. Other disease-causing species of the class Zygomycetes include *Absidia*, *Rhizopus*, and *Mortierella*.¹⁰⁹ Characteristic of these fungi are nonseptate, branching hyphae that are difficult to culture. Infection occurs via inhalation of spores. Immunocompromised patients, including patients with neutropenia, acidosis, diabetes, and hematologic malignancy all predispose to clinical susceptibility. In the lungs, disease consists of blood vessel invasion, thrombosis, and infarction of infected organs.

Tissue destruction is significant, along with cavitation and abscess formation. Initial treatment is to correct underlying risk factors and administer antifungal therapies, although

the optimal duration and optimal total dose are unknown. Lipid formulations of amphotericin B are recommended at this time. Surgical resection of any localized disease should be performed after initial medical treatment attempts fail.

Primary Fungal Pathogens

Histoplasma capsulatum *Histoplasma capsulatum* is a dimorphic fungus existing in mycelial form in soil contaminated by fowl or bat excreta and in yeast form in human hosts. The most common of all fungal pulmonary infections, histoplasmosis, primarily affects the respiratory system after spores are inhaled. It is endemic in the Midwest and Mississippi River Valley of the United States, where about 500,000 new cases arise each year. In immunocompromised patients, the infection becomes systemic and more virulent; because cell-mediated immunity is impaired, uninhibited fungal proliferation occurs within pulmonary macrophages and then spreads. Acute forms of the disease present as primary or disseminated pulmonary histoplasmosis; chronic forms present as pulmonary granulomas (histoplasmoses), chronic cavitary histoplasmosis, mediastinal granulomas, fibrosing mediastinitis, or bronchiolithiasis. Histoplasmosis is definitively diagnosed by fungal smear, culture, direct biopsy of infected tissues, or serologic testing.

The clinical presentation depends on the inoculum size and on host factors.

Symptoms of acute pulmonary histoplasmosis are fever, chills, headache, chest pain, musculoskeletal pain, and nonproductive cough. CXRs may be normal or may show mediastinal lymphadenopathy and patchy parenchymal infiltrates. Most patients improve in a few weeks; mild to moderate disease can be treated with itraconazole. Amphotericin B is the treatment of choice if moderate symptoms persist for 2 to 4 weeks or if the illness is extensive, including dyspnea and hypoxia, and if patients are immunosuppressed.¹¹⁰

As the pulmonary infiltrates from acute histoplasmosis heal, consolidation into an asymptomatic solitary nodule or histoplasmosis may occur and is usually seen incidentally on radiographs as a coin-shaped lesion. Central and concentric calcification may occur; if so, no further treatment is required. Noncalcification of the lesion requires further diagnostic workup including chest CT scan, needle biopsy, or surgical excision to rule out a malignancy. Figure 19-34 demonstrates the differences in pathologic findings between infections in normal and immunocompromised hosts.¹¹¹

When lymph nodes and pulmonary granulomas calcify over time, pressure atrophy on the bronchial wall may result in erosion and migration of the granulomatous mass into the bronchus, causing bronchiolithiasis. Typical symptoms include cough, hemoptysis, and dyspnea. Life-threatening complications include massive hemoptysis or bronchoesophageal fistula. In addition to radiography, bronchoscopy should be performed to aid in diagnosis. Definitive treatment requires surgical excision of the bronchial mass and repair of the airway and contiguous structures. Endobronchial debridement is not advised as this can result in massive, fatal bleeding.

Fibrosing mediastinitis is an uncommon manifestation of histoplasmosis but can be fatal due to progressive distortion and compression of the major vessels and central airways.

Diagnosis can be difficult, and symptoms may be present for extended periods, even years, before the diagnosis is made. The differential diagnosis for the disease process includes granulomatous mediastinitis related to recent infection, malignancy,

and chronic pulmonary thromboembolism. A trial of itraconazole is worthwhile, although it is not proven to be effective. In cases where radiographic or physiologic improvement is achieved after a trial of 12 week of therapy, continuation of therapy is considered for a full 12 months. In the majority of patients, however, antifungal therapy has not been proven. There is no role for corticosteroids at this time or for antifibrotics. Occasionally, intravascular stents have been helpful for severe vascular compromise. Balloon dilatation and endobronchial silicone stents may be needed for airway compromise, although this should be directed by a surgeon with expertise in mediastinal and airway disease management.

Chronic pulmonary histoplasmosis occurs in about 10% of patients who become symptomatic after infection. Most such patients have preexisting lung pathology, particularly emphysema, which becomes colonized, and subsequent pneumonitis and necrosis, cavity enlargement, new cavity formation, and pulmonary dissemination occur. Nonspecific symptoms, such as cough, sputum production, fever, weight loss, weakness, and hemoptysis are common. Chest radiography may reveal intrapulmonary cavitation and scarring. Occasionally, partial resolution of the inflammatory changes may be observed. Itraconazole provides effective therapy, but must be given for 12 to 24 months. It is superior to ketoconazole and fluconazole; these should only be used if itraconazole is not tolerated. Voriconazole and posaconazole have been found to be useful for salvage therapy. Serum itraconazole levels should be monitored to ensure that the drug is being absorbed. Occasionally, lipid-associated amphotericin B is necessary for more severe infections. Surgical excision should be considered in patients with adequate pulmonary reserve and localized, thick-walled cavities that have been unresponsive to antifungal therapy.

Disseminated histoplasmosis occurs most frequently in patients who are severely immunocompromised, such as post-transplantation patients, patients with HIV, and patients using immunosuppressive medications. Presentation ranges from nonspecific signs of fever, weight loss, and malaise, to shock, respiratory distress, and multiorgan failure. Diagnosis can be made with a combination of *Histoplasma* urine antigen, serologic assay, and fungal culture and should be suspected in patients with the above symptoms in any endemic area, particularly if the patient is immunosuppressed.¹¹² Any of the antifungal therapies can be used in treatment of disseminated histoplasmosis. Use of amphotericin B has decreased the mortality rate to less than 25% in this type of serious infection.

Coccidioides immitis *Coccidioides immitis* is an endemic fungus found in soil and dust of the southwestern United States. Agricultural workers, military personnel, and other occupations with extensive exposure to soil, especially in areas of endemic growth, are at highest risk, as are immunocompromised individuals.¹¹³ Spores (arthroconidia) are inhaled, swell into spherules, and subdivide into endospores, and subsequent infection develops. Diagnosis can be achieved through serum analysis for anticoccidioidal antibody, spherule identification in tissue, or by isolating the fungus in cultures from sputum, other body fluid, or tissue.

Inhalation of the fungus causes pulmonary involvement in 95% of patients with symptomatic disease. Three main categories of pulmonary involvement, based on the associated signs and symptoms, are possible: primary, complicated, and residual pulmonary coccidioidomycosis. Primary pulmonary

Figure 19-34. Pathologic findings of infection in normal and immunocompromised hosts. Histopathologic preparations are shown contrasting acute diffuse pulmonary involvement in a lung segment of a normal host with a probable primary infection (A through D) with pulmonary granulomas from an immunocompromised patient who had an opportunistic reinfection with *Histoplasma capsulatum* (E, F). **A.** Diffuse interstitial pneumonitis in an adult (normal host) with recent heavy environmental exposure and subsequent development of progressive pulmonary disease. There is an inflammatory cell infiltrate primarily involving the interalveolar interstitial spaces but present within many alveolar spaces as well. The exudate consists mostly of mononuclear phagocytes, lymphocytes, and occasional plasma cells. Many of the alveolar walls are markedly thickened (hematoxylin and eosin stain [H&E], $\times 50$). **B.** Another area from the same lung as in A showing focal vasculitis with an infiltrate of lymphocytes and macrophages (H&E, $\times 25$). **C.** Relatively large alveolar macrophages packed with single and budding yeasts 2 to 4 μm in diameter (same lung as in A and B). The basophilic cytoplasm of these yeasts is retracted from their thin outer cell walls, leaving halo-like clear areas that can be confused with capsules (H&E, $\times 500$). **D.** Intracellular and extracellular yeasts, 2 to 4 μm in diameter, some of which are single, budding, or in short chains (Gomori methenamine silver stain, $\times 500$). **E.** Nonnecrotizing (sometimes called epithelioid cell or noncaseating) granuloma from a patient who had recently received chemotherapy for a germ cell tumor (different patient than in A through D). This lesion consists of a focal collection of macrophages (sometimes referred to as histiocytes or epithelioid cells) plus lymphocytes and occasional plasma cells. A few multinucleated macrophages are present. A thin layer of fibroblasts circumscribes the lesion. Yeasts of *H capsulatum*, probably present within macrophages of this lesion at an earlier stage, were not identified in this granuloma or in any of several other nonnecrotizing granulomas within the specimen. Lesions of this type often undergo necrosis to become necrotizing granulomas (H&E, $\times 50$). **F.** Necrotizing (sometimes referred to as caseating) granuloma from the same lung as in E. This lesion has a necrotic center surrounded by macrophages, encapsulating fibroblasts, fibrous connective tissue in the periphery, and scattered lymphocytes. A prominent giant cell is present in the lower left of the granuloma (at approximately 8 o'clock). Microorganisms are usually present only in relatively small numbers in these types of lesions. They are most frequently detected within the most central necrotic material in these granulomas (H&E, $\times 25$). (Reproduced with permission from Hage CA, Wheat LJ, Loyd J, et al: Pulmonary histoplasmosis, *Semin Respir Crit Care Med.* 2008 Apr;29(2):151-165.)

coccidioidomycosis occurs in about 40% of people who inhale spores. The other 60% will remain asymptomatic and develop life-long immunity. The constellation of symptoms of “valley fever,” including fever, chills, headache, erythema multiforme, erythema nodosum, polyarthralgias, nonproductive cough, and chest pain, and a CXR showing hilar and paratracheal adenopathy are highly suggestive of pulmonary coccidioidomycosis. In many patients, initial diagnosis is community-acquired pneumonia, and it is only when the patient fails to respond to appropriate antibiotic therapy that pulmonary coccidioidomycosis is considered. The disease is self-limited in the majority of patients, and treatment is not required in these cases.

Therapy should be considered for (a) patients with impaired cellular immunity; (b) comorbid illnesses that are adversely impacted by the infection, including chronic pulmonary dysfunction, renal failure, and congestive heart failure; and (c) when symptoms and radiographic findings persist for more than 6 to 8 weeks, at which time the disease is considered to be persistent coccidioid pneumonia and occurs in approximately 1% of patients. Progression to caseous nodules, cavities, and calcified, fibrotic, or ossified lesions indicates complicated or residual stages of coccidioidomycosis.

There are several relative indications for surgery in pulmonary coccidioidomycosis. A rapidly expanding (>4 cm) cavity that is close to the visceral pleura is a high risk for rupture into the pleural space and subsequent empyema. Other indications for operative intervention include life-threatening hemoptysis; hemoptysis that is persistent despite medical therapy; symptomatic fungus ball; bronchopleural fistula; cavitory lesions with persistent positive sputum; and pulmonary nodules that degenerate over time. Finally, any nodule with signs that are concerning for malignancy should undergo further evaluation, including biopsy or resection, to determine the underlying etiology.

Diagnosis of coccidioidomycosis is confirmed by histopathologic, mycologic, and serologic evaluation. Extrapulmonary disease may develop in approximately 0.5% of infected patients, with involvement of meninges, bones, joints, skin, or soft tissues. Immunocompromised patients are especially susceptible to disseminated coccidioidomycosis, which carries a mortality rate over 40%. Treatment options for this disease vary depending on the severity of the disease as well as the stage. Amphotericin B deoxycholate or the triazoles continue to be the primary antifungal medications. If meningeal involvement is identified, fluconazole or itraconazole therapy is required for the remainder of the patient’s life. Intrathecal amphotericin B can also be administered in some cases.

Blastomyces dermatitidis *Blastomyces dermatitidis* is a round, single-budding yeast with a characteristic thick, refractile cell wall. It resides in the soil as a nonmotile spore called *conidia*. Exposure occurs when contaminated soil is disturbed and the conidia are aerosolized. The spore is inhaled and transforms into a yeast phase at body temperature.¹¹⁴ Infection is typically self-limited. A small minority of patients will develop chronic pulmonary infection or disseminated disease, including cutaneous, osteoarticular, and genitourinary involvement. *B dermatitidis* has a worldwide distribution; in the United States, it is endemic in the central states.¹¹⁵ With chronic infection, the organism induces a granulomatous and pyogenic reaction with microabscesses and giant cells; caseation, cavitation, and fibrosis may also occur. Symptoms are nonspecific and consistent with chronic pneumonia in 60% to 90% of patients. They include cough, mucoid sputum production, chest pain, fever,

malaise, weight loss, and, uncommonly, hemoptysis. In acute disease, radiographs are either completely negative or have nonspecific findings; in chronic disease, fibronodular lesions (with or without cavitation) similar to tuberculosis are noted. Pulmonary parenchymal abnormalities in the upper lobe(s) may be noted. Mass lesions similar to carcinoma are frequent, and lung biopsy is frequently used. Over 50% of patients with chronic blastomycosis also have extrapulmonary manifestations, but less than 10% of patients present with severe clinical manifestation.¹¹⁴

Once a patient manifests symptoms of chronic blastomycosis, antifungal treatment is required to achieve resolution. Mortality approaches 60% if untreated.¹¹⁴ While controversial, a short course of triazole therapy (oral itraconazole 200 mg daily) for 6 months is the treatment of choice for most patients with mild to moderate forms of the disease. Because itraconazole has poor CNS penetration, the most common site of recurrence after apparently successful therapy is in the CNS. In the absence of therapy, close follow-up is warranted for evidence of progression to chronic or extrapulmonary disease. Amphotericin B is warranted for patients with severe or life-threatening disease, CNS involvement, disseminated disease, or extensive lung involvement and in immunocompromised patients. After adequate drug therapy, surgical resection of known cavitory lesions should be considered because viable organisms are known to persist in such lesions.

Massive Hemoptysis

Massive hemoptysis is generally defined as expectoration of over 600 mL of blood within a 24-hour period. It is a medical emergency associated with a mortality rate of 30% to 50%. Most clinicians would agree that losing over a liter of blood via the airway within 1 day is significant, yet use of an absolute volume criterion presents difficulties. First, it is difficult for the patient or caregivers to quantify the volume of blood being lost. Second, and most relevant, the rate of bleeding necessary to incite respiratory compromise is highly dependent on the individual’s prior respiratory status. For example, the loss of 100 mL of blood over 24 hours in a 40-year-old male with normal pulmonary function would be of little immediate consequence, because his normal cough would ensure his ability to clear the blood and secretions. In contrast, the same amount of bleeding in a 69-year-old male with severe COPD, chronic bronchitis, and an FEV₁ of 1.1 L may be life-threatening.

Anatomy. The lungs have two sources of blood supply: the pulmonary and bronchial arterial systems. The pulmonary system is a high-compliance, low-pressure system, and the walls of the pulmonary arteries are very thin and delicate. The bronchial arteries, part of the systemic circulation, have systemic pressures and thick walls; most branches originate from the proximal thoracic aorta. Most cases of massive hemoptysis involve bleeding from the bronchial artery circulation or from the pulmonary circulation pathologically exposed to the high pressures of the bronchial circulation. In many cases of hemoptysis, particularly those due to inflammatory disorders, the bronchial arterial tree becomes hyperplastic and tortuous. The systemic pressures within these arteries, combined with a disease process within the airway and erosion, lead to bleeding.

Causes. Significant hemoptysis has many causes, most commonly including pulmonary, extrapulmonary, and iatrogenic. Table 19-20 summarizes the most common causes of hemoptysis. Most are secondary to inflammatory processes. Aneurysms

Table 19-20

Pulmonary and extrapulmonary causes of massive hemoptysis

PULMONARY	EXTRAPULMONARY	IATROGENIC
Pulmonary parenchymal disease Bronchitis Bronchiectasis Tuberculosis Lung abscess Pneumonia Cavitory fungal infection (e.g., aspergilloma) Lung parasitic infection (ascariasis, schistosomiasis, paragonimiasis) Pulmonary neoplasm Pulmonary infarction or embolism Trauma Arteriovenous malformation Pulmonary vasculitis Pulmonary endometriosis Wegener's granulomatosis Cystic fibrosis Pulmonary hemosiderosis	Congestive heart failure Coagulopathy Mitral stenosis Medications	Intrapulmonary catheter

of the pulmonary artery (referred to as Rasmussen's aneurysm) can develop within pulmonary cavities and can result in massive bleeding. Hemoptysis due to lung cancer is usually mild, resulting in blood-streaked sputum. Massive hemoptysis in patients with lung cancer is typically caused by malignant invasion of pulmonary artery vessels by large central tumors. Although rare, it is often a terminal event.

Management. Life-threatening hemoptysis is best managed by a multidisciplinary team of intensive care physicians, interventional radiologists, and thoracic surgeons. Treatment priorities begin with respiratory stabilization; intubation with isolation of the bleeding lung may be required to prevent asphyxiation. This can be done with main-stem intubation into the nonbleeding lung, endobronchial blockers into the bleeding lung, or double-lumen endotracheal intubation, depending on the urgency of the situation and the expertise of the providers. Once adequate ventilation has been achieved, the bleeding site should be localized; bronchoscopy can often provide direct visualization of blood coming from a specific area of the tracheobronchial anatomy. Control of the hemorrhage is then achieved endobronchially with laser or bronchial occlusion, endovascularly with bronchial and/or pulmonary artery embolization, or surgically with resection of the involved area.¹¹⁶ The order of priorities in management is detailed in Table 19-21.

Table 19-21

Treatment priorities in the management of massive hemoptysis

1. Achieve respiratory stabilization and prevent asphyxiation.
2. Localize the bleeding site.
3. Control the hemorrhage.
4. Determine the cause.
5. Definitively prevent recurrence.

The clinically pragmatic definition of massive hemoptysis is a degree of bleeding that threatens respiratory stability. Therefore, clinical judgment of respiratory compromise is the first step in evaluating a patient.^{117,118} Two scenarios are possible: (a) bleeding is significant and persistent, but its rate allows a rapid but sequential diagnostic and therapeutic approach, and (b) bleeding is so rapid that emergency airway control and therapy are necessary.

Scenario 1: Significant, Persistent, but Nonmassive Bleeding

Although bleeding is brisk in scenario 1, the patient may be able to maintain clearance of the blood and secretions with his or her own respiratory reflexes. Immediate measures are admission to an intensive care unit; strict bed rest; Trendelenburg positioning with the affected side down (if known); administration of humidified oxygen; cough suppression; monitoring of oxygen saturation and arterial blood gases; and insertion of large-bore intravenous catheters. Strict bed rest with sedation may lead to slowing or cessation of bleeding, and the judicious use of intravenous narcotics or other relaxants to mildly sedate the patient and diminish some of the reflexive airway activity is often necessary. Also recommended are administration of aerosolized adrenaline, intravenous antibiotic therapy if needed, and correction of abnormal blood coagulation study results. Finally, unless contraindicated, intravenous vasopressin (20 U over 15 minutes, followed by an infusion of 0.2 U/min) can be given.

A CXR is the first test and often proves to be the most revealing. Localized lesions may be seen, but the effects of blood soiling of other areas of the lungs may predominate, obscuring the area of pathology. Chest CT scan provides more detail and is nearly always performed if the patient is stable. Pathologic areas may be obscured by blood soiling.

Flexible bronchoscopy is the next step in evaluating the patient's condition. Some clinicians argue that rigid bronchoscopy should always be performed. However, if the patient is clinically stable and the ongoing bleeding is not imminently threatening, flexible bronchoscopy is appropriate. It allows diagnosis of airway abnormalities and will usually permit

localization of the bleeding site to either a lobe or even a segment. The person performing the bronchoscopy must be prepared with excellent suction and must be able to perform saline lavage with a dilute solution of epinephrine.

Most cases of massive hemoptysis arise from the bronchial arterial tree; therefore, the next therapeutic option frequently is selective bronchial arteriography and embolization.

Prearteriogram bronchoscopy is extremely useful to direct the angiographer. However, if bronchoscopy fails to localize the bleeding site, then bilateral bronchial arteriograms can be performed. More recently, use of multidetector CT angiography in patients with hemoptysis that is not immediately life-threatening has been shown to facilitate endovascular intervention; reformatting of the images in multiple projections allows clear delineation of the pulmonary vascular anatomy.¹⁰⁵ With this approach, abnormal bronchial and nonbronchial arteries can be visualized and subsequently targeted for therapeutic arterial embolization.¹¹⁹ Once the targeted arterial system has been embolized, immediate control and cessation of the hemoptysis is achieved in more than 80% of patients. If bleeding persists after bronchial artery embolization, a pulmonary artery source should be suspected and a pulmonary angiogram performed at the same setting.

Recurrence is seen in 30% to 60% of cases and is very common in the setting of invasive fungal infections such as aspergilloma. Recurrence after bronchial artery embolization is less common in the setting of malignancy and active tuberculosis but does occur and can ultimately result in patient death.¹²⁰ Repeat embolization can be effective and is warranted for initial management of recurrent hemoptysis, but early surgical intervention should be considered, particularly in the setting of aspergilloma or other cavitary lesions.¹⁰⁵

If respiratory compromise is impending, orotracheal intubation should be performed. After intubation, flexible bronchoscopy should be performed to clear blood and secretions and to attempt localization of the bleeding site. Depending on the possible causes of the bleeding, bronchial artery embolization or (if appropriate) surgery can be considered.

Scenario 2: Significant, Persistent, and Massive Bleeding

Life-threatening bleeding requires emergency airway control and preparation for potential surgery. Such patients are best cared for in an operating room equipped with rigid bronchoscopy. Immediate orotracheal intubation may be necessary to gain control of ventilation and suctioning. However, rapid transport to the operating room with rigid bronchoscopy should be facilitated. Rigid bronchoscopy allows adequate suctioning of bleeding with visualization of the bleeding site; the nonbleeding side can be cannulated with the rigid scope and the patient ventilated. After stabilization, ice-saline lavage of the bleeding site can then be performed (up to 1 L in 50-mL aliquots); bleeding stops in up to 90% of patients.¹²¹

Alternatively, blockade of the main stem bronchus of the affected side can be accomplished with a double-lumen endotracheal tube, with a bronchial blocker, or by intubation of the nonaffected side by an uncut standard endotracheal tube. Placement of a double-lumen endotracheal tube is challenging in these circumstances, given the bleeding and secretions.

Proper placement and suctioning may be difficult, and attempts could compromise the patient's ventilation. The best option is to place a bronchial blocker in the affected bronchus with inflation. Endovascular embolization can be performed to stop the bleeding after control has been achieved with the

bronchial blocker. The blocker is left in place for 24 hours; after 24 hours, the area is reexamined bronchoscopically.

Surgical Intervention. In most patients, bleeding can be stopped, recovery can occur, and plans to definitively treat the underlying cause can be made. In scenario 1 (significant, persistent, but nonmassive bleeding), the patient may undergo further evaluation as an inpatient or outpatient. A chest CT scan and pulmonary function studies should be obtained preoperatively. In scenario 2 (patients with significant, persistent, and massive bleeding), surgery, if appropriate, will usually be performed during the same hospitalization as the rigid bronchoscopy or main stem bronchus blockade. In a small number of patients (<10%), immediate surgery will be necessary due to the extent of bleeding. The bleeding site in these patients is localized using rigid bronchoscopy with immediate thoracotomy or sternotomy to follow.

Surgical treatment is individualized according to the source of bleeding and the patient's medical condition, prognosis, and pulmonary reserve. General indications for urgent surgery are presented in Table 19-22. In patients with significant cavitary disease or with fungus balls, the walls of the cavities are eroded and necrotic; rebleeding will likely ensue. In addition, bleeding from cavitary lesions may be due to pulmonary artery erosion, which requires surgery for control.

End-Stage Lung Disease

Lung Volume Reduction Surgery. The ideal patient for lung volume reduction surgery (LVRS) has heterogeneous emphysema with apical predominance, meaning the worst emphysematous changes are in the apex (seen on chest CT scan) of the lungs. The physiologic lack of function of these areas is demonstrated by quantitative perfusion scan, which shows minimal or no perfusion. By surgically excising these nonfunctional areas, the volume of the lung is reduced, theoretically restoring respiratory mechanics. Diaphragm position and function are improved, and there may be an improvement in the dynamic small airway collapse in the remaining lung.

Operative mortality in the initial experience was 16.9%, with a 1-year mortality of 23%. In response, the National Emphysema Treatment Trial (NETT) performed a randomized trial of 1218 patients in a noncrossover design to medical versus surgical management after a 10-week pretreatment pulmonary rehabilitation program. Subgroup analysis demonstrated that in patients with the anatomic changes delineated by Cooper and colleagues, LVRS significantly improved exercise capacity, lung function, quality of life, and dyspnea compared to medical therapy. After 2 years, functional improvements began to decline toward baseline. Similar parameters in medically treated patients steadily decline below baseline. LVRS was associated with increased short-term morbidity and mortality and did not confer a survival benefit over medical therapy.¹²²

Table 19-22

General indications for urgent operative intervention for massive hemoptysis

1. Presence of a fungus ball
2. Presence of a lung abscess
3. Presence of significant cavitary disease
4. Failure to control the bleeding

Lung Transplantation. The most common indications for lung transplant are COPD and idiopathic pulmonary fibrosis (IPF). Most patients with IPF and older patients with COPD are offered a single-lung transplant. Younger COPD patients and patients with α 1-antitrypsin deficiency and severe hyperinflation of the native lungs are offered a bilateral-lung transplant. Most patients with primary pulmonary hypertension and almost all patients with cystic fibrosis are treated with a bilateral-lung transplant. A heart-lung transplant is reserved for patients with irreversible ventricular failure or uncorrectable congenital cardiac disease.

Patients with COPD are considered for placement on the transplant waiting list when their FEV₁ has fallen to below 25% of its predicted value. Patients with significant pulmonary hypertension should be listed earlier. IPF patients should be referred when their forced vital capacity has fallen to less than 60% or their DLCO has fallen to less than 50% of their predicted values.

In the past, patients with primary pulmonary hypertension and New York Heart Association (NYHA) class III or IV symptoms were listed for a lung transplant. However, treatment of such patients with intravenous prostacyclin and other pulmonary vasodilators has now markedly altered that strategy. Virtually all patients with primary pulmonary hypertension are now treated with intravenous epoprostenol. Several of these patients have experienced a marked improvement in their symptoms associated with a decrease in their pulmonary arterial pressures and an increase in exercise capacity. Listing of these patients is deferred until they develop NYHA class III or IV symptoms or until their mean pulmonary artery pressure rises above 75 mmHg.

Medium-term and bronchiolitis obliterans syndrome (BOS)–free survival rates of patients who underwent a lung transplant at the University of Minnesota are shown in Figs. 19-35 and 19-36. The mortality of patients while waiting for transplants is about 10%. In an effort to expand the number of lung donors, many transplant groups have liberalized their criteria for donor selection. Still, the partial pressure of arterial oxygen (Pao₂) should be greater than 300 mmHg on a fraction of inspired oxygen (Fio₂) of 100%. In special circumstances, lungs may be used from donors with a smoking history; from donors older than 50 years of age; and from donors with positive Gram stains or infiltrates on CXR.^{123,124} The use of two living donors, each donating a single lower lobe, is another strategy for increasing the donor pool. Recipient outcomes are similar to those with cadaver donors in carefully selected patients.

Figure 19-35. The overall survival rate after lung transplantation at the University of Minnesota.

Figure 19-36. The survival rate after lung transplantation in the absence of bronchiolitis obliterans syndrome (BOS) at the University of Minnesota.

Most of the early mortality after lung transplant is related to primary graft failure resulting from a severe ischemia-reperfusion injury to the lung(s) (Fig. 19-37). Reperfusion injury is characterized radiographically by interstitial and alveolar edema and clinically by hypoxia and ventilation-perfusion mismatch. Donor neutrophils and recipient lymphocytes probably play an important role in the pathogenesis of reperfusion injury. The most important impediment to longer-term survival after a lung transplant is the development of BOS, a manifestation of chronic rejection. Episodes of acute rejection are the major risk factors for developing BOS. Other injuries to the lung (including early reperfusion injury and chronic gastroesophageal reflux disease) may also adversely affect long-term outcomes of patients.^{125,126}

CHEST WALL

Chest Wall Mass

Clinical Approach. Surgeons confronted with a patient with a chest wall mass must be cognizant that their approach to diagnosis and treatment has significant impact on the patient's chances

Figure 19-37. The survival rate after lung transplantation at the University of Minnesota as a function of primary graft failure (PGF).

for long-term survival. All chest wall tumors should be considered malignant until proven otherwise. It is critically important that the surgeon(s) be mindful of this tenet and well versed in the diagnostic and treatment principles for chest wall malignancies. These tenets must be applied from the initial biopsy, as the placement of the incision can impact significantly on the successful complete resection and reconstruction of the chest wall. Complete resection is imperative if there is any hope for cure and/or long-term survival. A general approach is outlined in Figs. 19-38 and 19-39.

Patients with chest wall tumors, regardless of etiology, typically complain of a slowly enlarging palpable mass (50% to 70%), chest wall pain (25% to 50%), or both. Interestingly, growing masses are often not noticed by the patient until they suffer a trauma to the area. Pain from a chest wall mass is typically localized to the area of the tumor; it occurs more often and more intensely with malignant tumors, but it can also be present in up to one-third of patients with benign tumors. With Ewing's sarcoma, fever and malaise may also be present. Benign chest wall tumors tend to occur in younger patients (average age 26 years), whereas malignant tumors tend to be found in older patients (average age 40 years). Overall, between 50% and 80% of chest wall tumors are malignant.

Evaluation and Management. Laboratory evaluations are useful in assessing chest wall masses for the following:

1. **Plasmacytoma.** Serum protein electrophoresis demonstrates a single monoclonal spike, which is measuring the overproduction of one immunoglobulin from the malignant plasma cell clone.

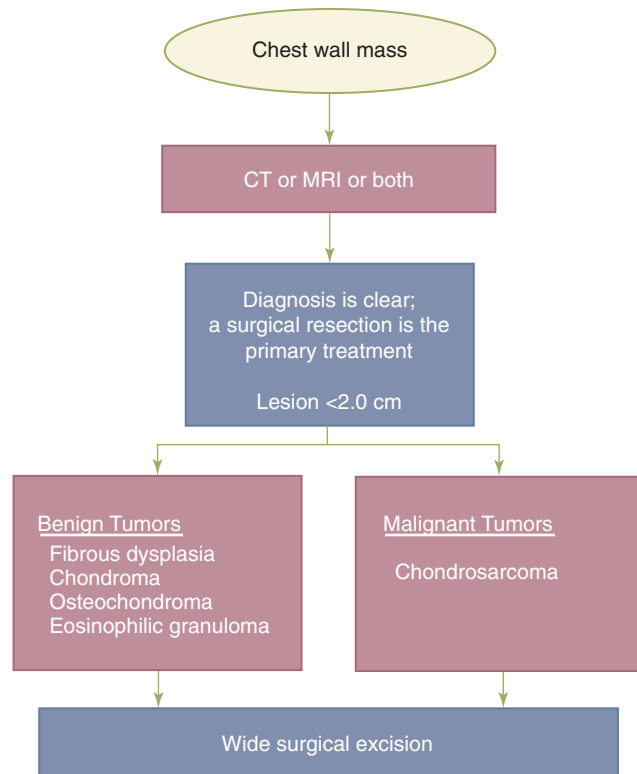

Figure 19-38. Systematic approach for evaluating a chest wall mass when the clinical scenario is uncomplicated and initial imaging studies suggest a clear diagnosis. CT = computed tomography; MRI = magnetic resonance imaging.

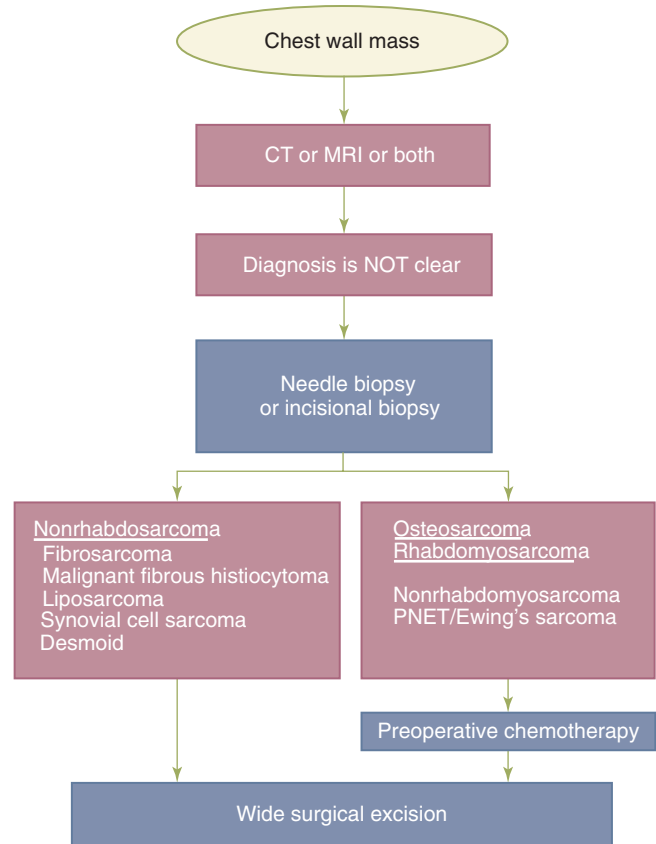

Figure 19-39. Systematic approach for evaluating a chest wall mass for which the diagnosis is not unequivocal. A tissue diagnosis is critical for effective management of chest wall masses. CT = computed tomography; MRI = magnetic resonance imaging; PNET = primitive neuroectodermal tumor.

2. **Osteosarcoma.** Alkaline phosphatase levels may be elevated.
3. **Ewing's sarcoma.** Erythrocyte sedimentation rates may be elevated.

Radiography CXR may reveal rib destruction, calcification within the lesion, and if old films are available, a clue to growth rate. CT scanning, however, is necessary to determine the relationship of the chest wall mass to contiguous structures (e.g., mediastinum, lung, soft tissues, and other skeletal elements), evaluate for pulmonary metastases, and assess for extraosseous bone formation and bone destruction, both typically seen with osteosarcoma.

Because MRI provides multiple planes of imaging (coronal, sagittal, and oblique), better definition of the relationship between tumor and muscle, and tumor and contiguous or nearby neurovascular structures or the spine, it is an important radiographic adjunct for preoperative planning. Compared to CT scan alone, MRI may further delineate tissue abnormalities, potentially enhancing the ability to distinguish benign from malignant sarcoma.

Biopsy The first step in the management of all chest wall tumors is to obtain a tissue diagnosis. Inappropriate or misguided attempts at tissue diagnosis through casual open biopsy techniques have the potential (if the lesion is a sarcoma) to seed surrounding tissues and contiguous body cavities (e.g., the pleural space) with tumor cells, potentially compromising local

tumor control and patient survival. Tissue diagnosis is accomplished using one of three methods: needle biopsy (typically CT-guided, FNA, or a core biopsy), incisional biopsy, or excisional biopsy in limited and specific situations.

1. **Needle biopsy.** Pathologists experienced with sarcomas can accurately diagnose approximately 90% of patients using FNA cytology. A needle biopsy (FNA or core) has the advantage of avoiding wound and body cavity contamination (a potential complication with an incisional biopsy).
2. **Incisional biopsy.** If a needle biopsy is nondiagnostic, an incisional biopsy may be performed, with caveats. First, the skin incision must be placed directly over the mass and oriented to allow subsequent scar excision and skin flaps, and drains should be avoided. If the surgeon believes a hematoma is likely to develop, a drain is useful for limiting soft tissue contamination by tumor cells. At the time of definitive surgical resection, the en bloc resection includes the biopsy scar and the drain tract along with the tumor.
3. **Excisional biopsy.** Any lesion less than 2.0 cm can be excised as long as the resulting wound is small enough to close primarily. Otherwise, excisional biopsy is performed only when the initial diagnosis (based on radiographic evaluation) indicates that the lesion is benign or when the lesion has the classic appearance of a chondrosarcoma (in which case, definitive surgical resection can be undertaken).

Benign Chest Wall Neoplasms

1. **Chondroma.** Chondromas, seen primarily in children and young adults, are one of the more common benign tumors of the chest wall. They usually occur at the costochondral junction anteriorly and may be confused with costochondritis, except that a painless mass is present. Radiographically, the lesion is lobulated and radiodense; it may have diffuse or focal calcifications; and it may displace the bony cortex without penetration. Chondromas may grow to huge sizes if left untreated. Treatment is surgical resection with a 2-cm margin. Large chondromas may harbor well-differentiated chondrosarcoma and should be managed with a 4-cm margin to prevent local recurrence.¹²⁷
2. **Fibrous dysplasia.** As with chondromas, fibrous dysplasia most frequently occurs in young adults and may be associated with trauma. Pain is an infrequent complaint, and the lesion is typically located in the posterolateral aspect of the rib cage. Radiographically, an expansile mass is present, with cortical thinning and no calcification. Local excision with a 2-cm margin is curative.
3. **Osteochondroma.** Osteochondromas, often found incidentally as a solitary lesion on radiograph, are the most common benign bone tumor. Osteochondromas occur in the first two decades of life, and they arise at or near the growth plate of bones. Osteochondromas in the thorax arise from the rib cortex. They are one of several components to the autosomal dominant syndrome, hereditary multiple exostoses. When part of this syndrome, osteochondromas have a high rate of degeneration into chondrosarcomas. Any patient with hereditary multiple exostoses syndrome who develops new pain at the site of an osteochondroma or who notes gradual growth in the mass over time should be carefully evaluated for osteosarcoma. Local excision of a benign osteochondroma

is sufficient. If malignancy is determined, wide excision is performed with a 4-cm margin.

4. **Eosinophilic granuloma.** Eosinophilic granulomas are benign osteolytic lesions. Eosinophilic granulomas of the ribs can occur as solitary lesions or as part of a more generalized disease process of the lymphoreticular system termed Langerhans cell histiocytosis (LCH). In LCH, the involved tissue is infiltrated with large numbers of histiocytes (similar to Langerhans cells seen in skin and other epithelia), which are often organized as granulomas. The cause is unknown. Of all LCH bone lesions, 79% are solitary eosinophilic granulomas, 7% involve multiple eosinophilic granulomas, and 14% belong to other forms of more systemic LCH. Isolated single eosinophilic granulomas can occur in the ribs or skull, pelvis, mandible, humerus, and other sites. They are diagnosed primarily in children between the ages of 5 and 15 years. Because of the associated pain and tenderness, they may be confused with Ewing's sarcoma or with an inflammatory process such as osteomyelitis. Healing may occur spontaneously, but the typical treatment is limited surgical resection with a 2-cm margin.
5. **Desmoid tumors.** Soft tissue neoplasms arising from fascial or musculoaponeurotic structures, desmoid tumors consist of proliferations of benign-appearing fibroblastic cells, abundant collagen, and few mitoses. Desmoid tumors possess alterations in the adenomatous polyposis coli (APC)/ β -catenin pathway. Cyclin D1 dysregulation is thought to play a significant role in their pathogenesis.¹²⁸ Associations with other diseases and conditions are well documented, especially those with similar alterations in the APC pathway, such as familial adenomatous polyposis (Gardner's syndrome). Other conditions with increased risk of desmoid tumor formation include increased estrogen states (pregnancy) and trauma. Surgical incisions (abdominal and thorax) have been the site of desmoid development, either in or near the scar.

Clinically, patients are usually in the third to fourth decade of life and have pain, a chest wall mass, or both. The tumor is usually fixed to the chest wall, but not to the overlying skin. There are no typical radiographic findings, but MRI may delineate muscle or soft tissue infiltration. Desmoid tumors do not metastasize, but they have a significant propensity to recur locally, with rates as high as 5% to 50%, sometimes despite complete initial resection with histologically negative margins.¹²⁹ Such locally aggressive behavior is secondary to microscopic tumor infiltration of muscle and surrounding soft tissues and prompts some to consider them a low-grade form of fibrosarcoma.

Because the lesions have low cellularity and poor yield with FNA, an open incisional biopsy for lesions over 3 to 4 cm is often necessary, following the caveats listed earlier (see biopsy section). Surgery consists of wide local excision with a 2- to 4-cm margin and intraoperative frozen section assessment of resection margins. Typically, chest wall resection, including the involved rib(s) and one rib above and below the tumor with a 4- to 5-cm margin of rib, is required. A margin of less than 1 cm results in much higher local recurrence rates. If a major neurovascular structure would have to be sacrificed, leading to high morbidity, then a margin of less than 1 cm would have to suffice. Survival after wide local excision with negative margins is 90% at 10 years.¹³⁰

Primary Malignant Chest Wall Tumors

Malignant tumors of the chest wall are either metastatic lesions from another primary tumor or sarcoma. Soft tissue sarcomas of the chest wall include fibrosarcomas, liposarcomas, malignant fibrous histiocytomas (MFHs), rhabdomyosarcomas, angiosarcomas, and other extremely rare lesions (Fig. 19-40). Despite the prevalence of localized disease, soft tissue sarcomas of the chest wall have significantly worse survival than similar tumors located on the extremities or the head and neck region. The factors impacting on risk of death from soft tissue sarcomas of the chest wall are presented in Table 19-23. All sarcomas have a propensity to spread to the lungs.

While many varieties of sarcoma exist, the primary features affecting prognosis are histologic grade and responsiveness to chemotherapy (Table 19-24). Preoperative (neoadjuvant) chemotherapy offers the ability to (a) assess tumor chemosensitivity by the degree of tumor size reduction and microscopic necrosis; (b) determine tumor sensitivity to specific chemotherapeutic agents; and (c) improve resectability by reducing tumor size. Patients whose tumors are responsive to preoperative chemotherapy have a much better prognosis than those with a poor response. Information about tumor response to chemotherapy, the patient's physiologic state and capacity to receive treatment, and metastatic disease status is used to determine optimal therapy. The initial treatment is either (a) preoperative chemotherapy (for patients with osteosarcoma, rhabdomyosarcoma, primitive neuroectodermal tumor, or Ewing's sarcoma) followed by surgery and postoperative chemotherapy; (b) primary surgical resection and reconstruction (for patients with nonmetastatic MFH, fibrosarcoma, liposarcoma, or synovial sarcoma); or (c) preoperative chemotherapy followed by surgical resection if indicated in patients presenting with metastatic soft tissue sarcomas. Contiguous involvement of underlying lung

or other soft tissues or the presence of pulmonary metastases does not preclude successful surgery. In fact, patients receiving surgical intervention have significantly better overall survival. Median survival with surgical resection is 25 months compared to 8 months without resection. Additional prognostic variables that are important for long-term survival include tumor size, grade, stage, and negative re-resection margin.¹³¹ With the exception of rhabdomyosarcomas, the primary treatment of these lesions is wide surgical resection with 4-cm margins and reconstruction.¹³²

The following is an overview of several chest wall sarcomas.

1. **Chondrosarcoma.** Chondrosarcomas are the most common primary chest wall malignancy. As with chondromas, they usually arise anteriorly from the costochondral arches. CT scan shows a radiolucent lesion often with stippled calcifications pathognomonic for chondrosarcomas (Fig. 19-41). The involved bony structures are also destroyed. Most chondrosarcomas are slow-growing, low-grade tumors; these often painful masses can reach massive proportions.¹²⁷ For this reason, any lesion in the anterior chest wall likely to be a low-grade chondrosarcoma should be treated with wide (4-cm) resection after metastatic disease to the lungs or bones is ruled out.

Chondrosarcomas are not sensitive to radiation or chemotherapy. Prognosis is determined by tumor grade and extent of resection. With a low-grade tumor and wide resection, patient survival at 5 to 10 years can be as high as 60% to 80%.

2. **Osteosarcoma.** While osteosarcomas are the most common bone malignancy, they represent only 10% to 15% of all malignant chest wall tumors.^{133,134} They primarily occur in young adults as rapidly enlarging, painful masses; however, osteosarcomas can occur in older patients as well,

Figure 19-40. Chest computed tomography scan showing a right chest wall tumor (arrow). Tissue diagnosis revealed that this mass was a leiomyosarcoma.

sometimes in association with previous radiation, Paget's disease, or chemotherapy. Radiographically, the typical appearance consists of spicules of new periosteal bone formation producing a sunburst appearance. Osteosarcomas have a propensity to spread to the lungs, and up to one-third of patients present with metastatic disease. Osteosarcomas are potentially sensitive to chemotherapy. Currently, pre-operative chemotherapy is common. After chemotherapy, complete resection is performed with wide (4-cm) margins, followed by reconstruction. In patients presenting with lung metastases that are potentially amenable to surgical resection, induction chemotherapy may be given, followed by surgical resection of the primary tumor and of the pulmonary metastases. Following surgical treatment of known disease, additional maintenance chemotherapy is usually recommended.

Figure 19-41. Chest computed tomography scan showing a right posterior lung tumor. In the appropriate clinical setting, stippled calcifications (white streaks in right lung mass) are highly indicative of chondrosarcomas.

- Malignant fibrous histiocytoma.** Originally thought to derive from histiocytes because of the microscopic appearance of cultured tumor cells, these tumors likely originate from the fibroblast. MFHs are generally the most common soft tissue sarcoma of late adult life, although they are rare on the chest wall. The typical age at presentation is between age 50 and 70 years. Presentation is pain, with or without a palpable mass. Radiographically, a mass is usually evident, with destruction of surrounding tissue and bone. Treatment is wide resection with a margin of 4 cm or more and reconstruction. Over two-thirds of patients suffer from distant metastasis or local recurrence.
- Liposarcoma.** Liposarcomas make up 15% of chest wall sarcomas. Most liposarcomas are low-grade tumors that have a propensity to recur locally, given their infiltrative nature. They typically present as a painless mass. Treatment is wide resection and reconstruction. Intraoperative margins should be evaluated (as with all sarcomas) and resection continued, if feasible, until margins are negative. Local recurrence can be treated with reexcision, with occasional use of radiotherapy.
- Fibrosarcoma.** Often presenting as a large, painful mass, these lesions are visible on plain radiograph or CT, with surrounding tissue destruction. Treatment is wide local excision with intraoperative frozen-section analysis of margins, followed by reconstruction. Local and systemic recurrence is frequent. Patient survival at 5 years is about 50% to 60%.
- Rhabdomyosarcoma.** Rhabdomyosarcomas are rare tumors of the chest wall. Microscopically, they are a spindle cell tumor. The diagnosis often depends on immunohistochemical staining for muscle markers. Rhabdomyosarcomas are sensitive to chemotherapy. Treatment consists of preoperative chemotherapy with subsequent surgical resection.

Other Tumors of the Chest Wall

- Primitive neuroectodermal tumors (PNETs) and Ewing's sarcoma.** PNETs (neuroblastomas, ganglioneuroblastomas, and ganglioneuromas) derive from primordial neural crest

cells that migrate from the mantle layer of the developing spinal cord. Histologically, PNETs and Ewing's sarcomas are small, round cell tumors; both possess a translocation between the long arms of chromosomes 11 and 22 within their genetic makeup. They also share a consistent pattern of proto-oncogene expression and have been found to express the product of the *MIC2* gene.

Ewing's sarcoma occurs in adolescents and young adults who present with progressive chest wall pain, but without the presence of a mass. Systemic symptoms of malaise and fever are often present. Laboratory studies reveal an elevated erythrocyte sedimentation rate and mild white blood cell elevation. Radiographically, the characteristic onion peel appearance is produced by multiple layers of periosteum in the bone formation. Evidence of bony destruction is also common. The diagnosis can be made by a percutaneous needle biopsy or an incisional biopsy.

These tumors have a strong propensity to metastasize to the lungs and skeleton; patient survival rates are thus only 50% or less at 3 years. Increasing tumor size is associated with decreasing survival. Treatment has improved significantly and now consists of multiagent chemotherapy, radiation therapy, and surgery. Patients are typically treated preoperatively with chemotherapy and reevaluated with radiologic imaging. When residual disease is identified, surgical resection and reconstruction are performed followed by maintenance chemotherapy.

- Plasmacytoma.** Solitary plasmacytomas of the chest wall are very rare, with approximately 25 to 30 cases per year in the United States.¹³³ The typical presentation is pain without a palpable mass. Plain radiographs show an osteolytic lesion in the region of the pain. As with other chest wall tumors, a needle biopsy under CT guidance is performed for diagnosis. Histologically, the lesion is identical to multiple myeloma, with sheets of plasma cells. It occurs at an average age of 55 years. Evaluation for systemic myeloma is performed with bone marrow aspiration, testing of calcium levels, and measurement of urinary Bence Jones proteins. If the results of these studies are negative, then a solitary

plasmacytoma is diagnosed. Surgery is usually limited to a biopsy only, which may be excisional.¹³⁴ Treatment consists of radiation with doses of 4000 to 5000 cGy. Up to 75% of patients develop systemic multiple myeloma with 10-year survival of approximately 20%.

Chest Wall Reconstruction

The primary determinant of long-term freedom from recurrence and overall survival is margin status; therefore, adequate margins of normal tissue must be included in the en bloc resection. En bloc resection should include involved ribs, sternum, superior sulcus, or spine if necessary; invasion of these structures should not be considered a contraindication to surgery in an otherwise fit patient. The resection should include at least one normal adjacent rib above and below the tumor, with all intervening intercostal muscles and pleura. In addition, an en bloc resection of overlying chest wall muscles is often necessary, such as of the pectoralis minor or major, serratus anterior, or latissimus dorsi. When the periphery of the lung is involved with the neoplasm, it is appropriate to resect the adjacent part of the pulmonary lobe in continuity (Fig. 19-42). Involvement of the sternum by a malignant tumor requires total resection of the sternum with the adjacent cartilage. Techniques for postoperative respiratory support are now good enough that resection should not be compromised because of any concern about the patient's ability to be adequately ventilated in the early postoperative period.

The extent of resection depends on the tumor's location and on any involvement of contiguous structures. Laterally based lesions often require simple wide excision, with resection of any contiguously involved lung, pleura, muscle, or skin. Anteriorly based lesions contiguous with the sternum require partial sternectomy. Primary malignant tumors of the sternum may require complete sternectomy. Posterior lesions involving the rib heads over their articulations with the vertebral bodies may, depending on the extent of rib involvement, require partial en bloc vertebrectomy.

Optimal management of larger tumors includes careful preoperative planning and execution of the surgery by the thoracic surgeon and an experienced plastic surgeon in

order to ensure optimal physiologic and cosmetic results. With these measures, reconstruction at the same operation can be accomplished.¹³⁵ Reconstruction of a large defect in the chest wall requires the use of some type of material to prevent lung herniation and to provide stability for the chest wall (see Fig. 19-42). Mild degrees of paradoxical motion are often well tolerated if the area of instability is relatively small. Historically, a wide variety of materials have been used to reestablish chest wall stability, including rib autografts, steel struts, acrylic plates, and numerous synthetic meshes. The current preference is either a 2-mm polytetrafluoroethylene (Gore-Tex) patch or a double-layer polypropylene (Marlex) mesh sandwiched with methylmethacrylate. There are several properties that make Gore-Tex an excellent material for use in chest wall reconstruction: (a) it is impervious to fluid, which prevents pleural fluid from entering the chest wall and minimizes the formation of seromas, which can compromise the myocutaneous flap viability and provide a nidus for infection; and (b) it provides excellent rigidity and stability when secured taut to the surrounding bony structure and, as a result, provides a firm platform for myocutaneous flap reconstruction. Except for smaller lesions, tissue coverage requires the use of myocutaneous flaps (latissimus dorsi, serratus anterior, rectus abdominis, or pectoralis major muscles).^{136,137}

MEDIASTINUM

Anatomy and Pathologic Entities

The mediastinum can be divided into compartments for classification of anatomic components and disease processes, which, despite substantial overlap, facilitates understanding of general concepts of surgical interest. Several classification schemes exist, but for the purposes of this chapter, the three-compartment model is used (Fig. 19-43). The anterior compartment lies between the sternum and the anterior surface of the heart and great vessels. The visceral or middle compartment is located between the great vessels and the trachea. As the name implies, the posterior compartment lies posterior and includes the paravertebral sulci, bilaterally, and the paraesophageal area.

A

B

Figure 19-42. Principles of reconstruction after resection of a chest wall tumor (osteogenic sarcoma) are shown. **A.** En bloc resection of the involved chest wall, including normal ribs above and below the tumor as well as pulmonary parenchyma, must be performed. The resected specimen is shown. **B.** A prosthesis has been sewn in place. In the lower third of the prosthesis, the line of diaphragm reattachment is seen. The skin defect was closed with a myocutaneous flap from the ipsilateral rectus muscle.

Figure 19-43. Anatomic division of the mediastinum.

The normal content of the anterior compartment includes the thymus gland or its remnant, the internal mammary artery and vein, lymph nodes, and fat. The thymus gland is large during childhood, occupying the entire anterior mediastinum (Fig. 19-44) but decreases in both thickness and length after adolescence and takes on a more fatty content, with only residual islands of thymic cellular components (Fig. 19-45). The middle mediastinal compartment contains the pericardium and its contents, the ascending and transverse aorta, the superior and inferior venae cavae, the brachiocephalic artery and vein, the phrenic and upper vagus nerves, the trachea and main bronchi and corresponding lymph nodes, and the central portions of the pulmonary arteries and veins. The posterior compartment contains the descending aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and lymph nodes. Numerous pathologic variants may be present in the various compartments, with much overlap. Table 19-25 includes the most common pathologic entities listed by compartment.^{138,139}

History and Physical Examination

Mediastinal pathology varies significantly by patient age. In children, neurogenic tumors of the posterior mediastinum are

most common, followed by lymphoma, which is usually located in the anterior or middle compartment. Thymoma in childhood is rare (Table 19-26). In adults, the most common tumors include neurogenic tumors of the posterior compartment, benign cysts occurring in any compartment, and thymomas of the anterior mediastinum (Table 19-27). In both age groups, about 25% of mediastinal tumors are malignant. Pediatric tumors will be discussed in Chapter 39.

Up to two-thirds of mediastinal tumors in adults are discovered as asymptomatic abnormalities on radiologic studies ordered for other problems, particularly now that screening CT examinations are more prevalent. When symptomatic, these tumors are significantly more likely to be malignant. Characteristics such as size, location, rate of growth, and associated inflammation are important factors that correlate with symptoms. Large, bulky tumors, expanding cysts, and teratomas can cause compression of mediastinal structures, in particular the trachea, and lead to cough, dyspnea on exertion, or stridor. Chest pain or dyspnea may be reported secondary to associated pleural effusions, cardiac tamponade, or phrenic nerve involvement. Occasionally, a mediastinal mass near the aortopulmonary window may be identified in a workup for hoarseness because of left recurrent laryngeal nerve involvement. The patient in Fig. 19-46 presented with hoarseness due to nodal compression of the left recurrent laryngeal nerve from a primary lung cancer with metastases to the level 5 and 6 lymph nodes in the region of the aortopulmonary window.

The history and physical examination in conjunction with the imaging findings may suggest a specific diagnosis (Table 19-28). In one series, systemic symptoms were present in 50% of patients with a mediastinal mass and a lymphoproliferative disorder, as compared with only 29% of patients with other masses (such as thymic or neurogenic). Laboratory signs of inflammation were also noted; the erythrocyte sedimentation rate and C-reactive protein levels were elevated and leukocytosis was present in 86% of patients with a lymphoproliferative disorder, as compared with only 58% of patients with other types of mediastinal masses.

Imaging and Serum Markers

Chest CT or MRI is required to fully delineate the anatomy.¹⁴⁰ A contrast-enhanced CT scan enables clear delineation of the

Figure 19-44. Normal appearance of the thymus gland in childhood. Ao = aorta; PA = pulmonary artery; VC = vena cava.

Figure 19-45. Computed tomography scan showing the normal appearance of an involuted thymus gland in an adult. Note the near-total fatty appearance of the gland with only tiny islands of soft tissue scattered within it (*small arrows*).

soft tissue structures from the vasculature and is preferred over noncontrast studies. If there is concern for invasion of vascular structures or spinal involvement, MRI is more accurate than CT scan and provides important information regarding resectability.

If an endocrine origin is suspected, several other imaging modalities are available (Table 19-29). Single-photon emission CT (SPECT) technology may be used to improve image contrast and give information on three-dimensional localization, largely replacing conventional two-dimensional nuclear imaging studies. If a thyroid origin is suspected, a thyroid scan using ^{131}I or ^{123}I can identify most intrathoracic goiters and identify the extent of functioning thyroid tissue. If indicated, the thyroid

scan should precede other scans requiring iodine-containing contrast agents because they would subsequently interfere with iodine tracer uptake by thyroid tissue. If a pheochromocytoma or neuroblastoma is suspected, the octreotide scan or ^{123}I -metaiodobenzylguanidine (MIBG) scans are helpful in diagnosis and localization. The sestamibi scan may be useful for diagnosing and localizing a mediastinal parathyroid gland. PET is useful for distinguishing malignant from benign tumors and may help detect distant metastases in some patients. However, the role of routine PET imaging for staging surgically resectable lesions of the mediastinum has not been established.

The use of serum markers to evaluate a mediastinal mass can be invaluable in some patients. For example, nonseminomatous and seminomatous germ cell tumors can frequently be diagnosed and often distinguished from one another by the levels of α -fetoprotein (AFP) and human chorionic gonadotropin (hCG). In over 90% of nonseminomatous germ cell tumors, either the AFP or the hCG level will be elevated. Results are close to 100% specific if the level of either AFP or hCG is greater than 500 ng/mL. Some centers institute chemotherapy based on this result alone, without biopsy confirmation of the diagnosis. In contrast, the AFP level in patients with mediastinal seminoma is always normal; only 10% will have elevated hCG, which is usually less than 100 ng/mL. Other serum markers, such as intact parathyroid hormone level for ectopic parathyroid

Table 19-25

Usual location of the common primary tumors and cysts of the mediastinum

ANTERIOR COMPARTMENT	VISCERAL COMPARTMENT	PARAVERTEBRAL SULCI
Thymoma	Enterogenous cyst	Neurilemoma-schwannoma
Germ cell tumor	Lymphoma	Neurofibroma
Lymphoma	Pleuropericardial cyst	Malignant schwannoma
Lymphangioma	Mediastinal granuloma	Ganglioneuroma
Hemangioma	Lymphoid hamartoma	Ganglioneuroblastoma
Lipoma	Mesothelial cyst	Neuroblastoma

adenomas, may be useful for diagnosing and also for intraoperatively confirming complete resection. After successful resection of a parathyroid adenoma, this hormone level should rapidly normalize.

Diagnostic Nonsurgical Biopsies of the Mediastinum

The treatment of up to 60% of patients with anterior mediastinal masses is ultimately nonsurgical, so it is essential to understand all options for obtaining adequate tissue for a definitive diagnosis using the least invasive approach. CT-guided needle biopsy, EBUS- and EUS-guided FNA, and even core-needle biopsy (either CT-guided and EUS-guided) have proven most useful for cytologic and tissue diagnosis of mediastinal masses and lymphadenopathy.

When FNA and core-needle biopsy were combined, the accuracy was 98%, compared to 79% for each modality independently. In addition, core-needle biopsy changed the diagnosis in nine cases that had been missed by FNA due to inadequate specimens. Finally, core-needle biopsy was better at diagnosis for benign diseases compared to FNA. Accessible nodal stations

Table 19-28

Signs and symptoms suggestive of various diagnoses in the setting of a mediastinal mass

DIAGNOSIS	HISTORY AND PHYSICAL FINDINGS	COMPARTMENT LOCATION OF MASS
Lymphoma	Night sweats, weight loss, fatigue, extrathoracic adenopathy, elevated erythrocyte sedimentation rate or C-reactive protein level, leukocytosis	Any compartment
Thymoma with myasthenia gravis	Fluctuating weakness, early fatigue, ptosis, diplopia	Anterior
Mediastinal granuloma	Dyspnea, wheezing, hemoptysis	Visceral (middle)
Germ cell tumor	Male gender, young age, testicular mass, elevated levels of human chorionic gonadotropin and/or α -fetoprotein	Anterior

include subcarinal (level 7), aortopulmonary (level 5), paraesophageal (level 8), and inferior pulmonary ligament (level 9) as well as paratracheal (level 4).¹⁴¹ Technical expertise in these modalities should be pursued by thoracic and general surgeons.

Historically, needle biopsies of anterior mediastinal masses were reportedly sensitive and specific for most carcinomatous tumors, but there were questions regarding accuracy for diagnosing lymphomas.¹⁴² However, advances in cytopathology as well as needle biopsy technology have substantially improved diagnostic accuracy such that most centers are reporting yields ranging from 75% to 80% for the diagnosis of lymphoma as well. To achieve maximal diagnostic yield for mediastinal masses suggestive of a lymphoma, it is necessary to obtain multiple fine-needle aspirates, preferably with immediate onsite rapid cytologic analysis to confirm sampling of the target tissue and adequate cellularity. This also facilitates processing of the sample to ensure that proper studies for lymphoma, including flow cytometry, are obtained. If the needle biopsy is inconclusive, surgical biopsy can be performed.^{143,144} If the lesion is accessible by CT-guided or EUS-guided core-needle biopsy, intraoperative frozen section or immediate cytologic smear of a core biopsy can also be performed. Currently, core-needle biopsy with EBUS is not possible. The authors perform their own endobronchial, endoscopic, and CT-guided transbronchial and transthoracic biopsies, and in our experience, lack of cellularity in the aspirate is readily apparent. In general, plans to proceed with surgical biopsy are made in combination with the image-guided aspiration and, as such, are performed in the same setting. This enables the authors to avoid a more invasive surgical procedure when FNA or core-needle biopsy is sufficient without contributing to delays in diagnosis by having multiple attempts from multiple providers (such as interventional radiology and pulmonology) before involvement of the surgeon in the diagnostic workup.

Table 19-29

Nuclear imaging relevant to the mediastinum

RADIOPHARMACEUTICAL, RADIONUCLIDE, OR RADIOCHEMICAL	LABEL	DISEASE OF INTEREST
Iodine	¹³¹ I, ¹²³ I	Retrosternal goiter, thyroid cancer
Monoclonal antibodies	¹¹¹ In, ^{99m} Tc	NSCLC, colon and breast cancer, prostate cancer metastases
Octreotide	¹¹¹ In	Amine precursor uptake decarboxylation tumors: carcinoid, gastrinoma, insulinoma, small cell lung cancer, pheochromocytoma, glucagonoma, medullary thyroid carcinoma, paraganglioma
Gallium	⁶⁷ Ga	Lymphoma, NSCLC, melanoma
Sestamibi	^{99m} Tc	Medullary thyroid carcinoma, nonfunctional papillary or follicular thyroid carcinoma, Hürthle cell thyroid carcinoma, parathyroid adenoma or carcinoma
Thallium	²⁰¹ Tl	See sestamibi

Surgical Biopsies and Resection of Mediastinal Masses

For tumors of the mediastinum that are not amenable to an endoscopic or CT-guided needle biopsy or that do not yield sufficient tissue for diagnosis, a surgical biopsy is indicated. The definitive approach to a surgical biopsy of the anterior mediastinum is through a median sternotomy. At the time of sternotomy, if the lesion is easily resectable, it should be completely removed. Given the invasiveness of the procedure and the inability in some patients to obtain a definitive diagnosis by frozen section, less invasive procedures are preferable if the lesion is large or if the CT scan or history suggests that surgery is not the best definitive treatment.

Masses in the paratracheal region are easily biopsied by mediastinoscopy. For tumors of the anterior or posterior mediastinum, a left or right VATS approach often allows safe and adequate surgical biopsies. In some patients, an anterior mediastinotomy (i.e., Chamberlain procedure) may be ideal for an anterior tumor or a tumor with significant parasternal extension. Before a surgical biopsy is pursued, a discussion should be held with the pathologist regarding routine histologic assessment, special stains and markers, and requirements for lymphoma workup.

Surgical resection using minimally invasive approaches, including video-assisted and robotic thoracoscopic surgery and transcervical, are now routine for the vast majority of middle and posterior tumors and for moderate sized (<5 to 6 cm) anterior mediastinal tumors.¹⁴⁵⁻¹⁴⁸ Outcomes comparing VATS to open thymectomy in patients with myasthenia gravis without thymoma were prospectively evaluated by Chang and colleagues in 2005, and no differences were seen in terms of response to therapy and recurrence of symptoms. Pain scores were significantly better in the VATS approach.¹⁴⁹ These reports and others support application of VATS for the majority of anterior mediastinal masses.

Other minimally invasive approaches are under study. For example, good results have been reported using a cervical

incision with a sternal retractor for thymus removal. The upward lift allows the surgeon reasonable access to the anterior mediastinum and has proven adequate in some centers for definitive resection of the thymus gland for myasthenia gravis.¹⁵⁰

For larger anterior mediastinal masses or in centers where expertise in thoracoscopy is not available, median sternotomy and thoracotomy remain excellent options for resection of anterior mediastinal masses. Occasionally, a lateral thoracotomy with sternal extension (hemi-clamshell) provides excellent exposure for extensive mediastinal tumors that have a lateral component.

Most surgeons would agree that if a larger anterior mediastinal tumor is seen or malignancy is suspected, a median sternotomy with a more radical resection should be performed.

Mediastinal Neoplasms

Thymic Hyperplasia. Diffuse thymic hyperplasia was first described in children after successful chemotherapy for lymphoma. It has now been described in adults and is referred to as “rebound thymic hyperplasia.”¹⁵¹ It is most frequently reported after chemotherapy for lymphoma or germ cell tumors. Initially, atrophy of the thymic gland is seen with subsequent thymic gland enlargement, which can be dramatic. The usual time course for thymic hyperplasia is about 9 months after cessation of chemotherapy (range 2 weeks to 12 months). Benign hyperplasia must be clearly distinguished from recurrent lymphoma or germ cell tumors, which may be difficult since thymic hyperplasia is dramatic in some patients; careful follow-up with serial CT scans is the minimum requirement. The role of PET scanning is unclear. Thymic hyperplasia is a known cause of false-positive PET scans; in many patients, CT scan will show a triangular soft tissue density in the retrosternal space that has a characteristic bilobed anatomic appearance consistent with thymus gland.¹⁵² In addition, a low standardized uptake value of tracer on PET scan suggests a benign tumor.¹⁵³ Biopsies may be required if the clinical index of suspicion is high.

Thymoma. While it is the most frequently encountered neoplasm of the anterior mediastinum in adults (seen most frequently between 40 and 60 years of age), thymoma is rare in children. Between 10% and 50% of patients with thymoma will have symptoms suggestive of myasthenia gravis or have circulating antibodies to acetylcholine receptor, but less than 10% of patients with myasthenia gravis have a thymoma. Most patients with thymoma are asymptomatic. Thymectomy leads to improvement or resolution of symptoms of myasthenia gravis in only about 25% of patients with thymomas. In contrast, in patients with myasthenia gravis and no thymoma, thymectomy results are superior: up to 50% of patients have a complete remission, and 90% improve. In 5% of patients with thymomas, other paraneoplastic syndromes, including red cell aplasia, hypogammaglobulinemia, systemic lupus erythematosus, Cushing's syndrome, or SIADH, may be present. Large thymic tumors may present with symptoms related to a mass effect, which may include cough, chest pain, dyspnea, or SVC syndrome.

The diagnosis may be suspected based on CT scan and history, but imaging alone is not diagnostic. In most centers, the diagnosis is made after surgical resection because of the relative difficulty of obtaining a needle biopsy and the likelihood that removal will ultimately be recommended. Biopsy should be avoided in cases where imaging is highly suggestive of thymoma. In most patients, the distinction between lymphomas and thymomas can be made on CT scan since most lymphomas have marked lymphadenopathy and thymomas most frequently appear as a solitary encapsulated mass. PET scan may have a role in differentiating thymic cancer from thymoma, as thymic cancer tends to be very FDG avid.¹⁵³ In addition, PET scan may facilitate identification of low-risk and minimally invasive thymoma; a standardized uptake value (SUV) <5 was associated with Masaoka stage I or II thymoma, whereas invasive thymoma and mediastinal lymphoma were more likely when the SUV was >5.¹⁵⁴ In cases where the diagnosis is unclear, transmediastinal, not transpleural, CT-guided FNA biopsy has a diagnostic sensitivity of 87% and a specificity of 95% in specialized centers.

The most commonly accepted staging system for thymoma is that of Masaoka.¹⁵⁵ It is based on the presence or absence of gross or microscopic invasion of the capsule and of surrounding structures, as well as on the presence or absence of metastases (Table 19-30). Histologically, thymomas are characterized by a mixture of epithelial cells and mature lymphocytes. Grossly, many thymomas remain well encapsulated. Even those with capsular invasion often lack histologic features of malignancy;

they appear cytologically benign and identical to early-stage tumors. This lack of classic cellular features of malignancy is why most pathologists use the term “thymoma” or “invasive thymoma” rather than “malignant thymoma.” Thymic tumors with malignant cytologic features are classified separately and referred to as “thymic carcinoma.”

The definitive treatment for thymoma is complete surgical removal; local recurrence rates and survival vary according to stage (Fig. 19-47). In centers with significant experience with VATS procedures, thymoma is not a contraindication to VATS approach, provided the principles of resection are adhered to, such as a complete resection without disrupting the capsule.¹⁵⁶ Otherwise, resection is generally accomplished by median sternotomy with extension to hemi-clamshell in more advanced cases. Even advanced tumors with local invasion of resectable structures such as the pericardium, SVC, or innominate vessels should be considered for resection with reconstruction.

A multidisciplinary approach to nonresectable and more advanced lesions (stage ≥II) is mandatory to optimize patient care. The goal for surgical resection should be complete excision of the mass with total thymectomy. All contiguous and noncontiguous disease is removed at the same setting; this may include resection of the pericardium or pleura, adjacent adherent lung, phrenic nerve, major vascular structures, and pleural metastasis. Bilateral phrenic nerve resection should be avoided, however, due to the major respiratory morbidity associated with bilateral paralyzed hemidiaphragms.

The role of adjuvant or neoadjuvant therapies for advanced-stage tumors remains unclear. Traditionally, stage II thymomas have been treated by complete surgical resection followed by mediastinal radiation, but randomized trials have not been done. A recent retrospective review of a single-institution series of stage II thymoma patients showed no difference in survival or local recurrence after complete surgical resection alone, as compared with surgical resection with radiotherapy. Advanced thymomas have been shown to respond to platinum-based chemotherapy and to corticosteroids.¹⁵⁷ One summary of chemotherapy trials showed an overall response rate of about 70%. Cisplatin/doxorubicin-based regimens appear to yield the best results. The combination radiotherapy and chemotherapy for local progression appears to prolong survival in some small series.¹⁵⁸ Radiation therapy in surgically resected stage III thymoma is likely beneficial in extending disease-specific survival; an analysis of the Surveillance, Epidemiology, and End Results (SEER) database identified 476 patients with stage III thymoma treated with primary surgery. Postoperative radiation was given

Table 19-30

Masaoka staging system for thymoma

Stage I	Encapsulated tumor with no gross or microscopic evidence of capsular invasion
Stage II	Gross capsular invasion or invasion into the mediastinal fat or pleura or microscopic capsular invasion
Stage III	Gross invasion into the pericardium, great vessels, or lung
Stage IVA	Pleural or pericardial dissemination
Stage IVB	Lymphogenous or hematogenous metastasis

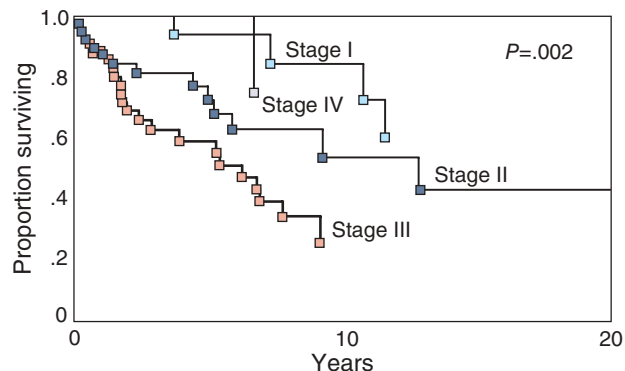

Figure 19-47. Stage-specific survival for thymomas.

to 322 patients with a significant improvement in survival (127 months compared to 105 months, $P = .038$) despite the fact that these patients were more likely to have had debulking rather than curative resection. In multivariate analysis, disease-specific survival was better in the adjuvant radiation group.¹⁵⁹ Therefore, it is imperative that all patients with thymomas undergo a thorough evaluation for potential resection. Current guidelines recommend radiation for patients with unresectable thymoma who have failed induction chemotherapy or for patients with incompletely resected invasive thymoma or thymic cancer. Planning the radiation ports requires input from the surgeon; it is important for the surgeon to carefully document areas of adherence between the thymoma and adjacent structures during the operation, with clips or other radiopaque markers placed to guide radiation therapy postoperatively. Extracapsular extension and positive surgical margins should be noted by the pathologist and correlated anatomically so that the surgeon and radiation oncologist can ensure appropriate radiation treatment.

Thymic Carcinoma. Thymic carcinomas are unequivocally malignant at the microscopic level. Suster and Rosai classified thymic carcinomas into low-grade and high-grade tumors.¹⁶⁰ Low-grade tumors are well differentiated with squamous cell, mucoepidermoid, or basaloid features. High-grade thymic carcinomas include those with lymphoepithelial, small cell neuroendocrine, sarcomatoid, clear cell, and undifferentiated or anaplastic features. Care must be taken to differentiate thymic carcinoma from lung cancer metastatic to the thymus gland as the histologic features can be similar between the two. Compared with thymomas, they are a more heterogeneous group of malignancies with a propensity for early local invasion and widespread metastases. Malignant pleural and pericardial effusions occur frequently.

Five-year survival rates are between 30% and 50%. Complete resection is occasionally curative and leads to improved survival, but most thymic carcinomas will recur and are

refractory to chemotherapy.¹⁵⁷ Management, therefore, depends on the completeness of the resection. Postoperative care includes radiation therapy, guided by residual gross disease or microscopically positive margins from the resection specimen. Chemotherapy may also be given, with carboplatin/paclitaxel recommended based on the best response rates with the least toxicity in clinical trials. The prognosis of patients with thymic cancer remains poor.

Thymolipoma. Thymolipomas are rare benign tumors that may grow to a very large size prior to diagnosis. On CT scan, their appearance can be dramatic, with a characteristic fat density dotted by islands of soft tissue density representing islands of thymic tissue (Fig. 19-48). Thymolipomas are generally well-encapsulated, soft, and pliable masses that do not invade surrounding structures. Resection is recommended for large masses.

Neurogenic Tumors. Most neurogenic tumors of the mediastinum arise from the cells of the nerve sheath, from ganglion cells, or from the paraganglionic system (Table 19-31). The incidence, cell types, and risk of malignancy strongly correlate with patient age. Tumors of nerve sheath origin predominate in adults. Most present as asymptomatic incidental findings, and most are benign. In children and young adults, tumors of the autonomic ganglia predominate, with up to two-thirds being malignant.¹⁶¹

Nerve Sheath Tumors. Nerve sheath tumors account for 20% of all mediastinal tumors. More than 95% of nerve sheath tumors are benign neurilemmas or neurofibromas. Malignant neurosarcomas are much less common.

Neurilemma. Neurilemmas, also called schwannomas, arise from Schwann cells in intercostal nerves. They are firm, well encapsulated, and generally benign. Two characteristic histologic components are referred to as Antoni type A and Antoni type B regions. Antoni type A regions contain compact spindle

Figure 19-48. Massive thymolipoma that was asymptomatic in an 18-year-old female.

Table 19-31

Classification of neurogenic tumors of the mediastinum

TUMOR ORIGIN	BENIGN	MALIGNANT
Nerve sheath	Neurilemoma, neurofibroma, melanotic schwannoma, granular cell tumor	Neurofibrosarcoma
Ganglion cell	Ganglioneuroma	Ganglioneuroblastoma, neuroblastoma
Paraganglionic cell	Chemodectoma, pheochromocytoma	Malignant chemodectoma, malignant pheochromocytoma

Reproduced with permission from Pearson FG, Cooper JD, Deslauriers J, et al: *Thoracic Surgery*, 2nd ed. New York, NY: Elsevier/Churchill Livingstone; 2002.

cells with twisted nuclei and nuclear palisading. Antoni type B regions contain loose and myxoid connective tissue with haphazard cellular arrangement. These characteristics distinguish neurilemoma from malignant fibrosarcomatous tumors, which lack encapsulation and have no Antoni features. If routine CT scan suggests extension of a neurilemoma into the intervertebral foramen, MRI is used to evaluate the extent of this “dumbbell” configuration (Fig. 19-49). Such a configuration may lead to cord compression and paralysis and requires a more complex surgical approach. Resection is recommended; VATS has been established as safe and effective for simple and, in experienced centers, even the more complex operations.¹⁶² It is reasonable to follow small, asymptomatic paravertebral tumors in older patients or in patients at high risk for surgery. In children, ganglioneuroblastomas or neuroblastomas are more common; therefore, all neurogenic tumors should be completely resected.

Neurofibroma. Neurofibromas consist of both nerve sheath and nerve cells and account for up to 25% of nerve sheath tumors. Up to 40% of patients with mediastinal fibromas have generalized neurofibromatosis (von Recklinghausen’s disease). About 70% of neurofibromas are benign, but malignant degeneration to neurofibrosarcoma occurs in 25% to 30% of patients.¹⁶³ The risk of malignant degeneration increases with advancing age, von Recklinghausen’s disease, and exposure to previous radiation. Neurofibrosarcomas carry a poor prognosis because of rapid growth and aggressive local invasion along nerve bundles. Complete surgical resection is the mainstay of treatment. Adjuvant radiotherapy or chemotherapy does not confer a significant benefit, but may be added if complete resection is not possible.¹⁶⁴ The 5-year survival rate is 53%, but it drops to 16% in patients with neurofibromatosis or with large tumors (>5 cm).

Ganglion Cell Tumors Ganglion cell tumors (ganglioneuromas, ganglioneuroblastomas, and neuroblastomas) arise from the sympathetic chain or from the adrenal medulla.

1. **Ganglioneuroma.** Well-differentiated, benign tumors characterized histologically by well-differentiated ganglion cells with a background of Schwann cells, these are most often found incidentally in asymptomatic young adults. Diarrhea related to secretion of a vasoactive intestinal peptide has been described in some patients. These tumors have a propensity for intraspinal canal extension, although they remain well-encapsulated; complete resection is curative, with a low risk of local recurrence.

Figure 19-49. Magnetic resonance image of a neurogenic tumor with extension into the spinal canal via the foramen, giving a typical dumbbell appearance.

2. **Ganglioneuroblastoma.** Ganglioneuroblastomas contain a mixture of benign ganglion cells and malignant neuroblasts. The distribution of these cells within the tumor is predictive of the clinical course. The nodular pattern has a high incidence of metastatic disease, whereas the diffuse pattern rarely metastasizes. Gross examination typically reveals encapsulated tumor; histologically, there are focal calcifications around regions of neuroblasts. Ganglioneuroblastomas arise most frequently in infants and children <3 years old. The majority are resectable, with 80% 5-year survival.
3. **Neuroblastoma.** Highly malignant, neuroblastomas are the most common extracranial solid malignancy of childhood. The primary site is intrathoracic malignancy in 14%; extension into the spinal canal and osseous invasion commonly present. These thoracic tumors are not as recalcitrant to chemotherapy and surgical resection as other chest malignancies; they are more likely to be resectable, with less invasion of surrounding organs. More than half occur in children under 2 years old; 90% arise within the first decade of life, and thus, these malignancies are discussed in more detail in Chapter 39.

Paraganglionic Tumors. Paraganglionic tumors arising in the thoracic cavity include chemodectomas and pheochromocytomas. Only 10% of all pheochromocytomas are located in an extra-adrenal site. Intrathoracic pheochromocytomas are one of the rarest tumors.

Approximately 10% of thoracic pheochromocytomas are malignant, a rate similar to that of adrenal tumors. The most common thoracic location is within the costovertebral sulcus, but paraganglionic tumors also arise within the visceral compartment of the mediastinum. These catecholamine-producing lesions can lead to life-threatening hemodynamic problems, so complete removal is important. Diagnosis is generally confirmed by measuring elevated levels of urinary catecholamines and their metabolites. Localization is by CT scan, aided by MIBG scintigraphy. Preoperative care includes α - and β -adrenergic blockade to prevent intraoperative malignant hypertension and arrhythmias. These tumors tend to be highly vascular and should be approached with care. Chemodectomas are rare tumors that may be located around the aortic arch, vagus nerves, or aorticosympathetics. They rarely secrete catecholamines and are malignant in up to 30% of patients.

Lymphoma. Overall, lymphomas are the most common malignancy of the mediastinum. In about 50% of patients who have both Hodgkin's and non-Hodgkin's lymphoma, the mediastinum may be the primary site. The anterior compartment is most commonly involved, with occasional involvement of the middle compartment and hilar nodes. The posterior compartment is rarely involved. Chemotherapy and/or radiation results in a cure rate of up to 90% for patients with early-stage Hodgkin's disease and up to 60% with more advanced stages.

Mediastinal Germ Cell Tumors. Germ cell tumors are uncommon neoplasms, but they are the most common malignancy in young men 15 to 35 years of age. Most germ cell tumors are gonadal in origin; primary mediastinal germ cell tumors comprise less than 5% of all germ cell tumors and less than 1% of all mediastinal tumors (usually occurring in the anterior compartment). If a malignant mediastinal germ cell tumor is found, it is important to exclude a gonadal primary tumor. Primary

mediastinal germ cell tumors (including teratomas, seminomas, and nonseminomatous malignant germ cell tumors) are a heterogeneous group of benign and malignant neoplasms thought to originate from primitive pluripotent germ cells "misplaced" in the mediastinum during embryonic development. Previously, most mediastinal germ cell tumors were thought to be metastatic. However, two lines of evidence suggest that many mediastinal germ cell tumors are primary, developing from pluripotent primordial germ cells in the mediastinum: (a) several autopsy series showed that patients with extragonadal sites of germ cell tumors, presumed previously to have originated from the gonads, had no evidence of an occult primary tumor or of any residual scar of the gonads, even after an exhaustive search; and (b) patients treated by surgery or radiation for their mediastinal germ cell tumors had long-term survival with no late testicular recurrences.¹⁶⁵

About one-third of all primary mediastinal germ cell tumors are seminomatous. Two-thirds are nonseminomatous tumors or teratomas. Treatment and prognosis vary considerably within these two groups. Mature teratomas are benign and can generally be diagnosed by the characteristic CT findings of multilocular cystic tumors, encapsulated with combinations of fluid, soft tissue, calcium, and/or fat attenuation in the anterior compartment. FNA biopsy alone may be diagnostic for seminomas, usually with normal serum markers, including hCG and AFP. In 10% of seminomas, hCG levels may be slightly elevated. FNA findings, along with high hCG and AFP levels, can accurately diagnose nonseminomatous tumors. If the diagnosis remains uncertain after assessment of FNA findings and serum marker levels, then core-needle biopsies or surgical biopsies may be required. Thoracoscopy is the most frequent diagnostic surgical approach.

1. **Seminoma.** Most patients with seminomas have advanced disease at the time of diagnosis and present with symptoms of local compression, including SVC syndrome, dyspnea, or chest discomfort. With advanced disease, the preferred treatment is combination cisplatin-based chemotherapy regimens with bleomycin and either etoposide or vinblastine. Complete responses have been reported in over 75% of patients treated with these regimens. Surgical resection may be curative for small asymptomatic seminomas that are found incidentally with screening CT scans. Surgical resection of residual masses after chemotherapy may be indicated.
2. **Nonseminomatous germ cell tumors.** Nonseminomatous germ cell tumors include embryonal cell carcinomas, choriocarcinomas, endodermal sinus tumors, and mixed types. They are often bulky, irregular tumors of the anterior mediastinum with areas of low attenuation on CT scan because of necrosis, hemorrhage, or cyst formation. Frequently, adjacent structures have been involved, with metastases to regional lymph nodes, pleura, and lungs. Lactate dehydrogenase (LDH), AFP, and hCG levels are frequently elevated. Chemotherapy is the preferred treatment and includes combination therapy with cisplatin, bleomycin, and etoposide, followed by surgical resection of residual disease. With this regimen, survival is 67% at 2 years and 60% at 5 years. Surgical resection of residual masses is indicated, as it may guide further therapy. Up to 20% of residual masses contain additional tumors; in another 40%, mature teratomas; and the remaining 40%, fibrotic tissue.

It is important to note that oxygen toxicity can occur in patients who have been exposed to bleomycin; high levels of oxygen supplementation in the perioperative setting should be avoided in these patients as respiratory failure and death can ensue.¹⁶⁶ Factors independently predictive of survival after induction chemotherapy followed by resection are elevated serum tumor markers after resection, postchemotherapy pathologic findings (complete necrosis vs. teratoma), and persistent germ cell or non-germ cell cancer in the pathologic specimen.¹⁶⁶

3. **Teratoma.** Teratomas are the most common type of mediastinal germ cell tumors, accounting for 60% to 70% of mediastinal germ cell tumors. They contain two or three embryonic layers that may include teeth, skin, and hair (ectodermal), cartilage and bone (mesodermal), or bronchial, intestinal, or pancreatic tissue (endodermal). Therapy for mature, benign teratomas is surgical resection, which confers an excellent prognosis. Rarely, teratomas may contain a focus of carcinoma; these malignant teratomas (or teratocarcinomas) are locally aggressive. Often diagnosed at an unresectable stage, they respond poorly to chemotherapy and in a limited manner to radiotherapy; prognosis is uniformly poor.

Mediastinal Cysts

Benign cysts account for up to 25% of mediastinal masses and are the most frequently occurring mass in the middle mediastinal compartment. A CT scan showing characteristic features of near water density in a typical location is virtually 100% diagnostic.¹⁶⁷

1. **Pericardial cyst.** Usually asymptomatic and detected incidentally in the right costophrenic angle, pericardial cysts typically contain a clear fluid and are lined with a single layer of mesothelial cells. For most simple, asymptomatic pericardial cysts, observation alone is recommended. Surgical resection or aspiration may be indicated for complex cysts or large symptomatic cysts.
2. **Bronchogenic cyst.** Developmental anomalies that occur during embryogenesis and occur as an abnormal budding of the foregut or tracheobronchial tree, bronchogenic cysts arise most often in the mediastinum just posterior to the carina or main stem bronchus. Approximately 15% occur within the pulmonary parenchyma. Thin-walled and lined with respiratory epithelium, they contain a protein-rich mucoid material and varying amounts of seromucous glands, smooth muscle, and cartilage. They may communicate with the tracheobronchial tree. In adults, over half of all bronchogenic cysts are found incidentally during workup for an unrelated problem or during screening. The natural history of an incidentally diagnosed, asymptomatic bronchogenic cyst is unknown, but it is clear that many such cysts do not lead to clinical problems. In one study of young military personnel, 78% of all bronchogenic cysts found on routine CXRs were asymptomatic. However, in other reports with more comprehensive follow-up, up to 67% of adults with incidentally found bronchogenic cysts eventually became symptomatic. Symptoms include chest pain, cough, dyspnea, and fever. If large (>6 cm) or symptomatic, resection is generally recommended since serious complications may occur if the cyst becomes larger or infected.

Complications include airway obstruction, infection, rupture, and, rarely, malignant transformation.^{168,169}

Traditionally, complete removal of the cyst wall has been via posterolateral thoracotomy.¹⁷⁰ Resection of infected cysts may be quite difficult because of dense adhesions; elective removal is often recommended before infection has a chance to occur. Thoracoscopic exploration and resection are possible for small cysts with minimal adhesions. With increasing experience using video-assisted or robotic-assisted thoracoscopy, a greater proportion of these lesions are amenable to minimally invasive resection.

3. **Enteric cyst.** Most clinicians agree that in contrast to bronchogenic cysts, esophageal cysts should be removed, regardless of the presence or absence of symptoms. Esophageal cysts have a propensity for serious complications secondary to enlargement, leading to hemorrhage, infection, or perforation. Thus, surgical resection is the treatment of choice in both adults and children. As with bronchogenic cysts, experienced surgeons are approaching enteric cyst resections using minimally invasive techniques with great success.
4. **Thymic cyst.** Generally asymptomatic, thymic cysts are often discovered incidentally. Simple cysts are of no consequence; however, the occasional cystic neoplasm must be ruled out. Cystic components occasionally are seen in patients with thymoma and Hodgkin's disease.
5. **Ectopic endocrine glands.** Up to 5% of all mediastinal masses are of thyroid origin; most are simple extensions of thyroid masses. Usually nontoxic, over 95% can be completely resected through a cervical approach. True ectopic thyroid tissue of the mediastinum is rare. About 10% to 20% of abnormal parathyroid glands are found in the mediastinum; most can be removed during exploration from a cervical incision. In cases of true mediastinal parathyroid glands, thoracoscopic or open resection may be indicated. Location can generally be pinpointed by a combination of CT scan and Sestamibi scans.

Mediastinitis

Acute Mediastinitis. Acute mediastinitis is a fulminant infectious process that spreads rapidly along the continuous fascial planes connecting the cervical and mediastinal compartments. Infections originate most commonly from esophageal perforations, sternal infections, and oropharyngeal or neck infections, but a number of less common etiologic factors can lead to this deadly process (Table 19-32). Clinical signs and symptoms include fever, chest pain, dysphagia, respiratory distress, and cervical and upper thoracic subcutaneous crepitus. In severe cases, the clinical course can rapidly deteriorate to florid sepsis, hemodynamic instability, and death. Thus, a high index of suspicion is required in the context of any infection with access to the mediastinal compartments.

A chest CT scan illuminates the extent of spread and guides selection of the best approach to surgical drainage. Acute mediastinitis is a true surgical emergency; treatment must be instituted immediately and aimed at correcting the primary problem, such as the esophageal perforation or oropharyngeal abscess, and debridement and drainage of the spreading infectious process within the mediastinum, neck, pleura, and other tissue planes. Antibiotics, fluid resuscitation, and other supportive measures are also important.

Table 19-32

Etiologic factors in acute mediastinitis**Esophageal perforation**

Iatrogenic

Debridement may need to be repeated and other planes and cavities explored depending on the patient's clinical status. Blood cell counts and serial CT scans may also be required. Persistent sepsis or collections on CT scan may require further radical surgical debridement.

Chronic Mediastinitis. Sclerosing or fibrosing mediastinitis results from chronic mediastinal inflammation that originates in the lymph nodes, most frequently from granulomatous infections such as histoplasmosis or tuberculosis. Chronic, low-grade inflammation leads to fibrosis and scarring, which can, in some patients, result in entrapment and compression of the low-pressure veins (including the SVC and innominate and azygos veins), the esophagus, and pulmonary arteries. There is no definitive treatment. Surgery is indicated only for diagnosis or in specific patients to relieve airway or esophageal obstruction or to achieve vascular reconstruction. Reports of palliative success with less invasive procedures (such as dilation and stenting of airways, the esophagus, or the SVC) are promising. In one series of 22 patients, ketoconazole was effective in controlling progression. In another series of 71 patients, 30% died from

disease-associated complications during long-term follow-up. Chronic mediastinitis is similar to retroperitoneal fibrosis, sclerosing cholangitis, and Riedel's thyroiditis.

PLEURA AND PLEURAL SPACE**Anatomy**

Each hemithorax has a mesothelial lining that invaginates at the hilum of each lung and continues on to cover each lung. The portion lining the bony rib cage, mediastinum, and diaphragm is called the parietal pleura, whereas the portion encasing the lung is known as the visceral pleura. Between these two surfaces is the potential pleural space, which is normally occupied by a thin layer of lubricating pleural fluid. A network of somatic, sympathetic, and parasympathetic fibers innervates the parietal pleura. Irritation of the parietal surface by inflammation, tumor invasion, trauma, and other processes can lead to a sensation of chest wall pain. The visceral pleura have no somatic innervation.^{171,172}

Pleural Effusion

Pleural effusion refers to any significant collection of fluid within the pleural space. Normally, between 5 and 10 L of fluid enters the pleural space each day by filtration through microvessels supplying the parietal pleura (located mainly in the less dependent regions of the cavity). The net balance of pressures in these capillaries leads to fluid flow from the parietal pleural surface into the pleural space, and the net balance of forces in the pulmonary circulation leads to absorption through the visceral pleura. Normally, 15 to 20 mL of pleural fluid is present at any given time. Any disturbance in these forces can lead to imbalance and accumulation of pleural fluid. Common pathologic conditions in North America that lead to pleural effusion include congestive heart failure, bacterial pneumonia, malignancy, and pulmonary emboli (Table 19-33).¹⁷³

Access and Drainage of Pleural Fluid Collections

Most patients with pleural effusions of unknown cause should undergo thoracentesis with the following exceptions: effusions in the setting of congestive heart failure, hepatic failure or renal failure, or small effusions associated with an improving pneumonia. If the clinical history suggests congestive heart failure as a cause, particularly in the setting of bilateral effusions, a trial of diuresis may be indicated (rather than thoracentesis). Up to 75% of effusions due to congestive heart failure resolve within 48 hours with diuresis alone. Similarly, thoracentesis can be avoided in patients with small effusions associated with resolving pneumonia. These patients typically present with cough, fever, leukocytosis, and unilateral infiltrate, and the effusion is usually a result of a reactive, parapneumonic process. If the effusion is small and the patient responds to antibiotics, a diagnostic thoracentesis may be unnecessary. If the effusion is large and compromising respiratory efforts, or if the patient has a persistent white blood cell count despite improving signs of pneumonia, an empyema of the pleural space must be considered. In these patients, early and aggressive drainage with chest tubes is required, possibly with surgical intervention.

Once the decision is made to access a pleural effusion, the next step is to determine if a sample of the fluid or complete drainage of the pleural space is desired. This step is influenced by the clinical history, the type and amount of fluid present, the

Table 19-33

Leading causes of pleural effusion in the United States, based on data from patients undergoing thoracentesis

CAUSE	ANNUAL INCIDENCE	TRANSUDATE	EXUDATE
Congestive heart failure	500,000	Yes	No
Pneumonia	300,000	No	Yes
Cancer	200,000	No	Yes
Pulmonary embolus	150,000	Sometimes	Sometimes
Viral disease	100,000	No	Yes
Coronary artery bypass surgery	60,000	No	Yes
Cirrhosis with ascites	50,000	Yes	No

Data from Light RW: *Pleural diseases*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.

nature of the collection (such as free-flowing or loculated), the cause, and the likelihood of recurrence. For small, free-flowing effusions, an outpatient diagnostic and/or therapeutic thoracentesis with a relatively small-bore needle or catheter (14- to 16-gauge) can be performed (Fig. 19-50). The appearance of the fluid is informative: clear straw-colored fluid is often transudative; turbid or bloody fluid is often exudative.

The site of entry for drainage of a pleural effusion or pneumothorax may be based on the CXR alone if the effusion is demonstrated to be free-flowing. For free-flowing effusions, a low approach at the eighth or ninth intercostal space in the posterior midclavicular line facilitates complete drainage.

If the effusion is loculated, CT- or ultrasound-guided drainage may be indicated. If the goal is complete drainage, a small-bore pigtail catheter is inserted and connected to a closed drainage system with applied suction (typically -20 cm H_2O). In general, the smallest-bore drainage catheter that will effectively drain the pleural space should be chosen. Smaller-diameter catheters significantly decrease the pain associated with the placement of chest tubes but are more prone to clogging and twisting.^{174,175} For clinical situations requiring biopsy or for potential interventions such as adhesiolysis or pleurodesis, minimally invasive surgery may be indicated, using a VATS approach.

Figure 19-50. Techniques for aspiration and drainage of a pleural effusion. **A.** Needle aspiration. With careful appraisal of the x-ray findings, the best interspace is selected, and fluid is aspirated with a needle and syringe. Large volumes of fluid can be removed with a little patience and a large-bore needle. **B.** Chest tube insertion. After careful skin preparation, draping, and administration of local anesthesia, a short skin incision is made over the correct interspace. The incision is deepened into the intercostal muscles, and the pleura is penetrated (usually with a clamp). When any doubt exists about the status of the pleural space at the site of puncture, the wound is enlarged bluntly to admit a finger, which can be swept around the immediately adjacent pleural space to assess the situation and break down any adhesions. The tube is inserted, with the tip directed toward the optimal position suggested by the chest X-rays. In general, a high anterior tube is best for air (pneumothorax), and a low posterior tube is best for fluid. A 28F to 32F tube is adequate for most situations. A 36F tube is preferred for hemothorax or for a viscous empyema. Many surgeons prefer a very small tube (16F to 20F) for drainage of simple pneumothorax. **C.** The tube is connected to a water-seal drainage system. Suction is added, if necessary, to expand the lung; it usually will be required in a patient with a substantial air leak (bronchopleural fistula).

Complications of Pleural Drainage. The most common complications of invasive pleural procedures are inadvertent injury to adjacent organs, including lung, with air leakage and pneumothorax; subdiaphragmatic entry and damage to the liver, spleen, or other intra-abdominal viscera; intercostal vessel injury with subsequent bleeding or larger vessel injury; and even cardiac puncture. Sometimes, bleeding may be the result of an underlying coagulopathy or anticoagulant therapy. Other technical complications include loss of a catheter, guidewire, or fragment in the pleural space and infections. Occasionally,

rapid drainage of a large effusion can be followed by shortness of breath, clinical instability, and a phenomenon referred to as postexpansion pulmonary edema. For this reason, it is recommended to drain only up to 1500 mL initially. Most complications can be avoided by consulting with a clinician experienced in pleural drainage techniques.

Pleural Fluid Analysis. Pleural fluid collections are generally classified as transudates and exudates (Table 19-34). Transudates are protein-poor ultrafiltrates of plasma that result from alterations in the systemic hydrostatic pressures or colloid

osmotic pressures (for example, with congestive heart failure or cirrhosis). On gross visual inspection, a transudative effusion is generally clear or straw-colored. Exudates are protein-rich pleural fluid collections that generally result from inflammation or pleural invasion by tumor. Grossly, they are often turbid, bloody, or purulent. Absent trauma, grossly bloody effusions are frequently malignant, but they may also occur in the setting of a pulmonary embolism or pneumonia.

Transudates and exudates can be differentiated using Light's criteria. An effusion is exudative if the pleural fluid-to-serum ratio of protein is greater than 0.5 and the LDH ratio is greater than 0.6 or the absolute pleural LDH level is greater than two-thirds of the normal upper limit for serum. If criteria suggest a transudate, a careful evaluation for congestive heart failure, cirrhosis, or conditions associated with transudates is undertaken. If criteria suggest an exudate, further diagnostic studies may be helpful. If total and differential cell counts reveal a predominance of neutrophils (>50% of cells), the effusion is likely associated with an acute inflammatory process (such as a parapneumonic effusion or empyema, pulmonary embolus, or pancreatitis). A predominance of mononuclear cells suggests a more chronic inflammatory process (such as cancer or tuberculosis). Gram stains and cultures should be obtained if possible, with inoculation into culture bottles at the bedside. Pleural fluid glucose levels are frequently decreased (<60 mg/dL) with complex parapneumonic effusions or malignant effusions. It is important to note that while the distinction between transudate and exudate can be diagnostically useful, the ultimate decision for prolonged chest tube drainage or surgery depends on the effusion size and adequacy of drainage, presence of loculations, adequacy of lung reexpansion after drainage, and recurrence after initial drainage.

A pleural effusion occurring in association with pleuritic chest pain, hemoptysis, or dyspnea out of proportion to the size of the effusion should raise concern for pulmonary embolism. These effusions may be transudative, but if an associated infarct near the pleural surface occurs, an exudate may be seen. If a pulmonary embolism is suspected in a postoperative patient, most clinicians would obtain a spiral CT scan. Alternatively, duplex ultrasonography of the lower extremities may yield a diagnosis of deep vein thrombosis, thereby indicating anticoagulant therapy and precluding the need for a specific diagnosis of pulmonary embolism. In some patients, a blood test for levels of D-dimer may be helpful; if a sensitive D-dimer blood test is negative, pulmonary embolism may be ruled out.

Malignant Pleural Effusion

Malignant pleural effusions may occur in association with a number of different malignancies, most commonly lung cancer, breast cancer, and lymphomas, depending on the patient's age and gender (Tables 19-35 and 19-36).¹⁷⁶ Cytologic testing should be done on exudative effusions to rule out an associated malignancy; accuracy is 70% when associated with adenocarcinomas, but it is less sensitive for mesotheliomas (<10%), squamous cell carcinomas (20%), or lymphomas (25% to 50%). If the diagnosis remains uncertain after drainage and fluid analysis, thoracoscopy and direct biopsies are indicated.^{177,178} Malignant effusions are exudative and often tinged with blood. An effusion in the setting of a malignancy means a more advanced stage; mean survival ranges from 3 to 11 months, depending on the primary tumor location.

Occasionally, effusions associated with a bronchogenic NSCLC are benign, and surgical resection may still be indicated.

Table 19-35

Primary organ site or neoplasm type in male patients with malignant pleural effusions

PRIMARY SITE OR TUMOR TYPE	NO. OF MALE PATIENTS	PERCENTAGE OF MALE PATIENTS
Lung	140	49.1

Effusion size and degree of associated dyspnea influence management. Symptomatic, moderate to large effusions should be drained by tunneled indwelling pleural catheter, tube thoracostomy (chest tube or pigtail catheter) with subsequent instillation of a sclerosing agent, or VATS with talc instillation. Management is based on patient preference, degree of known or anticipated lung reexpansion, and patient tolerance for operative intervention. Lung entrapment by tumor or adhesions limits reexpansion and generally predicts a poor result with pleurodesis; it is the primary indication for placement of indwelling pleural catheters. Patient preference is also considered, as is their life expectancy. Tunneled indwelling pleural catheters have dramatically changed the management of end-stage cancer treatment

Table 19-36

Primary organ site or neoplasm type in female patients with malignant pleural effusions

PRIMARY SITE OR TUMOR TYPE	NO. OF FEMALE PATIENTS	PERCENTAGE OF FEMALE PATIENTS
Breast	70	37.4
Female genital tract	38	20.3
Lung	28	15.0
Lymphoma	14	8.0

because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.¹⁷⁹ If the

11 ▶ lung is expected to fully expand and the patient has a longer life expectancy (e.g., malignant effusions in the setting of breast cancer), drainage with sclerosis is the preferred option. The choice of sclerosant includes mechanical pleurodesis or pleurectomy, talc, bleomycin, or doxycycline. Success rates range from 60% to 90% and are highest with talc. Typically, talc is administered as an aerosolized powder during video-assisted thoracoscopy, whereas doxycycline or a talc slurry is infused at the bedside through a previously placed pigtail catheter or larger bore chest tube. Figure 19-51 presents a decision algorithm for the management of malignant pleural effusion.

Empyema

Thoracic empyema is defined by a purulent pleural effusion. Patients of all ages can develop empyema, but the frequency is increased in older or debilitated patients. Common associated conditions include a pneumonic process in patients with pulmonary disorders and neoplasms, cardiac problems, diabetes mellitus, drug and alcohol abuse, neurologic impairments, postthoracotomy problems, and immunologic impairments. The mortality of empyema frequently depends on the degree of severity of the comorbidity; it may range from as low as 1% to over 40% in immunocompromised patients.

Pathophysiology. The most common causes are parapneumonic, but postsurgical, posttraumatic, and GI-associated (e.g., subphrenic or hepatic abscess, perforation of esophagus or other viscus) empyema is also common (Table 19-37). The spectrum of organisms involved in pneumonic processes that progress to empyema is changing. Pneumococci and staphylococci continue to be the most common, but gram-negative aerobic bacteria and anaerobes are becoming more prevalent. Cases involving mycobacteria or fungi are rare. Multiple organisms may be found in up to 50% of patients. Cultures may be sterile, however, if antibiotics were initiated before the culture or if the culture process was not efficient. It is also fairly common for *Pneumococcus* to grow in blood cultures but not to grow in the pleural fluid cultures. The choice of antibiotics, therefore, is guided

Table 19-37

by the clinical scenario and not just the organisms found on culture. Broad-spectrum coverage may be required even when cultures do not grow out an organism or if a single organism is grown when the clinical picture is more consistent with a multi-organism process. For example, a polymicrobial gram stain, particularly including yeast, is strongly suggestive of esophageal perforation. Common gram-negative organisms include *Escherichia coli*, *Klebsiella*, *Pseudomonas*, and Enterobacteriaceae. Anaerobic organisms may be fastidious and difficult to document by culture and are associated with periodontal diseases (especially *Streptococcus species*), aspiration syndromes, alcoholism, general anesthesia, drug abuse, or other functional associations with gastroesophageal reflux.

Organisms gain entry into the pleural cavity through contiguous spread from pneumonia, lung abscess, liver abscess, or another, adjacent infectious processes. Organisms may also enter the pleural cavity by direct contamination from thoracentesis, thoracic surgical procedures, esophageal injuries,
